The mean values of total sample were: 8.06(±5.50) for psychological symptoms, 4.63(±3.07) for somatic symptoms, 1.33(±1.48) for vasomotor symptoms, 1.18(±1.13) for loss of sexual interest and 15.90(±9.27) for total of these symptoms.
Effects of and Exercise on the Body Composition, Resting Metabolic Rate and Exercise Capacity of Patients with Severe Mental Illness

Giannopoulou, I., Skouroliakou, M., Kostara, C., Koutri, K., Danou, K.
University of Strathclyde; Harokopio University; Iaso Hospital, Greece

Weight gain is an established side effect of atypical antipsychotics in patients with severe mental illness (SMI). Previous studies have shown positive effects of lifestyle interventions of diet and exercise in weight loss in this population. The purpose of this study was to investigate the effects of a 3-month nutrition and exercise intervention on the body composition, resting metabolic rate and exercise capacity of SMI patients in Greece.

Forty-seven females (N=34), males (N=13) obese patients diagnosed with SMI (age: 41.5±1.8 years; body mass: 91.6±18.6 kg; body mass index: 33.4±6.2 kg/m²; mean±SD) volunteered to participate in the study. The duration of the study was 3 months and patients had to attend nutritional and exercise counselling sessions every 15 days. Prior to the start of the study patients' body weight, body composition (Bodpod, Life Measurement Inc, CA) and resting metabolic rate (RMR) (Cosmed, Italy) were assessed. Patients also participated in a sub-maximal exercise stress test in order to assess their maximal oxygen consumption (VO2max) (Cosmed, Italy). At the end of the study the same experimental measurements were performed to assess differences in body composition, RMR and VO2max. Significant improvements were found in the body weight (-5.5±0.7 kg, P<0.01), fat mass (-5.3±0.1 kg, P<0.01) and RMR (+244±43.2 kcal, P<0.01) of the patients in the 3-month intervention period. Exercise capacity was also found to be increased as a result of the intervention from 26.9±5.5 ml/kg/min to 30.4±5.3 ml/kg/min (P<0.01). The changes in VO2max were correlated to the changes in body weight (r=0.3, p<0.05) and fat mass (r=0.3, p<0.05) of the patients. When dividing the patients by gender, no differences among genders were found in the responses to the intervention in the body weight, body composition and RMR. However, significant gender differences were found in the improvements in exercise capacity, with females significantly improving VO2max by 15% (pre: 25.2±4.73 to post: 29.6±5.41 ml/kg/min, P<0.02), while no significant difference was found in males (pre: 31.3±4.34 to post: 32.5±4.34 ml/kg/min, P=0.05).

In conclusion, SMI patients respond favourably to lifestyle interventions of diet and exercise as demonstrated by improvements in their body weight, body composition, RMR and exercise capacity. More investigation is needed to examine whether gender differences exist in the exercise capacity of this population.

Short-term Psychosocial Changes in an Exercise Based Weight Management Program: A Study with Obese Outpatients Adolescents

Universidade Lusófona de Humanidades e Tecnologias; Hospital de Santa Maria; Technical University of Lisbon, Portugal

Purpose
The goal of this study was to analyze the changes in self-esteem, emotions, self-efficacy, exercise motivation and body image after the first two months of an exercise based weight management program in obese adolescents.

Methods
Subjects were 49 obese adolescents (BMI M=30.7 SD=4.5 kg/m², age M=13.6 SD=1.5 y, 25 girls) being followed in a tertiary health unit, who are participating in a long-term program that comprises medical, nutritional, physical activity and psychological interventions. The program comprises up to 3 sessions of exercise per week in addition to lifestyle physical activity recommendations. Self-esteem (Rosenberg, 1965), Emotions (PANAS, Watson et al., 1988), Weight Efficacy Lifestyle Questionnaire (WELQ, Clark et al., 1991), Exercise motivation (BREQ-2, Markland & Tobin, 2004), Body Size Dissatisfaction (BIA, Williamson et al., 1989), weight and height were measured at baseline and 2 months later during the program. Paired t-tests were used for the analysis of differences between baseline and 2 months’ values. Pearson correlations measured the association between psychosocial changes with weight and BMI changes, while independent t-test evaluated change differences between gender.

Results
Although no differences were found in weight or BMI, improvements were observed in positive emotions (p<0.03), intrinsic motivation (p<0.026), and in the WELQ's sub-scales: negative emotions (p<0.043), availability (p<0.026) and social pressure (p<0.013). There were also marginally significant improvements in identified motivation (p=0.094) and total self-efficacy (p=0.070). These improvements were similar between gender and were not associated with weight and BMI changes.

Conclusion
Despite the short-term time frame of the analysis, the positive changes observed in psychosocial variables suggested the same conclusions registered in studies with longer periods (Blaine et al., 2007). The improvements in the more self-determinate type of motivation, which should influence exercise and program adherence (Teixeira et al., 2006), represent a particularly strong sign that the program might be successful among the adolescents that increased their exercise’s intrinsic motivation. Further data with longer time periods, within the present study, should provide more scientific evidence of psychosocial processes in obese adolescents seeking weight loss.
MEDICAL PROFILE OF THE SENIOR GOLFER

Schrader, T., Herwegen, H.
University of Paderborn, Germany

Half of the German golfers are older than 50 years. A high percentage of them have a sport vita with characteristic injuries as well as diseases. The knowledge of anthropological and medical data constitutes the base of an optimised therapeutic care. The aim of the study was to create a medical profile of senior golfers (SG). This data was compared to the profile of non-golfing German seniors (GS) as well as to golfers of all ages (AG).

In 2007 an online questionnaire was available to all German golf clubs. The senior members were asked to fill in that questionnaire, which contained the following topics: golf biography, sport biography, actual health status, arthritic ailments and suffered golf-specific injuries.

395 golfers completed the questionnaire (mean age 65.68 years; 303 male; 92 female). Senior golfers suffered less often from the risk factors diabetes (SG 5.6%; GS 11.5%), high blood pressure (20.3%; 42.2%), overweight (SI 4.4%; 77.7%) and physical inactivity (3.4%; 42.1%). Furthermore they were less likely to smoke (34.5%; 19.4%). The ratio of injured body regions showed increased percentages in the back (SI 42%, AG 36%) and the shoulder (18%; 13%) on the one hand, as well as decreased percentages in the elbow (20%; 24%), the wrist and hand (12%; 14%), the knee (4%; 7%) and the ankle and foot (4%; 6%) on the other hand.

Referring to the risk factors senior golfers have a less dangerous health profile as non-golfing seniors. In comparison to the current literature the different body regions attacked of golf injuries show only few differences between senior and all-aged golfers, whereas the back and the shoulder tend to be injured more often. Senior golfers have an improved general health profile without an increased risk of specific orthopaedic injuries.

PREDICTION OF BODY FAT BY AIR PLETHYSMOGRAPHY, SKINFOLD AND BIOELECTRICAL IMPEDANCE IN HEALTHY YOUNG MALE ADULTS

Eston, R., Manolitsis, V.
University of Exeter, United Kingdom

Air displacement plethysmography (BodPod) is a popular method of body composition assessment (Dempsiter & Aitkens, 1995). Like hydrostatic weighing, it estimates body composition by determining whole body volume (corrected for residual lung volume) and uses this value to compute body density. The percentage body fat is estimated from assumed densities of fat and the average density of the lean compartment using well established equations (Siri, 1961). As the prediction of body density from hydrostatic method is based on hydrostatically determined whole body density, there should be a high correlation between skinfold techniques and BodPod. The purpose of this study was to compare prediction of %fat from the BodPod, with two generalized skinfold equations for men (DW, Dunnin and Womersley, 1974; JP, Jackson and Pollock, 1978) and bioelectrical impedance analysis (BIA). Fifteen healthy and fit young men (age 24.5 ± 3.1y) volunteered for the study. Measurements occurred across two consecutive days to assess reliability. The relationship between methods was assessed by correlation analysis (r). Reliability within methods was assessed by intraclass correlation analysis (RI). Repeated-measures ANOVA was used to compare differences between methods. All methods were highly reliable (r values between trials 1 and 2 were BodPod R = 0.991; BIA R = 0.980; DW R = 0.981; JP R = 0.966, all < 0.001). The correlations r between %fat values from trial 1 for BodPod were BIA = 0.682 P = 0.005, DW 0.764 P = .001; JP 0.705 P = 0.003. Values for trial 2 were similar. There were no differences between trial 1 and trial 2 for each measure, but there were significant differences between the four methods (F = 31.3-22, 31 df).

Repeated-measures ANOVA was used to compare differences between methods. All methods were highly reliable (r values between trials 1 and 2 were BodPod R = 0.991; BIA R = 0.980; DW R = 0.981; JP R = 0.966, all < 0.001). The correlations r between %fat values from trial 1 for BodPod were BIA = 0.682 P = 0.005, DW 0.764 P = .001; JP 0.705 P = 0.003. Values for trial 2 were similar. There were no differences between trial 1 and trial 2 for each measure, but there were significant differences between the four methods (F = 31.3-22, 31 df).

In the prediction of %fat from the BodPod, with two generalized skinfold equations for men (DW, Dunnin and Womersley, 1974; JP, Jackson and Pollock, 1978) and bioelectrical impedance analysis (BIA). The relationship between methods was assessed by correlation analysis (r). Reliability within methods was assessed by intraclass correlation analysis (RI). Repeated-measures ANOVA was used to compare differences between methods. All methods were highly reliable (r values between trials 1 and 2 were BodPod R = 0.991; BIA R = 0.980; DW R = 0.981; JP R = 0.966, all < 0.001). The correlations r between %fat values from trial 1 for BodPod were BIA = 0.682 P = 0.005, DW 0.764 P = .001; JP 0.705 P = 0.003. Values for trial 2 were similar. There were no differences between trial 1 and trial 2 for each measure, but there were significant differences between the four methods (F = 31.3-22, 31 df).

ASSOCIATIONS OF HABITUAL PHYSICAL ACTIVITY, ENERGY INTAKE AND INFLAMMATION WITH BODY WEIGHT AND COMPOSITION IN PATIENTS WITH RHEUMATOID ARTHRITIS

Stavropoulos-Kalinoglou, A., Metsios, G., Koutedakis, Y., Kitas, G.
University of Wolverhampton, United Kingdom

Obesity, a risk factor for several diseases, is very common among patients with rheumatoid arthritis (RA) [1]. Moreover, these patients exhibit increased levels of body fat compared to healthy controls of the same BMI [1]. The exact reasons for this remain undetermined. However, physical inactivity, altered energy intake and inflammation associated with the disease [2] could all result in increases in body weight and fat [3]. Thus, this study aimed to identify possible associations of habitual physical activity, diet and inflammation with body mass index (BMI) and body composition i.e. body fat-BF- and fat free mass -FFM- of patients with RA.

The total of 60 patients (40 females) with RA was assessed for BMI (weight divided by height squared) and body composition (bioelectrical impedance). Habitual physical activity was assessed using the long-form International Physical Activity Questionnaire (IPAQ) and diet with a food diary which assessed food intake over two week days and one weekend day. Pro-inflammatory cytokines i.e. interleukins (IL) -1a, -1b, -6 and tumour necrosis factor alpha (TNFα) were measured in participants’ blood. Disease characteristics were assessed following standard procedures. Duration of RA and smoking habits were also noted.

IPAQ was inversely correlated with weight (r=-0.327, p<0.001), BMI (r=-0.291, p<0.05) and BF (r=-0.264, p<0.05). Total energy intake was positively correlated with BMI (r=0.259, p<0.05). Pro-inflammatory cytokines did not correlate with any of the assessed parameters.

Following correlations for age, gender, disease duration and smoking status, IPAQ remained a significant predictor of the previously named parameters; however the association of energy intake with BMI became insignificant. Therefore, participants were grouped...
According to 1) their BMI and 2) their BF into under-, normal-, over-weight and obese. ANOVA found significant differences between both BMI and BF groups for IPAQ (p<0.05) but not for energy intake or pro-inflammatory cytokines.

In patients with RA increased body weight and fat seem to associate more with decreased physical activity than with increased energy intake or inflammation. Given the adverse health effects of obesity, RA patients should be advised to follow a more active lifestyle. However, exercise professional should take into account the movement limitations of these patients. Further research, investigating the suitability of exercise modalities and the resulting effects on RA, is advocated.

MAXIMAL AEROBIC CAPACITY IN POSTMENOPAUSAL WOMEN: RELATION BETWEEN BODY COMPOSITION AND THE CHARACTERISTICS OF MENOPAUSE

Moreira, M., Machado, B., Mota, M., Soares, J., Freitas, J., Leitão, J., Gabriel, R.
Universidade de Trás-os-Montes e Alto Douro, Portugal

This study aims to determine if body composition (BMI, body mass index, VFA, visceral fat area and SMI, skeletal mass index) and the characteristics of menopause (time and nature of menopause) are predictors of cardiovascular fitness in two groups of postmenopausal women (G1, 45 to 59-yr-old; G2, 60 to 79-yr-old). Subjects included 196 postmenopausal Caucasian women (age, 57.38±6.04 years old; VO2max, 28.79±5.29 mg/kg/min; BMI, 28.68±4.76 kg/m2); 135 in G1 and 61 women in G2. Skeletal muscle mass (SMM), VFA and basal metabolic rate (BMR) were estimated by tetrapolar bioimpedance. The whole-body adiposity was measured by the BMI (weight/height2) and the subjects were considered to have a normal SMM if their SMM (SMM/body mass × 100) was higher than 28% [2]. The cutoff to define the VFA related to high cardiovascular risk was 100 cm2 [1]. Waist circumference (WC) was measured in the narrowest area of the waist and VO2max was assessed by a modified Bruce treadmill protocol. Independent t tests were used to compare variables between groups and VFA in G1. Stepwise multiple regressions were used in two groups to quantify the independent contribution of predictor variables to VO2max.

Compared to G2, the youngest postmenopausal women had lower (p=0.01) levels of VFA (-13.73 cm2) and higher levels (p=0.05) of SMM (1.42%) and VO2max (2.26 ml/kg/min), but in relation to SMM and BMR there were no differences between groups. Maximal aerobic capacity was inversely (p=0.01) associated with VFA (r=-0.44 and r=-0.60 in G1 and G2, respectively) and WC (r=-0.25 and r=-0.45). By contrast, SMI was positively associated with a dependent variable (r=0.43 and r=0.59, respectively). VFA was the strongest independent variable correlated to VO2max in G1 (r = -0.44, p < 0.01) and G2 (r = -0.60, p < 0.01), explaining respectively 19% and 35% of the variance, when the BMI was controlled. In G1, subjects with high VFA had lower cardiovascular fitness (-4.99 ml/kg/min, p<0.01) and in G2 only 2 women had a normal VFA.

Our data suggest that the oldest postmenopausal women have a lower VO2max and an increased risk of central adiposity and sarcopenia. Visceral fat area is a significant predictor of cardiovascular fitness in postmenopausal women, besides the characteristics of menopause (time and nature) and BMI. The levels of VFA equal or superior to 100 cm2 in G1 are a biological marker that predisposes the youngest postmenopausal women to a lower maximal aerobic capacity.

RELATIONSHIP BETWEEN HABITUAL PHYSICAL ACTIVITY, NUTRITIONAL STATUS AND MOTOR PERFORMANCE FROM A SAMPLE OF BRAZILIAN SCHOOLCHILDREN

Ramos, L., Costa, A., Domingos, S., Souza, K.
Foundation of Superior Education of Passos, University of the State of Minas Gerais, Passos, Brazil

Objective: The purpose of this study was to evaluate the habitual physical activity, the nutritional status, the motor skills and the relationship of these variables of children aged 10-12 years. Methods: This study included 117 children (53.8% men), aged 10-12 years (10.6 ±0.7), randomly selected from the public and private school system from Passos, Minas Gerais. In order to evaluate the habitual physical activity (HPA) the subjects filled out the Physical Activity Questionnaire (PAQ-C). The nutritional status was assessed by anthropometric data (body mass index (BMI), waist circumference (WC) and waist-to-hip ratio (WHR)) and the motor skills were assessed through a physical fitness test battery (9-minute run/walk test, muscular strength/endurance abdominal test, medicine ball seated toss test, horizontal jump test).
test, sit and reach test, agility square test and 20 meters velocity test. Kruskal Wallis test was used to analyze associations among nutritional status classification with motor skills total scores and HPA total scores and to verify associations between HPA classification and motor skills total scores. Spearman test was performed to verify correlations between quantitative measures (HPA, nutritional status and motor skills). Differences between genders were performed by Mann-Whitney test. Results: Regarding to HPA, 15.4% were classified as very sedentary, 42.7% as sedentary, 33.3% as moderately active and 8.5% as active. According to BMI, 8.5% were classified as underweight, 65.8% as euthrophic and 25.6% as overweight. As assessed by the WC, 33.3% were in the first quartile, 23.1% in the second quartile, 22.2% in the third quartile and 21.4% in the forth quartile. According to WHR 32.5% were in the first quartile, 29.1% at second quartile, 15.4% in the third quartile and 23.1% in the forth quartile. The subjects showed a low performance for the most motor skills assessment, except in the sit and reach test. It was a positive relationship (p<0.05) between WC classification and medicine ball seated toss test total score. A negative relationship (p<0.05) among BMI classification and 9-minute run/walk test total score was observed, too. No statistically significant associations were found in any others comparisons performed with nutritional status (by BMI, WC and WHR classifications and total scores). Neither was found statistically significant association in any comparison performed with HPA classification. The boys showed a best performance (p<0.05) in the sit and reach test, were more physically active (p<0.05) and spent less time watching TV (p<0.05). No significant difference was found between gender and others analysis of motor skills and nutritional status. Conclusion. Studies should be directed to investigate and understand the relationship between physical fitness, motor performance and anthropometric profile, to improve quality of life and health conditions for children.

**Fatigue and Recovery in Individuals with Mental Retardation During High-Intensity Intermittent Exercise**

Zafeirdis, A., Giagazoglou, P., Karra, C., Salonikidis, K., Kellis, E.
Department of Physical Education and Sports Sciences at Serres, Aristotle University of Thessaloniki, Greece

The capacities of the muscle to resist fatigue and to recover after intense exercise are important components of neuromuscular function. Fatigue originates in peripheral and central (reduced muscle activation) sites. Individuals with mental retardation (MR) may have disturbed central and peripheral processing components, as indicated by the longer reaction and motor times, and the association between the brain nerve conduction velocity and intelligence. Thus, MR individuals might be in disadvantage vs. those without MR (NMR) when performing fatiguing exercise. On the other hand, MR individuals generate less absolute forces which suggest that they may fatigue less and recover faster during intermittent activity. The aims of this study were to compare fatigue and recovery characteristics of individuals with MR vs. NMR.

Nine men with mild-moderate MR (23.8±4.2 yrs.) and 11 NMR men (23.6±3.3 yrs.) performed 4 sets of 18 consecutive maximal knee extensions and flexions with 1 min rest at 120º/sec on an isokinetic dynamometer. Peak torque (PT) and total work (TW) for concentric knee flexors (FL) and extensors (EX) were measured in all sets. Fatigue was assessed as the rate of PT and TW decline in the 1st set calculated by the slope of a linear fit performed on 18 reps. The magnitude of recovery in the 2nd, 3rd, and 4th sets was calculated as a % of TW value achieved in the 1st set. HR was monitored throughout the protocol and blood samples were obtained after the 2nd and 4th sets to assess blood glucose and lactate. All data are presented as means ±SD. MR had lower (p<0.01) absolute values vs. NMR for PTFL (132±30 Nm vs. 169±33 Nm), PTEX (138±34 Nm vs. 94±24 Nm), and TW (5402±1030 J vs. 7560±1593 J). Expressed per unit body weight, the values were not different between groups for PTFL and TW, but different for PT (p<0.05). The slopes of the linear regressions for absolute and relative PTFL and PTEX were smaller (p<0.001-0.05) in MR vs. NMR. Recovery (%) was higher (p<0.05) in MR vs. NMR for TWFL in the 2nd (86±9 vs. 78±6), the 3rd (75±6 vs. 65±6) and the 4th (70±7 vs. 54±9) sets and for TWEX in the 3rd (73±11 vs. 66±9) and the 4th (68±10 vs. 58±7) sets. When % recovery was analyzed using PT and TW of the 1st set as covariates no differences between MR and NMR were observed. Lactate (mmol/L) was lower in MR vs. NMR after the 2nd and the 4th sets (p<0.01), while there were no differences between groups in glucose (mmol/L). The percent (%) of HR decline during the rest period after each set was greater in MR vs. NMR (p<0.01). In conclusion, fatigue develops at a slower rate, as suggested by the slopes, during fatiguing exercise and muscle abilities’ to produce work recover faster during intense intermittent exercise in individuals with MR vs. NMR. This may be due to the lower ability of MR individuals to generate absolute forces as well as to their less reliance on glycolysis for energy production and their greater rate of cardiac-pulmonary readjustment.

**Inpatient Multimodal Youth Obesity Therapy Alters Heart-Rate Variability**

Thiel, C., Vogt, L., Claussnitzer, G., Banzer, W.
J.W. Goethe University of Frankfurt, Germany

**Purpose**

Analysis of the natural variation in heart rate (HRV) is considered a valuable non-invasive tool to assess sympathetic heart rate regulation. Despite the accepted diagnostic value of HRV to predict the risk of future cardiac events in clinical cardiology, and the role of the autonomous nervous system (ANS) in metabolic energy homeostasis, studies evaluating exercise-induced modulation of cardiac autonomic function in obese children are scarce. The current study evaluated the effects of a four-week inpatient youth obesity therapy program on heart rate variability.

**Methods**

In a prospective, non-randomized controlled trial, HRV was obtained in mixed-gender obese youth before and immediately after a multimodal inpatient therapy including exercise, nutrition and behaviour modification (verum: 13.0±1.6 years, 32.7±4.1 kg/m², or at a corresponding time interval of 4 weeks (controls: 13.3±1.7 years, 30.7±3.5 kg/m²). Following 10 minute acclimatization, 5-min short-time resting tachograms were obtained by Polar S810® Heart Rate Monitors (Polar Electro Oy, Finland) in supine position in a temperature-controlled, quiet room. In accordance with the standards proposed by the Task Force of the European Society of Cardiology, segments of 256 RR intervals were exported as text files to HRV Analysis Software 1.1 (Department of Applied Physics, University of Kuopio, Finland) after visual inspection of the raw data. RMSSD, low frequency (LF) power within the frequency band of 0.04-0.15 Hz, high frequency (HF) power (0.15-0.4 Hz) and total power (TP) (0.02-0.4 Hz) were analysed by Mann-Whitney U test.

**Results**

No significant between-group differences could be detected in the initial measurement. Changes in BMI (kg/m²) (-2.4±0.6 vs. -0.4±0.7), RMSSD (ln ms) (+0.59±0.64 vs. -0.13±0.37), LF (ln ms2) (+0.72±1.02 vs. 0.44±0.58), HF (ln ms2) (+0.94±1.23 vs. -0.56±0.73) and TP (ln ms2) (+0.73±0.99 vs. 0.44±0.52) differed significantly between verum and controls (p<0.001).
CONCLUSION
The current results underscore the immediate efficacy of inpatient complex therapy in obese youth, reducing body weight and enhancing both sympathetic and parasympathetic nervous activities within four weeks. Absolute spectral values, as well as the magnitude of change differed markedly among individuals. Improving physical activity behaviour and eating patterns seems to induce a reversal effect on initially reduced ANS activity in obese youth, which might have important implications for metabolic energy homeostasis as well as cardiac health. The sustainability of the HRV modulations observed, as well as the general feasibility of HRV parameters as therapeutic outcome should be evaluated in future large-scale studies.

CLUSTERED CARDIOVASCULAR RISK AND AEROBIC FITNESS IN ADOLESCENTS
Steene-Johannessen, J., Nyvoll, K., Kelle, E., Anderssen, S. Andersen, I.
Norwegian School of Sport Sciences, Norway

Low aerobic fitness strongly and independently predicts all-cause mortality and cardiovascular disease (CVD) outcomes. CVD risk factors seem to cluster in some individuals, which is the case in subjects with metabolic syndrome, and in adults. Moreover, low aerobic fitness is associated with increased risk of developing metabolic syndrome (1). Recent reports have shown similar associations between aerobic fitness and clustering of CVD risk factors in paediatric populations (2,3). However, data from national representative samples are lacking. The aim was to examine the association between aerobic fitness and clustered CVD risk in a representative sample of Norwegian adolescents. Methods: This is a cross-sectional study including a randomly selected cohort of 983 15-year olds. The adherence rate was 73%. Maximal oxygen uptake was assessed directly (MetaMax III X) during a maximal test on a cycle ergometer. CVD risk factors selected to assess the degree of clustering were total cholesterol/high-density lipoprotein cholesterol ratio, triglycerides, insulin resistance (HOMA), sum of four skinfolds, and systolic blood pressure. Results: There was a moderate association between aerobic fitness and clustering of CVD risk factors ($r = -0.351$ and $r = -0.428$ for girls and boys respectively). Subjects in the lowest quintile of fitness ($35.9$ mlkg$^{-1}$min$^{-1}$ and $46.3$ mlkg$^{-1}$min$^{-1}$, for girls and boys respectively) had $8.3$ (95% CI 4.4;15.7) times greater risk of clustering of CVD risk factors compared with subjects having a VO2peak above these values. Conclusions: This is the first study to investigate the association between CVD risk factors and direct measurement of VO2peak in adolescents. We found that low aerobic fitness is associated with clustering of CVD risk factors.

EFFECTS OF AEROBIC EXERCISE ON WHOLE BLOOD FLUIDITY IN ELDERLY JAPANESE MEN
Nakagaiichi, M.
Research and Development Center for Higher Education, Japan

Disturbance of blood rheology is recognized not only as a coronary risk factor, but also as a risk predictor of cardiovascular disease. Despite the importance of blood rheology in health and disease, remarkably little is known about the effect of aerobic exercise on blood rheology in elderly people. The purpose of this study was to obtain information regarding the effects of long-term aerobic exercise on whole blood fluidity in elderly men. Twenty-four men (65.9±7.9 years), who continuously have taken aerobic exercise (walking, jogging, treking, etc.) for more than 5 years, served as subjects for this study. Whole blood fluidity was evaluated by the passage time of whole blood through artificial capillaries. Maximal oxygen uptake (VO2max) and oxygen uptake corresponding to lactate threshold (VO2LT) were measured using a maximal cycle ergometer protocol. Cardiorespiratory fitness was evaluated by VO2max score and VO2LT score, which were standardized by age. Analyses of the data indicated that the correlation coefficients between whole blood passage time (43.3±8.0 sec) and VO2max score, or VO2LT score were statistically significant ($r = -0.47$ and $r = -0.56$, respectively). Furthermore, Whole blood fluidity correlated linearly with number of red blood cells (464.7±37.7×10^4/ml; $r = 0.48$), and hematocrit (14.6±1.0 %; $r = 0.47$). These findings suggest that whole blood fluidity may be improved by long-term aerobic exercise, through the reduced hematocrit and/or number of red blood cells. These might affect cardiorespiratory fitness through tissue perfusion and oxygen carrying capacity, moreover, might contribute to a permanent reduction of load on cardiovascular system.

DIFFERENCES IN BODY MASS INDEX BETWEEN CHILDREN LIVING IN LARGE URBAN CITIES AND SMALL PROVINCIAL TOWNS
Gortsila, E., Maridaki, M., Philippou, A., Bogdanis, G.
UNIVERSITY OF ATHENS, Greece

The study investigated whether there are differences in body mass index (BMI) between children and adolescents living in large urban centers and smaller provincial towns. For this purpose the height and weight of 3763 Greek children were measured. There were 2046 girls (495 from large cities and 1551 from small towns) and 1717 boys (402 from large cities and 1316 from small towns). The process of stratified sampling included two randomizations. Firstly the schools in each area were proportionally and randomly selected and secondly the children in each school were again randomly selected. Six age groups (8 to 13 years) with at least 375 children in each group were formed. Care was taken not include children who had changed their place of residence since their birth. BMI was calculated by dividing weight in kilograms by the square of height expressed in meters. The dependent variable BMI was analyzed using three-way analysis of variance with age group (8, 9, 10, 11, 12 and 13), gender (female, male) and place of residence (large city, small town) as the three independent factors. The interactions of the factors were also taken into consideration. Post-hoc pairwise comparisons with Bonferroni corrections were also performed. Statistical significance was set at 0.01. The results of the ANOVA showed that all three factors had a significant effect on BMI. Age had the most significant effect on BMI (F5, 3739 = 44.2, p<0.01). Gender also had a significant effect on BMI (F1, 3739 = 12.2, p<0.01), which was smaller than the effect of the place of residence on BMI (F1, 3739 =49.2, p<0.01). Post-hoc comparisons showed that starting from the age of 9 and up to the age of 12 children from large cities had higher BMI values than children from small towns. At the age of eight the difference is significant only at the 0.05 level. The greater differences were observed at the
age of ten, when children from large cities had a mean BMI of 19.8±2.8, while children from small towns had a mean BMI of 18.7±2.7. The overall 95 percentile BMI for this age is 23.2, however only 3.6% of children from small towns had BMI larger than this value, while for children from large cities this proportion rose to 9.5%. The present findings indicate that there may be biases when a nationwide BMI growth curve is generated from children living in different areas. The differences in BMI between children living in large cities and small towns may be explained by the interaction of several factors such as nutrition, participation in sports and other activities, socioeconomic status and lifestyle.

RELATIONSHIPS BETWEEN HABITUAL PHYSICAL ACTIVITY AND MORPHOLOGICAL AND METABOLICAL FACTORS OF HEALTH-RELATED FITNESS AMONG ELDERLY MEN

Szeklicki, R., Osinski, W.

University School of Physical Education in Poznan, Poland

Health benefits resulting from undertaking appropriate physical activity by elderly people are indisputable nowadays. However, the results of studies on the relations between habitual physical activity (HPA) and health are not clear and potential benefits resulting from this type of activity are often omitted and underestimated. The aim of the study was to assess the relations between HPA and morphological and metabolic factors of health-related fitness (H-RF) among men over 60 years of age. The participants of the study were 137 men (60-88 years, average=72.6±5.8) living in Poznan (city in Poland, about 700 thousand inhabitants). The participants were retired, free from severe illness, who didn’t participate in any organized programme of physical activity. For measuring HPA the Caltrac accelerometer (Muscle Dynamics Fitness Network, USA) was used. HPA was expressed as a value of weekly energy expenditure related to physical activity (PA-EE). The value of PA-EE calculated per kg of weight (PA-EE/kg) was also used. In terms of somatic characteristics body height, weight, waist and hip circumferences, body composition (FFM and FFM), and bone mineral density (BMD) were established.

The analysis of relations between PA-EE and PA-EE/kg and morphological and metabolic components of H-RF showed a very diversified picture. Direct relations (irrespective of age) of a higher level of PA-EE/kg with a more beneficial distribution of fat tissue were found. Lower values of waist circumference (r=-0.29, p<0.01) and WHR (r=-0.31, p<0.001) were related with higher level of HPA. The remaining results of the study do not indicate a significant direct role of separately considered PA-EE and PA-EE/kg in optimization of body weight or improvement of body composition by reduction of FM and increasing the value of FFM. Also BMD and the concentration of lipoproteins, TG and Glc in blood plasma directly do not co-occur significantly with the level of PA-EE and PA-EE/kg. Only in case of HDL and Gc one can mention indirect relationship caused by mutual relations of PA-EE, PA-EE/kg and the discussed factors with age and body weight.

In conclusion, the significant role of HPA in more beneficial distribution of fat tissue was proved, when there is a lack of direct relationships between HPA and other somatic characteristics or between HPA and metabolic components of H-RF. These observations indicate that we should appreciate the significance of HPA for the health of elderly men. It was also showed the necessity of using the relative value of HPA, when expressed by energy expenditure, it must be calculated per kg of weight.

SUCCESSFUL PHYSICAL ACTIVITY AND NUTRITION INTERVENTION AT SEA

Johannsdottir, S., Olafsdottir, A., Johannsson, E.

Iceland University of Education, Iceland

Icelandic fishermen working at fish-processing plants live a potentially unhealthy lifestyle. Staying at sea for a month at time gives little opportunities for regular exercise, and being sleep-deprived and away from home easily leads to limited and unhealthy dietary choices. In this study a physical activity and nutrition intervention was undertaken to increase awareness and facilitate healthier lifestyle among fishermen at sea.

Body composition, health parameters i.e., blood pressure, EKG, triglycerides, cholesterol, physical activity level and food choices were investigated among 62 fishermen (intervention, n=31; control, n=31) before and after a 6-month lifestyle intervention, focussing on an increased physical activity and healthier food choices during tours at sea as well as breaks on land. Physical activity was measured in minutes/week by protocols and questionnaires and fitness by maximal cycle ergometer test. Questionnaires were used to assess food choices and health related quality of life. In order to encourage physical activity at sea a room with fitness equipment was arranged for.

To aid better food choices the cooks were assisted in changing cooking methods and increasing the variety of food available at sea.

The intervention was successful, leading to an average weight loss of 3.5±2.7 kg compared with an average weight loss of 0.2±5.1 kg in the control-group (p=0.002). Changes in waist circumference and percent bodyfat were significant for the intervention-group only (r=3.9±2.5 cm, p=0.001 and -1.7%, p=0.001 respectively). The intervention-group increased their physical activity by 233% compared with an 13.5% increase among controls, resulting in 14.3% gain in fitness in the intervention-group only (p<0.001). Furthermore, the intervention-group had an 11.4% increase in HDL-cholesterol (p<0.001), compared with a 6.1% decrease in the control-group (p=0.049). There were no significant changes in LDL-cholesterol, but triglycerides decreased by 18.6% (p=0.004) in the intervention-group. They also lowered their diastolic blood pressure by 3.3 mmHg (p=0.033). Positive changes in the factors associated with health related quality of life were only found in the intervention-group. These were decreased depression, decreased pain and increased fitness by self-evaluation (p<0.05).

Positive changes in food choice were only noticeable in the intervention-group. After the intervention they ate fresh vegetable and unsweetened breakfast cereals more often and less frequently consumed sweet cakes and biscuits. They also less frequently drank carbonated beverages and fruit drinks with added sugar (p<0.05).

The results state the profit of a work-place intervention among men working and living under potentially unhealthy conditions. Healthier lifestyles leading to better health among fishermen is valuable for their personal well-being and is good investment for their employers.
THE EFFECTS OF CAFFEINE AND WATER INTAKE ON BODY FLUID LOSS THROUGH URINE PRODUCTION AND SWEAT LOSS DURING 2000-M UNDERWATER WALKING

Takuya, Y., Akira, M., Futoshi, O., Takafulmi, H.

1. Hyogo University Faculty of Health Science, Japan

The aim of this study was to investigate the effects of caffeine and water intake on the body fluid loss during 2000-m walking in the pool. Eight healthy men (age: 20.6 ± 5 years, height: 173.6 ± 4.2 cm, weight: 70.5 ± 4.7 kg) were designated as three experimental conditions: water ingestion (WA), caffeine ingestion with water (CAF: a total of 40 mg of caffeine in 400 ml water), and no fluid ingestion (NO). The fluid was ingested before the start of exercise and during exercise with a rest interval at 1000 m. The pool had 25 m in length and 1.0 m in depth. The subjects walked 2000 m at a speed of 3 km/h in the pool at a water temperature 30.3 ± 0.3°C, a room temperature 29.5 ± 2.7°C, and a relative humidity 83.5 ± 2.7%. We measured the urine volume and osmolarity, sweat rate, heart rate, tympanic temperature, and blood pressure pre-exercise, during exercise with a rest interval at 500 m, 1000 m, and 1500 m, and after exercise. Urine volume after exercise increased in the CAF (253 ± 7 ± 211.3 ml) as compared with the NO (129 ± 7 ± 152.9 ml). There was no difference in the sweat loss among three conditions (NO: 321 ± 7 ± 127.5 g, WA: 281 ± 7 ± 119.3 g, and CAF: 361 ± 7 ± 135.3 g). The total body fluid loss as evaluated with the urine volume plus sweat loss in the CAF (635 ± 7 ± 216.2 g) was significantly increased and that in the WA (433 ± 7 ± 108.8 g) tended to increase to that in the NO (442 ± 7 ± 143.4 g) after exercise (p < 0.05). Post-exercise tympanic temperature in the NO and CAF was significantly higher than the pre-exercise value. Post-exercise urine osmolarity in the CAF and WA was significantly lower than that of the NO (p < 0.05). The systolic blood pressure significantly increased during exercise (in the NO at 500 m, in the WA at 1000 m, and in the CAF at 500 m and 1500 m) compared with the pre-value (p < 0.05). There was no difference in the heart rate and diastolic blood pressure among three conditions. We concluded that water ingestion with caffeine significantly increased total body fluid loss through urine production and sweat loss during 2000-m underwater walking.

BODY COMPOSITION, REGULAR PHYSICAL ACTIVITY AND AEROBIC ABILITY IN PUBERTARY CHILDREN AND ADOLESCENTS

Monterio, M., Moreira, M.

University of Trás-os-Montes e Alto Douro, Portugal

The aim of our study was to compare the mean values in the performance of the aerobic ability (AA) in boys and girls according to the cutoffs established for the waist circumference (WC) [1], percent fat mass (%FM) [2], and regular physical activity (RPA). The sample was composed by 690 pubertal children and adolescents (10-15 years), 340 females and 350 males. It was made an anthropometric evaluation (weight, height, skinfolds: tricipital, bicipital, suprailiac and geminal, WC in the narrowest waist), the Maturational Status (MS) was obtained through the Tanner stages [3], the RPA was evaluated by the Baeecke's questionnaire [4] and the AA was measured by the progressive aerobic endurance run (PACER) test resorting to the Fitnessgram software [5]. The %FM and the WC were the variables which have shown higher levels of correlation with AA, being the performance on PACER more influenced by the level of total adiposity in boys (r = -0.47, p < 0.01) and by a centralized distribution of fat mass (FM) in girls (r = -0.29, p < 0.01). The association of RPA with AA was positive and low in both genders, particularly in males with r = 0.11 (p < 0.05). The obese boys showed a lower performance in PACER comparing to those who are not obese, with a mean difference of -17.34 laps (p < 0.01). The presence of a more centralized distribution of FM compromised the performance of PACER in both genders, particularly in males. The most active girls registered a mean of +2.83 laps (p < 0.01) on PACER. The centralized distribution of FM consubstantiate in a higher WC, generate a lower performance in PACER in females and males and particularly in the last ones, where the presence of obesity influences negatively their performance in PACER. Girls with levels of RPA7.97 points and boys with RPA 7.5 points performed a higher number of laps in PACER.

ENERGY EXPENDITURE AND PHYSICAL ACTIVITY PATTERNS IN OVERWEIGHT AND LEAN 11-YEAR OLD CHILDREN IN CROATIA

Soric, M., Misigoj-Durakovic, M.

Faculty of Kinesiology, University of Zagreb, Croatia

The growing epidemic of obesity is becoming more and more pronounced, even among children. Physical inactivity, along with inadequate nutrition, is one of the main reasons of the growing prevalence of obesity. Therefore, as a part of a bigger survey, the aim of this study was to objectively evaluate energy expenditure and physical activity patterns in overweight and lean 11-year old children in Croatia. Ninety children (50 girls and 40 boys, mean age 11.3 ± 0.2 years) from six different elementary schools in Zagreb (Croatia) were selected to participate in the study. Height and weight were measured and body mass index (BMI) was calculated. Sixteen girls and sixteen boys were considered overweight or obese according to International Obesity Task Force BMI cut off points for age and gender. Energy expenditure and physical activity were assessed by a multisensor device (Sensewear Armband, BodyMedia, Pittsburgh, USA)2. The device was worn for four consecutive days. Group differences were tested using Student’s t-test for independent samples.

Total daily energy expenditure (TEE) was higher in overweight children (2243 ± 406 kcal/day) when compared with lean children (1756 ± 338 kcal/day), p < 0.001. No significant differences between groups were observed in energy expenditure for physical activity (PAEE) (637 ± 341 and 622 ± 323 kcal/day for overweight and lean children, respectively, p = 0.85). However, when energy expenditure is expressed relatively to body weight overweight children presented with lower values of both TEE (39.3 ± 5.9 and 44.1 ± 6.6 kcal/kg/day for over-

Friday, July 11th, 2008 14:15 - 15:15
weight and lean children, respectively, \( p<0.001 \) and PAEE \( (11.3 \pm 6.2 \) and \( 15.9 \pm 8.8 \) kcal/kg/day for overweight and lean children, respectively, \( p=0.009 \)). Also, the group of overweight children exhibited significantly lower values of daily physical activity \( (158 \pm 78 \) min/day) compared with the lean group \( (219 \pm 110 \) min/day, \( p=0.007 \). Concerning the intensity of physical activity, moderate intensity activity \( (13-6 \) MET) was lower in overweight children \( (145 \pm 68 \) min/day) when compared with the lean ones \( (196 \pm 97 \) min/day, \( p=0.009 \), while vigorous activity \( (6-9 \) MET) was not different between groups \( (11.2 \pm 13.1 \) and \( 17.8 \pm 18.7 \) min/day for overweight and lean children, respectively, \( p=0.08 \)).

In conclusion, it seems that overweight 11-year-old children in Croatia are less physically active than their non-overweight peers, but that energy expenditure expended for daily physical activity is the same in overweight and lean children.

EFFECTS OF A SUPERVISED HOME-BASED PHYSICAL ACTIVITY PROGRAM ON THE BURDEN IN INFORMAL CAREGIVERS OF PERSONS WITH DEMENTIA

University of Extremadura, Spain

Introduction: People who care for patients with dementia usually present lower mental health and a high burden because of caring. Caregivers suffer from the consequences of the disease and drastically reduced their opportunities to do their usual activities. Positive effects of physical activity on mood and subjective well-being in older people have been previously depicted.

Objectives: The purpose is to evaluate the influence of a home-based physical activity program on the perceived burden of the main informal caregiver (MIC) of a family member with Alzheimer Disease (AD).

Measurement and Method: Thirty-two female caregivers were randomly assigned either to an intervention group or to a control group. The intervention was a 3-month supervised and home-based program of physical exercise. The program consisted of two one-hour session per week. Each session included two blocks of aerobics and two of strengthening and mobility exercises. The burden was assessed by Zarit Scale.

Results: All the caregivers in the intervention group completed the program. After 3 months, the caregivers of the intervention group experienced an improvement in the perception of subjective burden in 12% (\( p=0.001 \)) compared to controls.

Conclusions: We conclude that the program is feasible, adherent and effective for reducing the burden of people caring for a patient with Alzheimer’s at home.

EFFECTS OF A 12-WEEK SUPERVISED HOME-BASED PHYSICAL EXERCISE PROGRAM ON THE HEALTH-RELATED QUALITY OF LIFE AND FUNCTIONAL CAPACITY IN PARALYTIC POLIO SURVIVORS

Gusi, N., Serrano, C., Madruga, M., Prieto, J.

University of Extremadura, Spain

Introduction: There are few new cases of polio infection but the survivors usually report low levels of functional fitness and health-related quality of life (HRQOL) for decades. Moreover, 25-85% of persons with paralytic polio sequel experience a new significant worsening of their health 10 to 40 years after they suffer the infection. Major symptoms are muscle and joint pain, weakness and fatigue. Purpose: To evaluate the influence of a 12-weeks supervised home-based physical exercise program in lower limb Paralytic Polio Survivors.

Measurement and Method: Twenty-three participants were randomly assigned either to an experimental group or control group. The program was administered at the home of patient. The weekly program included two one-hour sessions directly supervised by a physical technician and another self-administered by patient. Each session was structured into three parts: mobility, flexibility and resistance strength.

The main outcomes measured in the current study were HRQOL assessed by EQ-5D and the walk functional capacity evaluated by the 6-minute walking test. Results: After 12 weeks, the experimental group attended 82% of the programmed sessions. Compared to control group, exercise group improved its HRQOL in mobility (25%; \( p=0.003 \)), anxiety or depression (21%; \( p=0.037 \)) and time-trade-off tariff or preference (overall or utility index) (33%; \( p=0.004 \)). We also have found positive effects on the ability to walk (7%; \( p=0.001 \)) regarding the control group. Conclusions: We conclude that the program is feasible, specially the directly administered sessions, and it is effective in improving health-related quality of life and functional capacity walking.

THE KNOWLEDGE OF ANKARA UNIVERSITY LECTURERS ON EXERCISE RECOMMENDATIONS

Koz, M., Kaplan, G.

Ankara University, Turkey

Introduction: Physical inactivity is major risk factor for many diseases such as cardiovascular disease, stroke, diabates, obesity, hypertension and osteoporosis. Present data indicates that physical activity knowledge alone is not sufficient to elicit a behavior. The purpose of this study was to determine whether Ankara University lecturers know which traditional and lifestyle physical activities affect health and how they should be physically active to achieve a desired health benefit. Secondary purposes were to determine whether this knowledge is a function gender, education, age, level of income, type of school and faculties.

Methods: Items based on the Center for Disease Control and Prevention/ American College of Sports Medicine principles included knowledge of exercise guidelines, traditional and lifestyle physical activities. These information were obtained from 20 questions. The research has been performed on 632 lecturers in total, 355 of whom are male and 277 are female lecturer from Ankara UniversitySchool of Physical Education and Sports, Faculty of Dentistry, Faculty of Language, History and Geography, Faculty of Pharmacy, Faculty of Educational Sciences, Faculty of Science, Faculty of Law, Faculty of Teology, Faculty of Communication, Faculty of Engineering, Faculty of Political Sciences, Faculty of Medicine, Faculty of Veterinary Medicine, Faculty of Agriculture. Face-to-face interview method has been employed in obtaining the research data.

Results
By the end of research, we have seen that level of information of the lecturers about lifestyle physical activity is high (91%), about exercise prescription is less (65%), and on the traditional physical activities at the level of 68%. The differences between the levels of information about traditional and lifestyle physical activities only relates to education and age (P < 0.05). There were no significant affect on knowledge about exercise prescription was relatively low and there were no significant differences between schools or departments.

Conclusions
This reveals that the lecturers of Ankara University are informed about type of physical activities that is favorable for the health. But their knowledge about exercise prescription was relatively low and there were no significant differences between schools or departments.

THE PPAR GAMMA GENE, CARDIORESPIRATORY FITNESS AND METABOLIC SYNDROME IN YOUNG AND OLD JAPANESE MEN AND WOMEN
Sanada, K., Miyachi, M., Iemitsu, M., Murakami, H., Tabata, I., Yamamoto, K., Tanimoto, M., Kawano, H., Suzuki, K., Higuchi, M.
Waseda University, Japan

Objective: Little information is available regarding the relationships among human obesity-related genes, cardiorespiratory fitness and metabolic syndrome (MS) or predisposition to MS (IMP). The present study was performed to investigate the age differences of peroxisome proliferator-activated receptor gamma (PPARG) genotypes and cardiorespiratory fitness to the MS in Japanese men and women. Research Methods and Procedures: Sedentary and moderately active men (n = 149) and women (n = 412) aged 18-85 yrs participated in this study. We measured maximal oxygen uptake (VO2max) during an incremental cycle ergometer exercise test. Serum HDL-cholesterol, triglyceride and plasma glucose levels were measured in all subjects. Total and regional lean soft tissue and fat mass were also measured by dual-energy X-ray absorptiometry (DXA). We analysed the genotype of PPAR (C1431T) using a polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) assay.

Results: A total of 11 men (7.4%) and 10 women (2.4%) developed MS. In addition, a total of 35 men (23.5%) and 29 women (7.0%) showed MS. VO2max in men and women with MS (29.3 ± 5.3 and 23.6 ± 4.6 ml/kg/min) were significantly (P < 0.05) lower than in healthy men and women (40.1 ± 10.2 and 32.7 ± 7.8 ml/kg/min). Two-way ANOVA indicated that in younger group, the number of risk factors of MS in low fitness group was significantly higher than that in high fitness group (P < 0.05), and also in C1431T (CC) genotype was significantly higher than that in C1431T (CT + TT) genotype (P < 0.05). In addition, the interaction between fitness and genotype in the number of risk factors was significant. However, in middle-age and older group, the number of risk factors of MS in low fitness group was significantly higher than that in high fitness group (P < 0.05), but not observed in C1431T genotype effect. Furthermore the interaction between fitness and genotype in the number of risk factors of MS was not significant.

Discussion: We concluded that poor VO2max was associated with the prevalence of MS independent of age group. The C1431T genotype in PPAR in younger subjects is associated with the risk factors of MS, but not in middle-aged and older Japanese men and women.

LIFESTYLE PHYSICAL ACTIVITY CHOICES OF CHILDREN AND YOUNG PEOPLE: AN EXPLORATION OF THE GLOUCESTERSHIRE PUPIL ON-LINE SURVEY
Matthews, N., Kilgour, L.
University of Gloucestershire, United Kingdom

Public health concerns relating to the increasing sedentary nature of contemporary living have prompted the UK Government to support initiatives that promote healthy lifestyles and increase physical activity (PA) participation. In particular, current guidelines to promote PA to children and young people derive from the need to develop preventative health strategies for future generations and reduce health inequalities. The most recent guidelines recommended for this population to reap health benefits are 5 x 60 minutes of moderate physical activity per week (DoH, 2004a).

This reveals that the lecturers of Ankara University are informed about type of physical activities that is favorable for the health. But their knowledge about exercise prescription was relatively low and there were no significant differences between schools or departments.

A WHOLE-BODY VIBRATION PROGRAM WITH SHORT BOUTS IMPROVES MOBILITY BUT NOT SLEEP IN WOMEN WITH FIBROMYALGIA
Parra, J., Gusi, N., Olives, P., Adsuar, J.
University of Extremadura, Spain

Introduction.
As for as women with fibromyalgia (FM) suffers widespread pain, it is usually inaccommoded that exercise in low ballistic impact activities. Whole-Body Vibration (WBV) is an exercise modality that allows it, but to our knowledge these is a lack of evidence about its use in persons with fibromyalgia.

Objective:
The purpose of this study is to assess the feasibility and efficacy of WBV program with short buts on the quality of life in women’s with fibromyalgia.

Method:
Fifty women with FM were randomly assigned to an intervention or to a control one. The intervention consisted of 3 sessions per week than 12 weeks. Each session of exercise consisted of 6 series of vibration in the platform Galileo Fitness (Galileo, Germany), to a frequency of 12.5 Hertz and with a progressive duration of 30 seconds during the first 4 weeks, 45 seconds in the 4 following and 60 seconds during the 4 last weeks. The quality of life was measured with the questionnaire of quality of life 15D.

Results:
96% of intervention group completed the program the score of the dimension of mobility in the questionnaire 15-D has taken place an improvement (p<.05) in the group that has made the vibratory exercise, nevertheless in the dream score has taken place a decrement (p<.05).

Discussion:
The whole body vibration training proposed improves the mobility but not the quality of the dream in people with fibromyalgia. Previous studies with aerobic training have been obtained improvements in mobility and sleep, whereas the made whole body vibration mainly has an neuromuscular activation component. One sets out to study if a training by vibratory exercise with series of greater duration and therefore with greater aerobic component, would improve or at least, it would not negatively affect the capacity to sleep.

Conclusions:
12 weeks of whole body vibration with series of short duration produces improvements in the dimension of mobility of the 15-D questionnaire, but it causes a decrement in the dimension of dream.

THE EFFECT OF 6-MONTHS EXERCISE INTERVENTION ON THE COGNITIVE-MOTOR FUNCTION IN THE MIDDLE-AGED AND ELDERLY JAPANESE

Kasaoka, S., Ohashi, H., Taniguchi, Y., Konishi, Y., Inoue, T., Minami, S.
International Budo University, Japan

Introduction
It was reported that six months aerobic training (Kramer, A. F., et al., 1999) or resistance exercise (Cassilhas, R. C., et al., 2007) intervention improved cognitive function of the elderly. However there are few studies about the effect on the brain function by the overall fitness program in which many people popularly participate for improving their physical fitness. We investigated whether the cognitive-motor function in middle-aged and elderly people were affected by the participation in 6-months exercise program which included aerobic and anaerobic exercise.

Methods:
Three men and seven women (mean age 62.8 ± 4.1 years old) participated in a 6-months exercise program. All the subjects gave their informed consent for participation in the study. One hour exercise class, including aerobic exercise, strength exercise and stretching, was held once a week. Before and after the 6-months exercise program, the cognitive-motor function and physical fitness of subjects were evaluated. In present study, the ability that subject reproduces some movement following demonstration is regarded as the cognitive-motor function. After watching 4 cycles of 4 count step pattern projected onto the screen in front of the subject, he/she reproduced 8 cycles of the same movement to synchronize with video pictures. It was evaluated how many cycles were needed to synchronize with the step pattern accurately in the spatial and temporal viewpoints. Subjects performed 13 step patterns at random order. Six in 13 patterns were the single lead leg step in which cycles were started always with the right leg. The rest patterns were the alternating lead leg step in which cycles were started with the right or left leg alternately.

Results and Discussion
Subjects took more cycles to synchronize with video pictures in the alternating lead step patterns than in the single lead step patterns in both the spatial and temporal viewpoints. After the participation in 6-months exercise program, the number of cycle to synchronize with video pictures was significantly reduced in 3 of 7 alternating lead steps in the spatial viewpoints and in 5 of 7 alternating lead steps in the temporal viewpoints. In any of the single lead step, the number of cycle needed to synchronize was not changed. It was suggested that the improvement of cognitive function by aerobic exercise appeared selectively in the task condition depending on executive control processes (Kramer, A.F., et al., 1999). In the present study, the alternating lead step patterns are more difficult than the single lead step patterns and may need more executive control processes.

MUSCULAR STRENGTH, BONE MINERAL DENSITY AND BODY COMPOSITION IN ADULTS WITH MENTAL RETARDATION (WITH AND WITHOUT DOWN SYNDROME)

Marmeleira, J., Cruz, S.
University of Évora, Portugal

The purpose of this study was to compare the characteristics of muscular strength, bone mineral density (BMD) and body composition (BC) between individuals of three distinct groups: (i) moderate/mild mental retardation with Down Syndrome (DS); (ii) moderate/mild mental retardation without Down Syndrome (WMR); (iii) without mental retardation (WNR).

Forty-six persons of both genders (20 to 40 years old) participated in this study. 15 DS (29.7 ± 5.1 years), 16 MR (28.7 ± 5.8 years) and 15 WMR (25.7 ± 4.2 years). Participants with DS and MR were recruited from three local vocational and educational training centres, all of them lived at home and received special education services in specialized centres 5 days per week. These services included 2 to 3 exercise sessions per week, 60 min each. The participants WMR were not engaged in any competitive sport and the majority practised recrea-
Total fat (%) was determined from a total body scan by dual-energy X-ray absorptiometry (Hologic®). The same instrument was used to conduct evaluations of BMD in lumbar spine (L2-L4), right hip (femoral neck) and upper and lower limbs (mean of the left and right sides). Isokinetic knee strength was measured using an Isokinetic Dynamometer (Biodex System 3). The variables measured were peak torque (highest peak torque of 3 repetitions at 60°.sec⁻¹ and average power (25 repetitions at 180°.sec⁻¹). Mean values of the left and right sides at flexion and extension were used for comparisons. The results showed significant differences between groups for all measures of muscle strength (p<0.001), BMD and BC (p<0.05). Post hoc analysis revealed that: (i) MR have greater isokinetic knee strength then DS (p<0.05 for all), WMR have greater knee isokinetic strength then MR and DS (p<0.01 for all); (ii) WMR have smaller total fat then MR (p=0.035) and DS (p=0.036); (iii) WMR have bigger BMD than DS and MR in the right hip and lower limbs (p<0.01 for all) and WMR also have superior BMD then DS in upper limbs (p=0.003). Among DS, the prevalence of osteoporosis and osteopenia was 6.7% and 73.3% for femoral neck, and 20.0% and 53.3% for lumbar spine, respectively; among MR, the prevalence of osteoporosis and osteopenia was 12.5% and 31.3% for femoral neck, and 6.3% and 43.8% for lumbar spine, respectively. WMR have a smaller prevalence of osteopenia, namely 6.7% for femoral neck and 20.0% for lumbar spine.

We concluded that persons with mental retardation when compared with persons without mental retardation have obvious disadvantages in muscle strength, BMD and BC, these disadvantages are more evident for persons with Down Syndrome. High prevalence of osteoporosis and osteopenia occurs among young adults with mental retardation.

TRENDS IN HEALTH-RELATED PHYSICAL FITNESS (FITNESSGRAM): A POPULATION STUDY IN CHILDREN AND ADOLESCENTS FROM ESPOSENDE, NORTH OF PORTUGAL

Faculty of Sport/University of Porto, Portugal

PURPOSE. The aims of this study were: (1) to describe passing rates in individual health-related tests, (2) to identify rates of success in all fitness tests and, (3) to test for specific trends across age in each gender.

MATERIAL AND METHODS. A random and stratified sample representing 87% of the total population of students from 10-17 years of age living in the area of Esposende, north of Portugal, were enrolled in the study (males, n=1412; females, n=1458). Health-related physical fitness was assessed with the Fitnessgram test battery (1 mile run-walk, trunk-lift, curl-up and push-up). Intra-class correlation coefficients were computed to estimate reliability. Chi-square statistic were used to test for trends of unfit-fit across age in each gender. SPSS 15 and PEPI 4 were used in all computations.

RESULTS. Reliability estimates for all tests ranged from 0.84 and 0.95 in girls and 0.78 and 0.96 in boys. Across tests, and in both genders, the rate of success was evident. The only trend of interest is a push-up in girls, where the prevalence of unfit across all ages is 58.6%. In all tests and in boys and girls no significant trend (p>0.05) was evident for passing rates. Success rate in all tests ranged from 18% at 10 years to 33% at 17 years in girls (trend, p>0.05); in boys, the range was increasing, from 25% at 10 years to 71% at 17 years (linear trend, p<0.05). There are marked differences in success rate favoring boys at all ages (p<0.05).

CONCLUSION. In conclusion, these results show that notwithstanding the success rate in health-related physical fitness in these youngsters, there are also problems associated with unfit ones (from 8% to 58%) in different fitness components. The implementation of specific programs to surpass this fitness failure is needed. Moreover, a specific attention should be given to avoid low levels of physical activity-sports practice, and other co-morbidities such as overweight-obesity that are usual linked in unfit youngsters.

ACUTE EXERCISE, OXIDATIVE AND INFLAMMATORY INJURY IN TYPE 2 DIABETES

Oliveira, A., Sapata, K., Cunha, G., Rossato, J., Rocha, R., Moreira, J., Homem de Bittencourt Jr, P., Friedman, R.
Universidade Federal do Rio Grande do Sul, Brazil

Diabetes is associated to oxidative injury and inflammatory process. Physical activity, which is part of diabetes treatment, increases free radicals formation and, in counterpart, improves antioxidant defenses. Nevertheless, little is known about the effects of acute exercise on the oxidant and antioxidant system of type 2 diabetics. This study aimed to assess the effects of acute exercise on oxidative stress and inflammatory markers in type 2 diabetic. This study was approved by the ethics committee of HCPA-UFRGS (06252) and all patients signed a consent form. Thirty type 2 diabetic patients (age = 50.57 ± 6.28 years; years of disease = 6.0 (1.0 – 25.0); weight = 74.88 ± 9.99 kg, height = 162 ± 0.94 cm, body fat = 33.36 ± 9.34%; VO2peak = 23.96 ± 7.71 ml.kg⁻¹.min⁻¹, maximal workload = 140 ± 42.35 W and Antf = 16.23 ± 36 ml.kg⁻¹.min⁻¹) without complications took part in this study. In the first test, a progressive cycling protocol, in which initial workload was 25 W with an increment of 25 W per minute, was used to determine the individual’s VO2peak, aerobic threshold (AeT), and anaerobic threshold (AnT = 16.23 ± 36 ml.kg⁻¹.min⁻¹) and average power (25 repetitions at 180°.sec⁻¹) without complications took part in this study. In the second test, that was performed one week after the previous visit, patients performed a submaximal cycling exercise at an intensity based on the oxygen uptake of the anaerobic threshold. In the second test, that was performed one week after the previous visit, patients performed a submaximal cycling exercise at an intensity based on the oxygen uptake of the anaerobic threshold.
The prevalence of obesity was 31-38% in males (n=16) and 17% in females (n=12) using IOTF and CDC age- and gender-specific BMI cut-offs. Children (7.43 yrs ± 0.5 mths). Percentage body fat (%BF) was calculated using the equation of Siri (1961). The BMI results of participants were employed to examine the weight profiles of 28 children aged 7 - 8 years from a socio-economic disadvantaged primary school.

This study aimed to investigate the weight profiles of children aged 7 - 8 years from a socio-economic disadvantaged primary school.

Body mass index (BMI), waist circumference and skin fold thickness at four sites were employed to examine the weight profiles of 28 children (7.43 yrs ± 0.5 mths). Percentage body fat (%BF) was calculated using the equation of Siri (1961). The BMI results of participants were classified using the International Obesity Task Force (IOTF) devised by Cole et al. (2000) and the CDC growth charts (CDC, 2000a). The prevalence of obesity was 31-38% in males (n=16) and 17% in females (n=12) using IOTF and CDC age- and gender-specific BMI cut-off points respectively. Using the IOTF cut-off points and CDC standards, the level of overweight was 44% in males and 37% in females. A significant difference was found between 7 and 8 year old males for %BF (P<0.05). A strong relationship existed between BMI and %BF (r=0.86, P<0.01) suggesting that BMI may not be a poor index of body fatness in socio-economic disadvantaged children.

The current investigation contributes to the limited body of knowledge available concerning the weight profiles of Irish children and illustrates that children of this socio-economic disadvantaged school, especially males, have more adverse weight profiles than children from past national and international data. The current investigation contributes to the limited body of knowledge available concerning the weight profiles of Irish children and illustrates that children of this socio-economic disadvantaged school, especially males, have more adverse weight profiles than children from past national and international data.

Characterization of a seven minutes aquatic exercise maximum effort and health risk determination

FADEUP, Portugal

Literature on hydrogymnastics is scarce and has been situated mainly on the estimation of aerobic performance indicators. According to the guidelines of the ACSM (Haskell et al., 2007) healthy adults need moderate-intensity aerobic physical activity. Anaerobic performance development as been neglected in fitness field without any sustained reason. Apparently, this kind of efforts still needs to be studied and possible health risks associated to it should be assessed. The aim of the present study was to characterize a long effort peak and detect possible health risk factors associated with it. Ten healthy women (36.3±6.1 yrs) experienced in hydrogymnastics participate in the study. Exercise protocol consisted on a 3 min warm up (level 11 in Borg’s 6 to 20 Rate of Perceived Exertion (RPE) Scale), followed by 5 min of aquatic exercise of moderate intensity (13 to 15 in Borg’s RPE scale), and a peak effort (18 to 20 in Borg’s RPE scale) of 7 min duration. Rest HR values (POLAR Vantage NV™) were obtained both on land and in water and during exercise. Blood pressure (BP) was evaluated at rest and after exercise by experienced health professionals using a sphygmomanometer and a stethoscope. Mean BP was also calculated using systolic (SBP) and diastolic blood pressure (DBP) [MBP=1/3 (SBP-DBP)+DBP] and used as a health risk factor. Blood lactate concentration (L.0-I) was determined at rest and after exercise (LactatePRO). Due to the lower number of subjects studied, both non-parametric Wilcoxon test and parametric Paired Samples T-Test were applied to data. The level of significance was established on 5%.

Differences obtained through both statistical procedures led to the same results. HR rest values were significantly lower on water (69.9±11.60 bpm) comparatively to land (75.7±11.63 bpm). Peak and mean HR values of the 7 min peak were 185.3±11.54 and 179.9±10.81 bpm, respectively. After exercise systolic blood pressure was significantly higher (mean difference of 26.40±15.02 mmHg) and diastolic blood pressure was significantly lower (mean difference of 21.3±8.5 mmHg) than in rest. The same MBP was observed in rest (88.3±12.22 mmHg) and after exercise (83.4±14.41 mmHg), showing a lower cardiovascular risk associated to an exercise performed at maximum intensity during a seven minutes period. Lactate values were significantly higher than in rest (0.4±0.1 mmol/l-I) comparatively to rest (0.8±0.1 mmol/l-I) and showed the high level of participation of the anaerobic metabolic pathway during the 7 min peak. BP and L.0-I results combined leads to the conclusion that anaerobic exercise could be safely used in hydrogymnastics with healthy subjects.

References.
Human health depends on the level of physical maturity and activity which is established in childhood and youth. The best opportunity to prepare the majority of people to live physically active, healthy lives is through sports. Regular physical exercises and participation in various physical activities influence the functional state of organism favourably. Physical inactivity is one of the major risk factors for fatness, cardiovascular diseases, type 2 diabetes, and certain cancers (I). The recognition of the importance of regular physical activity for physical fitness has led to an increased interest in the study of different aspects of physical activity. The aim of the work was to compare sport activities of different age Latvian primary and basic school students. The questionnaire of Latvian primary school (4th grade) students and basic school (6th and 8th grade) students about their sport activities and interest about sports was carried out. The results of investigation showed that the most active lifestyle have 6th grade students. 17% of 6th grade students go into sports more than 8 hours in a week, 34% of 6th grade students go into sports 4-8 hours in a week, 23% of these students go into sports 2-4 hours in a week, 16% of 6th grade students go into sports 1-2 hours in a week and 10% of 6th grade students don’t participate in regular sport activities. The activities of 4th grade students and also 8th grade students are lower than 6th grade students. The majority of 4th grade students go into sports 1-2 hours in a week (40%) or 2-4 hours in a week (35%) or 1-2 hours in a week (21%). 30% of 4th grade students, 38% of 6th grade students and 35% of 8th grade students regularly train in separate branch of sports. The greatest number of students who go in for sports in order to reach high results in separate branch of sports are in 6th grades. Most of all students among boys as well as girls are going into basketball. The most popular branches of sports among boys are sport games (basketball, football and hockey). Rather many boys go into various branches of wrestling. Among girls popular are such branches of sports as basketball, volleyball, swimming, sport dances and aerobics. The main factors why students go in for sports are improvement of health, necessity to sustain good physical state and they are fascinated by the process of going in for sports. For many basic school students sport is the most important hobby. The main factor, which doesn’t allow students to go in for sports more than they do it, is a lack of time. The mission of sport teachers and pedagogues is to increase interest of children and young people about physical activities and sports.

TRACKING OF HEALTH-RELATED PHYSICAL FITNESS FROM CHILDHOOD TO ADOLESCENCE: A 4-YEAR PROSPECTIVE STUDY IN BRAZIL
Ronque, E., Reichert, F., Serassuelo Jr, H., Cyriino, E., Arruda, M.
Universidade Estadual de Londrina, Brazil

INTRODUCTION: Epidemiological studies have shown a positive association between health-related physical fitness components and lower risks of mortality in adulthood1,2. Physical fitness is also important in youth. For example adequate levels of body composition and cardiorespiratory endurance are positively associated with health outcomes3. Thus the maintenance of high levels of the health-related physical fitness components throughout the life is desirable. OBJECTIVE: To verify the tracking of health-related physical fitness components from childhood to adolescence. METHODS: Four birth cohorts (1992, 1993, 1994 and 1995) were selected and visited in 2002 and 2005 (ages 7 to 10 years among the youngest and 10 to 13 years among the oldest). Participants were selected from a private school in the city of Londrina - Brazil. The following measurements were taken following standardized protocols: tricipital and subescapular skinfolds, the sit and reach flexibility test, the 1min sit up test, and a cardiorespiratory test of nine or twelve minutes. Based on the results of each test, individuals were classified as sufficiently fit (SF) or insufficiently fit (IF) according to the Physical Best criteria. This criterion takes into account age and gender of the individual. Thereafter, the results of the first assessment (2002) were compared with the later one (2005), comprising four groups: a) SF (first assessment) and SF (fourth assessment), b) SF and IF, c) IF and SF and; d) IF and IF. The McNemar and Kappa (K) statistics were applied to evaluate the tracking of the physical fitness. RESULTS: A total of 375 individuals participated in the study (197 (52.5%) boys). The overall proportion of individuals classified as SF in all tests decreased from 21.1% in the first assessment to 10.4% in the fourth one (p < 0.001) (K=0.31). The health-related component who presented the highest prevalence of IF throughout the study was the cardiorespiratory endurance (67.5% in the first test and 74.1% in the last one). The overall proportion of individuals who changed from SF to IF was much higher than IF to SF (69.6% and 5.1%, respectively). CONCLUSION: A markedly decrease in fitness was observed in this longitudinal study, suggesting that the risk of several adverse health outcomes increased. Thus, interventions aimed to keep or improve physical fitness among children and adolescents are warranted.

PREVALENCE OF OVERWEIGHT AND OBESITY IN LEIRIA’S ELEMENTARY SCHOOL PUPILS
Cruz, J., Morouço, P.
Leiria’s Polytechnic Institute (I.P.Leiria), Portugal

The prevalence of overweight and obesity has shown a worldwide increase in recent years, both considered key factor risks in the development of cardiovascular diseases, a major cause of mortality in developed and developing countries[1]. In recent years several studies have shown a global trend for increasing overweight/obesity in children and youth, Portugal is no exception: one of Europe’s highest prevalences[2], where almost one third of 7-9-y-o(3) and 7-11-y-o[4] are obese/overweight. The aim of this study was to assess the prevalence of overweight and obesity in Leiria’s elementary school students, aged 7-11-y-o.
Data were collected in 2006 in 5 randomly chosen city’s elementary schools, comprising 773 children. Overweight/obesity was assessed according to CDC’s BMI percentile classification and a simple questionnaire was given to the students focusing on 1) school transportation, and 2) type of off-school leisure time activities.

We have found a total percentage of 18.4% overweight and 11.0% obese children, which indicate a prevalence of 29.4% of overweight/obesity. Boys presented a higher prevalence of obese individuals over girls (12.5% vs. 9.4%). Girls had a higher prevalence of overweight/obesity at ages 7 and 9-y-o (36.5% vs. 31.9% and 35.1% vs. 23.6%). On the other hand, boys were significantly more overweight/obese at age 10 (37.1% vs. 15.5%).

Most of the children did not engage in any kind of off-school leisure time activity (67.8%) and only 32.2% did have a regular sports practice. Boys were significantly more engaged in sports practice than girls (38.4% vs. 25.5% p=0.000). Children mainly use motorized school transport (67.2%) and only about a third walked to/from school (31.5%). No association was found between overweight/obesity and type of school transport use.

These results on overweight/obesity are consistent with Padez et al. (2004) and Lobstein et al. (2005), school transportation cannot be regarded as a single factor to promote an increase in physical activity and prevent overweight/obesity.[5]

PREVALENCE OF OVERWEIGHT AND OBESITY IN LEIRIA’S 2ND GRADE SCHOOL PUPILS

Cruz, J.
Leiria’s Polytechnic Institute (I.P.Leiria), Portugal

The economic burden of obesity on total health care costs ranges from 2.7%-underestimated[1] and in the USA it is expected to increase to 20% and 25% by 2020 and 2030[2]. In Portugal, obesity costs have been steadily increasing since 1996 from 396.7 M to 497.3 M euros in 2002[3]. 4) Obesity is a major risk factor for cardiovascular diseases and is highly associated to sedentary lifestyle patterns. Portuguese citizens show the highest rate of sedentary lifestyle all over the European Union (70%[5]) and a high prevalence of overweight/obesity (OW/O) both in youth and adults. Adult obesity can be linked to early OW/O, 7) so primary prevention plays a central role in reducing the impact of this epidemics.

The purpose of this study was to assess the prevalence of overweight and obesity in Leiria’s 11-13-y-o. Data were collected in 2007 in 4 randomly chosen city’s 2nd grade schools, comprising 567 children. OW/O was based on Cole et al. [8] BMI classification and a simple questionnaire was given to the students focusing on 1) school transportation, and 2) physical activity over 20 min a day (PA20min). Waist circumference (WC) measurement and shuttle run aerobic power test (VO2) were performed.

The prevalence of OW/O was 28.0%, higher in boys than girls (31.1% vs. 24.9%). Most children use motorized transportation to school (85.8%). Boys were significantly more active than girls (47.6% vs. 29.7%). More PA20min children were normal weight (NW) than OW/O (boys: 72.4% vs. 59.5%, p=0.051; girls: 70.0% vs. 21.0%). OW/O boys and girls had a significantly higher WC than NW subjects (p=0.000). O girls showed a WC over 88cm, which is a cutoff point to define increased cardiovascular risk. Boys had a significantly better VO2 than girls (44.0±15.1 ml.kg.min vs. 40.6±3.71 ml.kg.min, p=0.000). NW children were the fittest [43.4ml.kg.min, 39.9ml.kg.min, 37.6ml.kg.min, p=0.05].

EFFECT OF A SCHOOL-BASED INTERVENTION PROGRAM (KISS) ON CHILDREN’S PHYSICAL ACTIVITY IN DIFFERENT TIME PERIODS OF THE SCHOOL DAY

Meyer, U., Zahner, L., Puder, J., Roth, R., Kriemler, S.
Institute of Sports and Sports Sciences Basel, Switzerland

Background: Physical inactivity is associated with decreased bone health, fitness and increased cardiovascular disease risk. The school provides an excellent setting to enhance levels of physical activity (PA) since school-based intervention programs can reach many children at early age. Several intervention trials used intervention programs to enhance children’s PA, but only a few of them were successful and assessed PA by objective methods. The aim of this study was to evaluate a school-based PA intervention program by assessing PA objectively during different time periods of the day. Method: 15 schools (n = 340 children) were randomized in the intervention (INT, n = 9) or the control (CON, n = 6) group, stratified by grade (1st vs. 5th grade), living area (urban vs. rural) and by ethnicity (10-30% migrants). The intervention during one academic year consisted of 1. two additional physical education (PE) classes per week adding up to five PE classes per week, 2. several short PA breaks per day during academic lessons, 3. PA homework, and 4. additional playing material for recess. Before, at midterm and at the end of the intervention, PA was assessed by accelerometers over 7 days. Total PA, PA during PE classes, recess, class-time and out-of-school was assessed as mean counts per minute (CPM), time in moderate-to-vigorous (MVPA, 2000-2999 counts) and vigorous PA (VPA, >3000 counts). Half and overall effects of the intervention were estimated using a mixed linear
model with random effects for school and subject and with adjustment for grade and gender. Results: Complete accelerometer data were available for 253 children. Mean CPM of total PA in INT and CON children decreased during the intervention period (CON: -6.4%, 95% CI, -14.7 to 2.7%, INT: -11.1%, CI -17.7 to -4.0%, Pgroup = ns). Before adjusting for school as random factor, there was a significant difference of PA in favour of the INT children for CPM in total PA (half time), during PE and class-time (half time and overall), during recess (overall), for MVPA during recess (half time and overall and class-time (half time) and for VPA during PE, class-time and recess (half time and overall). However, after adjusting for school, the intervention effect was only significantly different for CPM (only overall) and MVPA (half time and overall) during recess in favour of the INT children. Moreover, INT children showed a stronger decrease than CON children in MVPA and mean overall CPM of out-of-school time. Discussion/Conclusion: Before, but not after adjusting for school, the intervention program was effective in positively influencing children’s PA in several day segments which shows the important influence of the school environment and the teachers. Additionally, PA during the school days was compensated during leisure time. We suggest that future PA intervention projects should have a stronger focus on family and out-of-school activities.

COULD EXERCISE BECOME A MEANS TO CONTROL MATERNAL WEIGHT GAIN AND TO PREVENT MACROSOMIA IN WOMEN WITH GESTATIONAL DIABETES?

Rodríguez-Cabrero, M., Barakat-Carballo, R., Montejo Rodríguez, R., Rojo González, J.
Universidad Politécnica de Madrid (UPM), Spain

Introduction.
Gestational diabetes mellitus is a common complication of pregnancy (represents nearly 90% of all pregnancies complicated by diabetes) (1) and in Spain its prevalence may range up to 12% (2). Gestational diabetes mellitus is associated with gestational and foetal complications. Infants of mother with gestational diabetes are at higher risk of macrosomia and women may suffer the complications associated with delivery of large babies (3).

Aim: Analyze the effect of exercise on maternal weight gain and birth weight in women with gestational diabetes. Analyze the influence of maternal weight gain on birth weight.

Methods.
24 gestational diabetic women participated in the study, 14 in the exercise group (age 33,43±4,33 kg/m^2, previous BMI 28,48±5,18 kg/m^2) and 10controls (34,60±2,84 kg/m^2 previous BMI 27,92±5,36 kg/m^2). The protocol consisted in 3 ses/wk, 35-40 minutes duration and intensity 50-60%HRRmax. Activities included aerobics, tonification, pelvic floor exercises, postural correction and relaxation. Diet treatment was based on pre-pregnancy BMI: BMI<20=38 cal/kg/day; BMI 20-26= 35 cal/kg/day and BMI>27=25 cal/kg/day. Diet included 5 meals a day. The distribution was 40% carbohydrates, 20% proteins and 40% lipids.

Results.
We did not find significant differences between exercise and control group in maternal weight gain (exercise 8,228±5,064 kg vs control 9,660±3,910 kg) nor birth weight (exercise 3060,79±335,029 g vs control 3397,30±297,242 g). In both cases, women from the exercise group presented lower values, but not statistically significant. We must remember the high previous BMI of both groups, and that a lower weight gain in these women is advised (circa 3kg/4). There was no case of macrosomia (>4000g) neither of low-birth-weight (<2500g) in the exercise group, nor in the control one. We did not find a positive correlation between maternal weight gain and birth weight (r= .179).

Conclusions.
Women who exercised had babies with lower birth weight, but always within the normal range; they also had a lower weight gain than the control group but this difference was not statistically significant. Exercise could be used as an adjunctive therapy for gestational diabetic women in order to prevent an excessive weight gain.

HIGH AEROBIC PERFORMANCES MAY BE POSSIBLE PREDICTIVE FACTORS OF ENHANCED ANTIOXIDANT CAPACITIES IN ENDURANCE RUNNERS

Falone, S., Mirabilio, A., Carbone, M., Passerini, A., Di Ilio, C., Gallina, S., Di Baldassarre, A., Amicarelli, F.
University “G. d’Annunzio”, Chieti, Italy

Intense and prolonged exercises may produce a dramatic elevation in reactive oxygen species (ROS) production; this could perturb the fine-controlled physiological balance between the oxidative reactions and antioxidant enzymatic and non-enzymatic cellular systems (König et al., 2001). High ROS levels can cause oxidative chemical attacks to biomolecules, such as membrane lipids and proteins, thus leading to impaired cell function (Halliwell and Whiteman, 2004).

Nevertheless, it is well known that antioxidant protection systems can be modulated by regular exercise, through the activation of redox-sensitive signalling pathways and that the aerobic performance is up-regulated as a function of the training program (Powers et al., 1999); hence, higher maximal oxygen uptake capacities (VO2max) may be a possible predictive factor of improved redox status and better resistance towards pro-oxidative challenges.

The aim of the present study was to analyze the possible correlations among the aerobic fitness and some of the major redox-related parameters in serum of regularly-trained male runners (n=37). In particular, indexes under observations were the total antioxidant capacity (TAC), which provides the overall cumulative effect of all antioxidants, and two of the most commonly used markers of oxidative molecular damage, such as thiobarbituric acid reactive substances (TBARS) and the protein carbonyl content (PCC).

We found that resistance runners with higher VO2max values showed increased total antioxidant capacities and reduced oxidatively-modified protein contents. This seems to suggest that training programs aimed at increasing aerobic performances might improve the antioxidant defences and help to attenuate the ROS-mediated damage to the plasmatic proteins, without affecting significantly lipid peroxidation processes.

Future research should address whether an antioxidant-supplemented diet may be a valid adjuvant in training programs to increase the aerobic fitness of endurance athletes.

References.
The maintenance of appropriate levels of range of motion (ROM) is crucial to the effectiveness in the implementation of the different movements involved in carrying out activities of daily living (Gonçalves, 2007) and consequently to maintain and develop the autonomy of the elderly. So its assessment becomes predominant in the control and evaluation of the programs of physical activity directed towards improving the autonomy of the elderly. The aims of the study were to evaluate lower and upper limb flexibility in aged women to investigate possible correlations between those measures and body mass index (BMI). The sample was integrated by 111 women (mean age = 67.36±5.21 years, weight = 64.45±10.05 Kg, height = 1.54±0.16 m and BMI = 27.28±4.18), performed the chair sit & reach (CSR) and the back scratch (BS) tests. Those tests were used as described by Jones & Rikli (2002). No correlation was found between age and the CSR test and BS tests and between the BMI and CSR test. However, we observed negative correlations between BMI and BS (r = -0.31, classified as medium low by Sigmound, 2004) and statistical significance (p = 0.001<0.05). The mean performance of the women in CSR and BS were 3.15±5.6 cm for CSR and -8.41±10.16cm for BS. We concluded that the subjects that were evaluated did presented a deficit of upper limbs flexibility. Moreover, this deficit increased with the BMI and was not influenced by the age. Therefore, engagement in physical activity programs that perform upper limbs flexibility was advised to the women that were evaluated.

USE OF DIETARY SUPPLEMENTS AND DIETARY BEHAVIOUR AMONG YOUNG PEOPLE WHO EXERCISE AT GYMS

Bianco, A., Mammina, C., Bellafiore, M., Paoli, A., Battaglia, G., Palma, A.
University of Palermo, Italy

Background
People who frequent gyms may use particular supplements for many reasons. Differences may exist in the choice of supplement depending on age, gender, or reason for exercise. Moreover many people learn about supplements from unqualified sources. This study examines dietary habits and use of dietary supplements by people who exercise and determines also the source from which these people obtained information.

Methods
A structured questionnaire containing socio-demographic characteristics, questions about supplement types, frequency of their use, dietary behaviours and source of information about nutrient intake was self-administered to a convenience sample of people, 18 y and older, who met inclusion criteria, i.e. attending a gym and exercising at least 4 times per wk at 1 h per session. T-tests, 2 statistic, and ANOVA were used to assess differences. The statistical significance was set at P < 0.05.

Results
The questionnaire was completed by 207 subjects, aged 26.3 ± 9.1, of whom 38.6% were females and 61.4% males. 75.4% had a high education level (≥13 years). 30.1% of the respondents used dietary supplements, without significant differences between females -23.8% and males -34.1% (P=0.06). These persons had been taking them for a mean of 2.5 ± 3.3 years. The four supplements that were taken more frequently by the largest proportion of the participants included: proteins (32.2%), multivitamin and minerals (29.0%), multivitamin (16.1%) and creatine (12.6%). Only approximately a third of participants indicated adhering to a specific dietary regimen, but the weekly frequencies of some foods were analyzed for all respondents.

High-protein intake proved to be significantly associated to supplement use: in particular, eating three days/week fish, eggs, poultry, tuna, milk and dairy products, legumes and nuts was significantly associated with regular supplement use (P<0.01). On the contrary, supplement use was negatively associated with consumne of snacks and bakery products (P<0.01).

Conclusion
The use of dietary supplements was common in both genders. The finding that supplement need is most of ten self-assessed and health professionals are infrequently consulted for supplement information is of concern. Beyond the adoption of a well defined dietary regimen, many supplement users refer unwise and potentially unhealthy food choices.

Gyms, such as those included in this study, need to have available to members qualified health professionals, who can supply accurate and science-based information about dietary supplements and their positive as well as adverse health effects.

COPING AND HEALTH-RELATED QUALITY OF LIFE IN THE ONE-YEAR REHABILITATION PROCESS

Kokkonen, M., Kinnunen, ML., Mikioaho,A., Pekkonen, M.
University of Jyväskylä, Finland

The aim of the present study was to investigate longitudinally the relationships between the self-reported use of different coping strategies and self-reported health-related quality of life (HRQL) in rehabilitators. In particular, we were interested in finding out whether the use of different coping strategies improved one's subsequent HRQL, or whether one's HRQL directed the subsequent choice of a particular coping strategy. The participants (n=116 females, 200 males) were working-aged clients from a rehabilitation centre situated in Central Finland, where they participated in an occupationally oriented medical rehabilitation. The procedure for the rehabilitation lasted one year, including three rehabilitation periods (5 + 12 + 5 days). Self-reported data on coping strategies and HRQL was gathered during the first (Time 1) and last (Time 2) rehabilitation periods. Four sum scores for coping, based on the Coping Inventory for Stressful Situations (CIS-S-21; Endler & Parker, 1990, 1999), were as follows: ‘Task-Oriented’, ‘Emotion-Focused’, ‘Treat oneself’, and ‘Contact a friend’. HRQL was measured using the RAND 36-item Health Survey (Sherbourne & Mazel 1993; Aalto, Aro, & Teperi 1999) where the sum score for ‘Physical HRQL’ included the sub scales of physical functioning, bodily pain, role limitations due to physical health problems, and general health
perceptions. The sum score for ‘Mental HRQL’ included the sub scales of role limitations due to personal or emotional health problems, emotional well-being, social functioning, and energy/fatigue. The path analysis revealed cross-legged associations between an Emotion-Focused coping strategy and Mental HRQL: a high Emotion-Focused coping strategy in Time 1 was linked to low Mental HRQL in Time 2, and low Mental HRQL in Time 1 to high Emotion-Focused strategy in Time 2. Low Mental HRQL in Time 1 also predicted a low tendency to treat oneself or contact a friend in Time 2. High Physical HRQL in Time 1 predicted a low tendency to treat oneself in Time 2. A high tendency to contact a friend in Time 1 predicted a higher Emotion-Focused strategy in Time 2. Thus, HRQL in the beginning of the rehabilitation process was more meaningful for the subsequent choice of coping strategy, than vice versa. An Emotion-Focused coping strategy and mental HRQL formed a vicious circle, which challenges the rehabilitation process to break this down.

GENETIC TESTING OF CHILDREN FOR IMPROVEMENT OF PHYSICAL EDUCATION IN ELEMENTARY SCHOOLS

Rogozkin, V., Ahmetov, I., Aastratenkova, I., Druzhnevskaya, A., Hakimullina, A., Komkova, A.
St Petersburg Research Institute of Physical Culture, Russia

Genetic studies may be applied to the study of factors that underlie human physical performance and are likely to prove very powerful in this regard. Testing of genetic variants can serve diverse purposes, including diagnostics, identification of future health risk, prediction of drug responses, personalized nutrition, and formation, development and manifestation of human physical qualities. It is now well established that regular physical activity reduces morbidity and mortality and exercise is, therefore, used for the prevention and treatment of diverse disease states (Williams et al., 2007). A considerable amount of data confirming the influence of genes on human health-related fitness and physical performance has been accumulated in the recent years (Rankinen et al., 2006, Rogozkin et al., 2007). As such, exploring the genetics of exercise-related traits will not only further develop sport but also allow improving physical education in elementary schools. The purpose of this study was to determine genetic predisposition to sports and to evaluate the risk for development of common complex diseases in pupils. The study involved 242 children (females, n=114, 12 ±0.2 yr; males, n=128, 10 ±0.1 yr) from 6 elementary schools of Surgut city (Siberia, Russia). ACE II/DI, ACTN3 R577X, HIFIA Pro582Ser, PCCIA Gly482Ser, PPARA G/C, PPARG Pro12Ala, PPARG +294T/C and VEGF G-634C gene polymorphisms were determined by PCR-RFLP. Determination of genetic predisposition to sports and risk for diseases’ development was based on the literature data in accordance with results of association studies. We found only 195 variants of genotype combinations (3% of possible 6551 combinations) in a whole cohort of children. In terms of genetic predisposition 39.2% of individuals had high endurance potential; 21.9% of pupils were predisposed to power/strength events; 9.1% of children had a very high risk for development of left ventricular hypertrophy; 24.4%, 22.7%, 13.2%, and 29.8% of children were highly predisposed to type II diabetes, obesity, atherosclerosis, and hypertension, respectively. In conclusion, combining information from several known common polymorphisms allows the identification of population subgroups with markedly differing genetic potentials for practicing sports and risks of developing common complex diseases. This approach may have a role in improvement of physical education in schools and in future preventative measures for polygenic diseases.

EFFECT OF AN 85 KM MOUNTAIN BIKE RACE ON PLASMA C-REACTIVE PROTEIN, INTERLEUKIN-6 AND SOLUBLE INTERLEUKIN-6 CONCENTRATION IN TRAINED CYCLISTS

Northumbria University, United Kingdom

Strenuous, prolonged exercise has consistently been shown to increase concentrations of interleukin-6 (IL-6). The effect of IL-6 on biological systems is dependent on the availability of IL-6 receptors, both membrane bound and soluble (sIL-6R) forms. Although much attention has been given to endogenous IL-6 production during strenuous exercise in healthy individuals, few studies have addressed the impact of exercise on sIL-6R levels. Furthermore, physiological concentrations of elevated C-reactive protein (CRP) can increase sIL-6R concentrations by inducing receptor shedding from neutrophils in vitro but this relationship has not been examined in vivo following prolonged exercise. The aim of the present study was to investigate changes in selected inflammatory biomarkers in response to a prolonged bout of mountain bike cycling. Thirteen healthy endurance trained male subjects (mean ±SD, mass 76 (6) kg, age 33 ± 4 years) partook in the study. The subjects cycled a total distance of 85 km over varied terrain with a total climb of 2.6 km. Mean time to complete the course was 375 (35) min and subjects cycled at a mean of 74 (15) % of maximum heart rate. Venous blood samples were obtained prior to, immediately post-race and the morning after the race. Blood samples were analysed for plasma CRP, IL-6 and sIL-6R concentrations. Plasma IL-6 was elevated immediately post-exercise but was unchanged the morning after the event (p<0.05). In contrast, sIL-6R and CRP levels were unchanged immediately post-exercise but were elevated the morning after (p<0.05). CRP was significantly correlated with sIL-6R (r = .80, p<0.05). In summary, we found that strenuous, prolonged mountain bike exercise stimulated a sustained inflammatory response. The novel finding of our study was that elevated CRP was positively related to plasma sIL-6R suggesting an exercise-induced mechanism for its release.
**STRENGTH TRAINING AND LEPTIN RECEPTOR EXPRESSION IN HUMAN SKELETAL MUSCLE**

Olmedillas, H., Fuentes, T., Delgado-Guerra, S., Guadalupe-Grau, A., Bernales, O., Dorado, C., Santana, A., Guerra, B., Calbet, J.

1University of Las Palmas de Gran Canaria, 2Genetic Unit, Chilhood Hospital-Materno Infantil de Las Palmas, 3Research Unit, Hospital de Gran Canaria Dr. Negrín, Spain

Purpose. The aim of this study was to determine if a physiological intervention causing a sustained reduction in plasma basal concentrations of leptin causes an alteration in the protein expression level of its receptors in human skeletal muscle. To achieve the reduction in serum leptin subjects were submitted to a weightlifting training program that reduced whole body fat mass.

Methods. Nine healthy untrained policemen [(mean ± SD), age: 34 ± 4.4 years, height: 176 ± 2.8 cm, body mass: 85 ± 12 kg and percentage of body fat: 23.8 ± 7.5% (DXA)] participated in a 12-week weightlifting training program (3 sessions/week). In each session subjects performed seven exercises (leg extension, press, half-squat, leg curl, bench press, seated rowing, cable triceps extension) in series of 10RM (1st week: 1-2, 2nd week: 2-3, 3rd week: 3-4, and then 4 series until the end of the training program) with 2 min resting periods between series. Prior to and at the end of the training program, muscle biopsies were taken from the middle portion of the musculus vastus lateralis. Serum leptin and serum leptin concentration. These findings are compatible with increased leptin sensitivity after strength training.

Supported by grants from Ministerio de Educación y Ciencia (BFU2006-13784/BFI, IBFU2006-56076-C06-04), and Gobierno de Canarias (PI042005/177).

**GENETIC PROGNOSIS OF CARDIOVASCULAR SYSTEM RESPONSE TO PHYSICAL EXERCISES**

Astratenkova, I., Semenova, V., Timshina, E.

St Petersburg Research Institute of Physical Culture, Russia

The renin-angiotensin system (RAS) plays an important role in mediating diverse physiological functions but major contributes to the maintenance of cardiovascular homeostasis in normal and after different stimuli including physical exercise. Angiotensin II (ANG II) considered the main effecter peptide of RAS is produced by angiotensin converting enzyme (ACE) and acts on specific receptors. Whereas most of well-known actions of ANG II such as vasoconstriction and aldosterone release are mediated by the AT1 receptor. ANG II mediates myocyte hypertrophy due to activation of the AT1 receptor as an adaptive response to increased myocardial function. While hypertrophy of cardiomyocytes for the initial as a compensatory mechanism to preserve cardiac function during physical exercise, it becomes a major risk factor for congestive heart failure and sudden cardiac death. AT2 is mediating the opposite effects of ANG II and plays an important role for the regulation of vascular tone and blood pressure. The activation of the nitric oxide (NO)-cGMP pathway via AT2 is less well established than activation via bradykinin and BK2 receptors. Experimental and clinical studies have suggested that D allele of ACE, A allele AGTR2, +9 allele BDKR2 and 4a allele NOS3 are associated with the risk of development of left ventricular hypertrophy (LVH). The purpose of this study was to determine genotype and allele frequencies of ACE (I/D), AGTR2 (C3123A), BDKR2 (-9/+9) and NOS3 (4a/b) alleles and NO3 NOS3 4a/b gene polymorphisms were determined by PCR-RFLP. Statistical analysis using InStat version 3 included the χ2 test for genotype and allele frequencies comparison between Athletes and control subjects. There was no significant difference in AGTR2 and BDKR2 genotype and allele frequencies between groups of athletes and controls. We found that the frequencies of ACE I1 genotype (27.9% vs. 24.2%, P=0.0413) and NOS3 4a/b genotype (32.8% vs. 24.5%, P=0.0013) were significantly higher in athletes than in controls, but the frequencies of ACE I/D genotype (44.7% vs. 49.0%, P=0.0414) and NOS3 4b/b genotype (62.7% vs. 73.1%, P<0.0001) were significantly lower. There was no significant difference in the risk of cardiovascular pathology between groups of athletes and controls. The genetic testing provides prognostic information identifying athletes with the risk of development of disease before the appearance of hypertrophy symptoms and the risk of sudden death. The ability to identify and separate individuals with high-risk LVH from those it provides further information for individual training program.

**NADPH OXIDASE P22PHOX POLYMORPHISM AND SYSTEMIC OXIDATIVE STRESS IN ENDURANCE ATHLETES**

1University of Torino, 2University of Palermo, 3University of Rome.”Tor Vergata”. 4University of Urbino. Italy

Even though several studies indicate that genetics may contribute to the systemic redox state, few data are still available on a genetic association between the systemic oxidative stress levels and the performance in aerobic training. An acute bout of exercise increases the production of reactive oxygen species (ROS) through a mechanism involving the NADPH oxidase system. We focused our attention on p22phox, a subunit of the NADPH oxidase that displays some allelic polymorphisms, one of the most important and frequent being the C242T. This polymorphism is known to affect functional activity of NADPH oxidase.

InStat version 3 included the χ2 test for genotype and allele frequencies comparison between athletes and control subjects. There was no significant difference in AGTR2 and BDKR2 genotype and allele frequencies between groups of athletes and controls. We found that the frequencies of ACE I1 genotype (27.9% vs. 24.2%, P=0.0413) and NOS3 4a/b genotype (32.8% vs. 24.5%, P=0.0013) were significantly higher in athletes than in controls, but the frequencies of ACE I/D genotype (44.7% vs. 49.0%, P=0.0414) and NOS3 4b/b genotype (62.7% vs. 73.1%, P<0.0001) were significantly lower. There was no significant difference in the risk of cardiovascular pathology between groups of athletes and controls. The genetic testing provides prognostic information identifying athletes with the risk of development of disease before the appearance of hypertrophy symptoms and the risk of sudden death. The ability to identify and separate individuals with high-risk LVH from those it provides further information for individual training program.
These results are in favour of PPAR-g implication in anti-atherogenic effects induced by physical exercise. Conversely, p<0.05; this response was less evident in the presence of the T allele, both in ethero- and homozygosis. CT response, indeed, was characterized by a two fold increase (mean 2.17 ± 0.35 fold, p<0.05) of urine MPO, whereas in TT genotype no differences or a decrease of the urine MPO concentration were observed (mean 83±33.5 % relative to the basal value). Our results support the influence of genetic component on the athletic performance. p22phox C242T polymorphism may influence both the cardio-respiratory fitness and the inflammatory response to the aerobic training, suggesting a strict association between systemic oxidative stress levels and performance.

**EFFECT OF EXERCISE TRAINING ON PPAR EXPRESSION IN APOE-/- DEFICIENT MICE**

Sztostak, J., Miguel-Alfonsi, C., Pellegrin, M., Bouzourene, K., Berthelot, A., Mazoziol, L., Laurant, P.

University of Franche-Comté, UFR STAPS/SMP, France

**Introduction:**

Atherosclerosis and its complications represent the leading cause of morbidity and mortality in the industrialised as well as in the developing countries. Atherosclerosis is a chronic inflammatory disease. Physical exercise significantly reduces atherosclerosis lesions and cardiovascular risk. However, the precise mechanisms are still unknown. Among potential molecules implicated into cardio-protection induced by physical exercise, Peroxosome Proliferator-Activated Receptor (PPARs) appears interest. Recent researches suggest PPAR vascular implication in anti-atherogenetic effects. Thus, it has been shown that PPAR-g ligands, such as Thaglitazone (TZDs) significantly inhibited fatty streak formation in ApoE-/- mice. We assessed the hypothesis that exercise training reduce atherosclerosis in ApoE-/- deficient mice by increased expression of PPAR-g in endothelial cells in response to shear stress exerted by increased fluid flow in response to exercise.

**Methods:**

Male mice for the distribution of ApoE gene (ApoE-/-) and normal C57Bl/6J mice as control, month of age, were used. ApoE-/- mice were fed with a high fat diet and were divided into three groups: the exercise group (ApoE-/-ex) underwent exercise training (60min swimming, 5 time/week) for 13 weeks, sedentary group (ApoE-/- sed) groups without exercise, and last group ApoE-/-ex + BADGE, this group were treated with exercise and an antagonist of PPAR-g Bisphenol A-diglycide ether. C57Bl/6J mice were used as control. They were divided into two groups control exercise and control sedentary.

**Results:**

Atherosclerotic lesions in ApoE-/- deficient mice were significantly decreased in ApoE-/- mice treated with swimming for 13 weeks compared to the group without the exercise. In contrast, exercise in ApoE-/- mice supplied with BADGE can't suppress atherosclerotic lesions. Moreover, exercise increase expression of PPAR-g in mice undertaken exercise. Interestingly, expression of PPAR-g in vascular wall is conversely correlated with wide lesions in ApoE-/- mice.

These results are in favour of PPAR-g implication in anti-atherogenic effects induced by physical exercise.

**MECHANICAL PRESSURE ACTIVATES THE GLUCOSE METABOLISM AND MAPK SIGNALING IN L6 SKELETAL MYOCYTES**

Morita, N., Iizuka, K., Kondo, Y., Fujisawa, Y., Horiuchi, M., Machida, T., Hirafuji, M., Okita, K.

Hokkaido Univ. Education, Japan

**BACKGROUND:** When skeletal muscle contracts during exercise and/or physical activity, the inner pressure elevation is generated in muscular tissues. Ballard et al. reported that intramuscular pressure of soleus muscle during walking exhibited approximately 180 mmHg (1). In addition, we previously reported that pressure stimuli without deformation of cell shape enhanced glucose uptake and energy metabolism in L6 myoblasts (2). However, biochemical effects of pressure stimuli in skeletal muscle cells are not yet well characterized. The purpose of the present study was to examine the effects of mechanical pressure on regulatory factors for the glucose metabolism and on MAPK intracellular signaling in L6 skeletal myoblasts.

**METHODS:** L6 myoblasts were cultured in 10-cm dishes with Dulbecco’s modified Eagle’s medium containing 5% fetal bovine serum and 1% penicillin-streptomycin solution. The cells were incubated at 37°C in a humidified 5% CO2 atmosphere. Atmospheric pressure at 160 mmHg for 3 hours was applied to the cells by using an original pressure loading apparatus (2). To raise internal atmospheric pressure of the apparatus chamber, a humidified 5% CO2 atmosphere was pumped in until the pressure reached 160 mmHg. The L6 cells were maintained under this pressure at 37°C. Protein and mRNA expressions were analyzed by using immunoblotting and real-time RT-PCR, respectively.

**RESULTS:** Compared with the non-pressurized cells, phosphorylated AMPK and GLUT4 in the plasma membrane were increased approximately 1.6- (p<0.05) and 1.7-fold (p<0.001), respectively, in the pressurized cells. Although mRNA expression related to the glucose metabolism (PGC-1, NRF, mTFA, FAT/CD36) was not altered by pressure, GAPDH mRNA increased 1.6-fold in the pressurized cells compared to that in the non-pressurized cells. Pressure application increased phosphorylation of ERK (1.7-fold, p<0.001) and JNK (1.4-fold, p<0.05), but not that of p38 MAPK.

**CONCLUSION:** These findings demonstrated that transient mechanical pressure partially activates the glucose metabolism and that the effects of elevating pressure at 160 mmHg are attributed to ERK and JNK signaling in myoblasts. Moreover, it was suggested that mechanical pressure has some effect on adaptive cellular responses.

This research was supported by the Grant-in-Aid for Young Scientists (B) 17790165 and the Grant-in-Aid for Young Scientists (B) 19700525Sof the Ministry of Education, Culture, Sports, Science and Technology of Japan.

ASSOCIATION OF MYF6 (MYOGENIC FACTOR 6) GENOTYPE WITH MUSCLE SIZE PHENOTYPE AND HYPERTROPHIC EFFECT IN MEN

Druzhkevskaya, A., Montgomery, H., Astratenkova, I., Li, K.W., Drenos, F., Rogazkin, V., Ahmetov, I., Humphries, S.
1 St. Petersburg Research Institute of Physical Culture, 2,3 University College London, Russia

Myogenic factor myf6 belongs to the transcription factor family and regulates embryonic myogenesis. Myf6 plays an important role in the maintenance of fully-differentiated myofibers and in muscle regeneration in adults. Myf6 has been identified as an additional factor of potential importance for muscle hypertrophy and as a possible regulator of fiber type transitions [1]. We have previously shown the C964T MYF6 gene variant (rs3121) to be associated with elite athletic performance [2].

The purpose of our present investigation was to examine the association between C964T MYF6 polymorphism and muscle phenotype and changes in muscle size after 12 weeks of intensive physical training in Caucasian males.

Our study was designed within a large and detailed 'Lichfield Bone Study'. Magnetic resonance imaging (MRI) of skeletal and muscle phenotype of the lower limbs of young men aged between 17 and 22 years was performed. The measurements were repeated again at the end of a structured intensive twelve-week period of physical training involving mixed strength and endurance training. MRI image analysis was carried out using CMR-Tools. The data for baseline muscle cross-sectional area (CSA) of m. vastus lateralis of 550 subjects and muscle CSA of the 333 subjects who completed the training was obtained. Values are presented as average value of left and right leg. Genotyping was performed by polymerase chain reaction and restriction fragment length polymorphism analysis. Baseline CSA was significantly associated with MYF6 genotype. The CC homozygotes showed smaller muscle CSA compared with heterozygotes and TT homozygotes (CC: 1413.11±262.40 mm² vs. CT+TT: 1482.71±254.72 mm²; P=0.02).

In conclusion, our data in a large sample size show that men with the T allele in MYF6 have greater muscle size. These results suggest that polymorphism in MYF6 gene is one of the factors that contribute to observed variance in muscle phenotype. However further investigations on MYF6 genotype are advocated.

ACTN3 POLYMORPHISM AND MUSCLE SIZE PHENOTYPE IN MEN

Druzhkevskaya, A. 1, Montgomery, H. 2, Astratenkova, I. 1, Li, K.W. 3, Drenos, F. 3, Rogazkin, V. 1, Ahmetov, I. 1, Humphries, S. 3
1 Department of Sport Biochemistry, St. Petersburg Research Institute of Physical Culture, Saint-Petersburg, Russia. 2 Biochemistry of Sport. 2 Division of Medicine, Institute for Human Health and Performance. 3 Division of Medicine, Centre for Cardiovascular Genetics

Alpha-actinin-3 (ACTN3) is a myofilament protein expressed in fast-twitch glycolytic muscle fibers, and an R577X polymorphism exists in its gene. It is reported that homozgyosity for the nonsense X allele results in loss of the protein expression [1] and impaired muscle performance, and that the X-allele may under-represent in elite sprint and strength athletes [2, 3].

The aim of the present study was to investigate the association of the ACTN3 R577X variant with muscle phenotype and changes in muscle size in a longitudinal study of male Caucasian army recruits with 12 weeks of intensive physical training.

Using magnetic resonance imaging (MRI), muscle cross-sectional area (CSA) of m. vastus lateralis was measured in 555 subjects prior to training, with repeat measures available in 338 (age 19.9±2.3; height 177.7±6.3; weight 73.2±9.8). Genotyping was performed by polymerase chain reaction and restriction fragment length polymorphism analysis. There was no significant association of ACTN3 R577X polymorphism with baseline muscle size but there was a non-significant trend for higher muscle CSA to be associated with the R-allele (RR - 1488.9±18.2 mm², RX - 1466.7±16.9 mm², XX - 1452.0±16.9 mm²; P=0.45).

In conclusion, ACTN3 genotype is not associated with skeletal muscle CSA in young males, nor with the scale of the hypertrophic response.

THE POWER OF ACE DELETION (D) ALLELE TO THE CHARACTERISTICS OF PROFESSIONAL ATHLETES IN LITHUANIA

Gineviciene, V., Kuinskas, V.
Faculty of Medicine, Vilnius University, Lithuania

Human angiotensin-1-converting enzyme (ACE) gene was one of the first genes to be associated with human physical performance. Alu insertion II and deletion (D) polymorphism (I/D polymorphism) in the ACE gene is involved in various pathophysiological conditions related to endurance. Nevertheless, the results of this I/D polymorphism are still inconsistent across studies and populations. In the present study, ACE gene I/D polymorphism was investigated in 561 Lithuanian professional athletes representing three functional groups (endurance (N=71), strength and speed (N=59), and team sports (N=431)), as well as in 174 samples from general population of Lithuania. Genomic DNA was extracted from peripheral blood leukocytes. Genotyping for ACE I/D polymorphism was performed using polymerase chain reaction (PCR) and genotypes were visualized on agarose 2% gel. Genotypes for athletes were identified as I/I (24.8%), I/D (47.2%) and D/D (28%) and in the population samples as I/I (24.1%), I/D 38.5% and 37.4% (P=0.004). Statistically significantly higher D allele frequency was found in endurance group (P=0.002), and in team sports group (P=0.002) in comparison to strength and speed group results, contrary to the prevailing data from other studies showing association of endurance with I allele. This might be as well due to the fact that D allele frequency appeared to be more frequent in the general population of Lithuania (60.4%), in comparison to the majority of other European populations (30-50%). The results of the present study imply that the role of ACE gene I/D polymorphism in athletic performance is not straightforward and can be masked by other genetic and non-genetic factors.
NO ASSOCIATION BETWEEN ACE INSERTION/DELETION POLYMORPHISM AND AEROBIC POWER IN BRAZILIAN WOMEN

Leite, T., Pereira, R., Lima, R., Da Silva, M., Freitas e Silva, M., Rabelo, H., Oliveira, R.

Universidade Católica de Brasília, Brazil

Aging is a dynamic and progressive process in which occurs physiologic modifications that induces a progressive loss in individual’s environment adaptation capacity. Among these modifications, there is a decrease in cardiorespiratory capacity, an increased risk of the development of cardiovascular diseases, and a decrease in quality of life. Aerobic power is influenced by environmental and genetic factors, and it could be associated to angiotensin converting-enzyme [ACE] gene, which codifies the ACE, a component of the rennin angiotensin system. Therefore, this study had the purpose of verifying the association between ACE genotype insertion/deletion IDI polymorphism and the phenotype of aerobic power (VO2peak) in 189 Brazilian elderly women [65,84 ± 4,94 yrs]. Physical activity level was assessed by the International Physical Activity Questionnaire (IPAQ). Also, a questionnaire was applied for sample characterization. Body composition was assessed by DXA and aerobic power was determined by indirect calorimetry during a maximal graded exercise test (GXT) using a ramp protocol with mean duration time of 9 minutes. Genomic DNA of high molecular weight was extracted from the blood leucocytes by salting out method and ID polymorphism was identified by PCR followed by a confirmatory-PCR. An ANCOVA was used to verify the differences on VO2peak among ACE genotype groups. Age, fat free mass, and percent body fat were used as covariates. The ID polymorphism genotype frequencies found were in agreement with the expected for Hardy-Weinberg’s equilibrium, although significant differences on aerobic power were not observed among II, ID and DD genotypes (p = 0,349). In conclusion, there is no association between ACE gene ID polymorphism and the phenotype of aerobic power (VO2peak).

ASSOCIATION BETWEEN APAI POLYMORPHISM OF THE IGF-2 GENE AND BONE MINERAL DENSITY IN ELDERLY BRAZILIAN WOMEN

Aguiar, L., Freitas e Silva, M., Pereira, R., Da Silva, M., Vinhal, P., Ribeiro, A., Oliveira, R.

Universidade Católica de Brasília, Brazil

Bone mineral density (BMD) is a phenotype which undergoes variations with aging. One of the causes of these alteration is the decline of anabolic hormones such as insulin-like growth factor 2 (IGF2), hormone that influences muscular mass and BMD. Previous studies have reported that IGF-2 is associated with BMD, however, the findings was limited only to children and young adults. Thus, there is a lack of reports about the interactions of BMD with this polymorphism of the IGF-2 gene in elderly. Therefore, the aim of this study was to examine the association between the ApaI polymorphism of IGF-2 gene and BMD in Brazilian elderly women. This study was approved by the local institution committee board [proc. N. 014 2007] and after that, 252 women with mean of age 66,94 ± 5,59 yrs; 66,40 ± 13,24 kg of body mass, 153,21 ± 6,69 cm of height and 28,22 ± 4,85 body mass index (BMI) volunteered to participate in the present investigation. Assessment of femoral neck, trochanter, Ward’s triangle, lumbar spine (L2-L4), hip and whole body BMD was performed by Dual Energy X-ray Absorptiometry. High molecular weight DNA extraction was performed by Salting out method (Miller et al., 1998) and genotype was determined by polymerase chain reaction (PCR) and restriction fragment length polymorphism (RFLP). It was conducted an one-way analysis of variance to determine differences in BMD sites among genotype groups. The significance level was established at p < 0,05.

Replacement of androgens has been shown to significantly reduce the myosin heavy chain (MHC) IIB protein expression in skeletal muscle of orchiectomized male rats. Based on this finding, the aim of the current study was to investigate the expression of genes in skeletal muscle (M-gastronemius) of female ovariectomized rats (OVX) in response to the treatment with estrogen receptor (ER) agonists and to assess the combinatory effects of high intensity running exercise and hormonal status. The expression of MHC and insulin receptor substrate-1 (IRS-1), a protein involved in the regulation of glucose uptake in skeletal muscle, were analyzed as representatives of structural and metabolic genes. OVX Wistar rats were treated with estradiol (E2) and the phytoestrogen genistin (Gen) or were fed an isoflavone (Phyto) enriched diet. Silverstain and Western Blot analysis was used to determine protein expression levels of IRS-1 and MHC IIB. Results show that the absence of female sex hormones in OVX rats and the substitution with E2 both have the tendency to change the expression pattern of MHC IIB. However, a 3-week period of high intensity treadmill running exercise induced a shift in the expression of MHC IIB towards higher levels of expression in skeletal muscle of exercised SHAM, Phyto, E2 and Gen rats relative to OVX animals. In OVX rats, the expression levels of IRS-1 are repressed after application of E2 and GEN suggesting that parameters involved in the regulation of glucose uptake are affected by the hormonal status. The combined effect of training and hormonal status on IRS-1 expression is currently under investigation.

Collectively, results of the study suggest that female sex hormones affect gene expression patterns in female skeletal muscle. The expression patterns of structure-related genes like MHC and genes involved in glucose metabolism are regulated by E2, Gen and Phyto (ER-agonists). This finding may have relevance with respect to the question whether menopause and hormone replacement therapy affect functional and metabolic diseases like sarcopenia and the metabolic syndrome. In addition, a combination of training, hormone replacement and nutrition may be a functional prevention concept for post-menopausal women.
CHANGES IN SKELETAL MUSCLE GENE EXPRESSION AND PROTEOLYSIS ARE INDUCED BY THREE DAYS OF UNLOADING

Gustafsson, T., Osterberg, T., Von Waldên, F., Trappe, T., Linnehan, R., Tesch, P.
Karolinska Institute, Stockholm, Sweden

Skeletal muscle atrophy evident after muscle disuse, unloading or spaceflight, is the result of decreased protein content, as a consequence of decreased protein synthesis or increased protein breakdown or both. These processes require signalling through the PI3K-Akt-mTOR and ubiquitin-proteasome pathways. This particular study assessed the effects of short-term unloading on muscle contractile proteolysis rate, and further whether PI3K-Akt-mTOR and ubiquitin-proteasome pathways are activated soon after withdrawal of weight bearing.

Methods: Muscle biopsies were obtained from mm vastus lateralis and soleus of eight healthy men prior to and following three days unilateral lower limb suspension (ULLS). Samples were analyzed for mRNA levels of IGF1, Caspase-3, Calpain-2, Foxo1A, Foxo3A, Atrogin-1, MuRF-1 and 4E-BPI. Myostatin were quantified in combination with protein measurements of Akt, Foxo1 and 3, p38 and mTOR. Also, using microdialysis interstitial samples were taken from mm vastus and analyzed for levels of 3-methylhistidine (3-MH).

Results: The 3-MH concentration following ULLS was 44% higher (p<0.05) than before ULLS. Atrogin-1, MuRF-1 and 4E-BPI mRNA increased (p<0.05) after ULLS in mm vastus lateralis but not in mm soleus. Myostatin increased (p<0.05) in both muscles. Total amounts and phosphorylation of Akt, Foxo1 and 3, p38 and mTOR were unaltered (p>0.05).

Conclusion: These results suggest 1) that proteolysis of myosin and actin occurs and that Atrogin1, MuRF1, 4E-BPI and Myostatin are pretranscriptional regulated in human skeletal muscle within three days of ULLS. Given that neither signalling pathway was altered, it appears that other pathways stimulated Atrogin1 and MuRF1 transcription and 2) the difference in gene expression pattern across mm soleus and vastus lateralis infers that mechanisms controlling muscle size may differ between muscles depending on function and/or phenotype.

INCREASED LEVELS OF HSP27 IN SKELETAL MUSCLE AFTER STRENGTH TRAINING

Ugelstad, I., Rannestad, B., Kvamme, N., Hallen, J., Raastad, T.
Norwegian School of Sport Science, Norway

Introduction: Hsp27 is part of a diverse family of heat shock proteins (stress proteins) which are involved in cell protection and cell remodeling in response to high force exercise. High force exercise acutely increases HSP27 expression in muscles (2), but the HSP27 response to long-term regular exercise is less studied. However, increased levels of HSP27 are reported in human muscles after 5-8 weeks strength training (1). The purpose of this study was to examine the HSP27 response to 11 weeks of heavy strength training in a leg muscle and an upper body muscle.

Methods: Twenty-five untrained men were randomly assigned into two groups. One group performed 3 sets in leg exercises and 1 set in upper body exercises (3L-1UB), while the other group performed 1 set in leg exercise and 3 sets in upper body exercise (1L-3UB). The subjects performed 3 workouts per week during 11 weeks. Biopsies were obtained from mm vastus lateralis and the upper part of mm trapezius before, after 2 weeks and after the training intervention. After homogenization, the cytosolic fractions were analyzed by a home made ELISA for HSP27 (3). Values presented are means ± SEM, p<0.05.

Results: The levels of HSP27 were significantly increased in both mm vastus lateralis and mm trapezius after 2 weeks (43 ± 12% and 47 ± 11%, respectively). After 11 weeks of strength training HSP27 in mm. vastus lateralis was further increased to 77 ± 16%, while no further increase was observed in mm. trapezius (35 ± 18% over baseline levels). There were no significant differences in HSP27 response between the two training groups in neither mm. vastus lateralis nor mm. trapezius.

Discussion/Conclusion: The main findings were a rapid increase in HSP27 in both muscles. Thereafter, HSP27 levels stabilized with only minor changes observed between 2 and 11 weeks of training in mm. trapezius, but a further increase was observed in mm. vastus lateralis. Training with 3 sets per exercise did not result in a larger HSP27 response than training with only one set per exercise. The observation that the HSP27 response seemed to be larger and more prolonged in mm. vastus lateralis than in mm. trapezius, could be due to the fact that there were only one exercise involving upper part of trapezius (shoulder press) and two exercises involving mm. vastus lateralis (leg press and knee extensions). However, baseline levels of HSP27 tended to be higher in mm. trapezius than in mm. vastus lateralis (18%, p=0.13). Because high force exercise acutely causes an accumulation in HSP27 in the myofibrillar part of the muscle cell (2), we will now analyze the HSP27 changes in this fraction from the obtained biopsies.

PROTEOMIC ANALYSIS ON BLOOD AND SKELETAL MUSCLE FOLLOWING SHORT-TERM INTENSIVE STRENGTH TRAINING IN HUMAN

Son, HJ, Kim, HJ, Ha, JY, Lee, YH, Cho, IH, Kim, HT, Yoon, JR, Oh, JG, Lee, YW, Kim, SH, Kim, CK.
Human Physiology, Korea National Sport University, Seoul, Korea, 1University of Seoul, Seoul, Korea, South

To investigate muscle proteome involved in exercise training type, we examined change of proteins expression in vastus lateralis by Two-dimensional gel electrophoresis and MALDI-TOF MS. Ten physically active young men (23.4±3.2yr, 179.2±3.5cm, 70.1±5.4kg) were trained in two types of exercise (aerobic; n=5/anaerobic; n=5) for 4 weeks. After the third week the exercise type was changed, and all volunteers performed 3 workouts per week during 11 weeks. Biopsies were obtained from mm vastus lateralis and the upper part of mm trapezius by a 10mm biopsy needle for proteomic analysis. The results showed differential pattern of muscle proteins expression to exercise type. Aerobic training changed ten proteins more than 200% from base line. Immunoglobulin heavy chain variable region, myosin heavy chain 1, carbonic anhydrase III, titin, chymosine 12, and fructose-1,6-bisphosphatase 2 were increased whereas pyruvate kinase 3 isofrom, ubiquitin carboxyl-terminal hydrolase, and phosphoglucomutase were decreased by aerobic training. On the other hand resistance training changed eight proteins, KIAA1529, apolipoprotein A-IV precursor, trabeculin-alpha, myosin light chain, and glyceraldehyde 3-phosphate dehydrogenase.

368 13th ANNUAL CONGRESS OF THE EUROPEAN COLLEGE OF SPORT SCIENCE
The findings, therefore, allow to suggest a number of peculiarities of voluntary motor activity and, possibly, a change of inter and intra-muscular coordination on the background of the studied disease.

NEUROPHYSIOLOGICAL MECHANISMS OF LEG MUSCLES EFFERENTS EXCITABILITY CONTROL

Povarestchenkova, J., Andriyanova, E., Petrov, D.
Velikiy Luki State Academy of Physical Education and Sports, Russia

Most researchers study the peculiarities of the spinal control of excitability of leg muscles in the athletes specializing in cyclic sports requiring endurance.

Skiracers and racing cyclists aged 20±0.9, with the height of 175±4.5 cm and weight 68±3.6 kg, who have achieved some results in sports, took part in the research. The used technique to eliciting multisegmental monosynaptic responses (MMRs) of the specified muscles was similar to that suggested, described and used by a group of authors (G. Courtine et al., 2007), with the only difference that in the present study the stimulation was carried out at the T12-L1 level. Reflex excitability of the motoneurons m. rectus femoris, m. gastrocnemius (caput mediale), m. tibialis anterior, m. soleus was investigated. Bipolar surface electrodes were mounted over 8 leg muscles bilaterally on the muscle belly. We placed the cathode over the skin between T12-L1 spinous processes and two large anodes bilaterally over the anterior spine of the iliac crest. Thresholds of each of the researched muscles and the maximal MMRs amplitude were registered.

It was established, that in the skiracers (n=9) reflex excitability of the low threshold efferents of the tested muscles is higher than that in the racing cyclists (n=8). The first MMRs were registered in these athletes at the strength of the current at the 20.1-26.5 V range, whereas in the cyclists the thresholds were revealed at the greater stimulating strength. The threshold reflex motor responses of the right leg muscles in the cyclists are comparable with the test results of the corresponding muscles of the skiracers and are registered at 24.9-26.8 V strength of the current. The threshold strength of the stimulation for the left leg muscles made 33.5-37.6 V, the differences of the results of the skiracers and the corresponding parameters of the right leg are reliable at p<0.05. We can suppose there's a functional asymmetry of working muscles in the racing riders.

The analysis of values of the reflex motor response maximal amplitudes, to a certain degree, specifies great reflex excitability of low threshold shin muscle efferents of the researched subjects. It is necessary to note, that the maximal MMRs amplitude bilaterally m. soleus, m. tibialis anterior and m. gastrocnemius is positively higher in the racing cyclists, than in the skiracers. Besides, it is the cyclists who have big maximal MMRs amplitudes of the left leg m. tibialis anterior, m. gastrocnemius. The results of multi-segmentary monosynaptic testing indicate great reflex excitability of high threshold motor units of m. soleus, m. tibialis anterior and m. gastrocnemius especially of the left leg.

THE STUDY OF PRINCIPLES OF DRAWING MOVEMENT BASED ON THE HIERARCHICAL THEORY OF MOTOR CONTROL

Mashhoodi, S., Mohkani, P.
Azad University, Iran

In motor control studies drawing and hand writing has been studied from many points of view, the main purpose of present study is concerned with an analysis of the rules which suggested by Goodnow and Levien to tested the hierarchy hypothesis. One hundred and fifteen individual's participated in this project. According to their age they were divided in to five groups (four consisted of children, the fifth was adult) and all subjects copied with their right hand. Fifteen designs were presented for each subject. Each subject being given as much time as he wished to draw. The practitioner recorded the direction and sequence of all strokes. Paths on correct copies were then analyzed for observance of rules. Of the seven principles suggested as rules, the fist two deal with starting points, the second two with starting strokes, and the final three with general progressions.

Summing up the observations showed that there has been a significant different between the observation frequencies with expected frequencies about comparison patterns of hand movement with principles has been suggested. In choosing direction hand movements to drawing symmetric shape with ball movement (a movement task for adult group) the result showed a significant statically correlation (r=0.62, p<.01) between the two performances.

In general results have shown that the pattern of hand movement may need to be changed across different configurations of the signs, direction of written(from left to right, or right to left, or even top to bottom) or shape.

LANDING SUCCESS IN FLOOR EXERCISE

Marinsek, M., Rajtmajer, D., Cuk, I.
Faculty of Education Maribor, Slovenia

Results from some researches show a rather low successfulness of landings on the competitions (McNitt-Gray, Requejo, Costa and Mathiyakom, 2001; Prassas and Gianikellis, 2002). Subject of this research are salto landings in floor exercise. In our research we will try to describe landing characteristics and find out which characteristics differ successful and unsuccessful landings. We analyzed landings of saltos performed independent or at the end of acrobatic series of saltos (N= 344). Analyzed saltos were performed by all gymnasts (N=97) who were competing in qualifications of European Championships 2004 in Ljubljana. We defined variables according to a theoretical model for the evaluation of salto landings in floor exercise (Marinsek & Cuk, 2007). We found out that 52,4 % of all performed saltos were landing happened when saltos were extremely under rotated (less than 30 deg. before vertical). Even though the most of the saltos were without a landing mistake. Landings were mostly performed in soft landing (64,2 %). Less were performed in stiff landing (32,6 %) and into support on arms (4,1 %). 62,5 % of analyzed saltos were under- and 37,5 % over- rotated. The most large errors and falls at landing happened when saltos were extremely under rotated less than 30 deg. before vertical. Even though the most of the saltos were under rotated the direction of movement after landing was mostly forward (42,7 %) in the same direction as salto was performed. Backward movement was less frequent (16,0 %) and movement aside even less (11,3 %).

INTERCEPTING MOVING TARGETS: USE OF VISUAL INFORMATION PROVIDED BY DIFFERENT VELOCITY DETECTION SYSTEMS

Teixeira, L., Caminha, L., Azevedo Neto, R.
University of São Paulo, Brazil

Visual tracking is the most commonly used visual strategy to extract information from a moving target for interception. In this case, an individual uses the head-eyes system to estimate target velocity, and then organize movements on the basis of the anticipated time of target arrival at the interception point. In a previous investigation, however, Montagne presented preliminary evidence that in catching moving balls an alternative velocity detection system might lead to equivalent or even superior performance in interception. Namely, when their participants kept the eyes stable at the point of ball departure (image-retina system), the rate of successfully grasped balls was similar to that achieved under continuous visual tracking in longer periods of observation, and superior when shorter periods were imposed. These results suggest that different visual strategies could be used in a flexible manner in order to estimate time to arrival of a moving target. At the same time, the extent to which distinct visual strategies can be successfully used to intercept moving targets was evaluated. The results showed that the centrifugal image-retina and head-eyes conditions presented similar results leading to lower temporal errors in comparison to the centripetal image-retina condition. In the kinematic analysis, the same relationship was found, with similar pattern of movements between the former visual conditions - as indicated by initiation time, movement time, initial movement velocity, and frequency of movement corrections -, which differed from the latter visual condition. These results showed that the centrifugal motion of the image from the fovea to the peripheral field in the retina provides as accurate information on time to target arrival as that provided by the head-eyes system in interception tasks. As a conclusion, the visuomotor system seems to be able to successfully use peripheral vision when intercepting moving targets.

FOOTEDNESS IN SOCCER PLAYER CHILDREN: PEDAL PREFERENCE AND PERFORMANCE ASYMMETRY

Teixeira, L., Teixeira, M.
University of São Paulo, Brazil

Cumulating evidence has shown that functional lateralization is a dynamic component of human motor development, observed both in performance asymmetry and preference between homologous limbs to execute motor actions. An explanation for such a dynamic process of lateralization is that an intrinsic advantage in motor control of one limb over the contralateral one would lead to a seminal lateral preference of limbs use early in development. With further lateralized practice movement control would be improved in the preferred limb, increasing over years interlateral performance asymmetry observed early in motor development. Such an increased performance advantage of one limb would then enlarge its preference for performing motor tasks. As training of motor skills by naive children in the sport context is featured by an emphasis on improving performance with the preferred limb, this constitutes a particularly interesting situation to test this hypothesis. That is, the greater the practice using a single limb the greater the probability of performance asymmetry on a given task, a fact that has been demonstrated by many researchers. In order to test this hypothesis, we evaluated interlateral performance asymmetry in kinematics of kicking a ball for power and preference in children with different amounts of lateralized practice. We compared the following modes of visual behavior: (a) continuous foveal tracking, employing the head-eyes system; (b) stabilization of visual focus at the point of target departure, employing the image-retina system with centrifugal image motion in the retina; and (c) stabilization of visual focus at the point of target interception, employing the image-retina system with centripetal image motion in the retina. These visual conditions were compared in the performance of a task in which participants had to intercept a moving luminous target at the end of its displacement through an electronic trackway. Target velocity motion was varied between trials. The motor action was a 60-cm long forehand drive using a badminton racquet, hitting a ball-like transducer embedded at the end of the trackway. Hitting movements were filmed at the frequency of 240 Hz, and the trackway sets were filmed at a spatial accuracy of 1 cm. The results showed that the centrifugal image-retina and head-eyes conditions presented similar results leading to lower temporal errors in comparison to the centripetal image-retina condition. In the kinematic analysis, the same relationship was found, with similar pattern of movements between the former visual conditions - as indicated by initiation time, movement time, initial movement velocity, and frequency of movement corrections -, which differed from the latter visual condition. These results showed that the centrifugal motion of the image from the fovea to the peripheral field in the retina provides as accurate information on time to target arrival as that provided by the head-eyes system in interception tasks. As a conclusion, the visuomotor system seems to be able to successfully use peripheral vision when intercepting moving targets.

INTERACTIONS BETWEEN IMPLICIT/EXPLICIT LEARNING AND FUNDAMENTAL MOVEMENT ABILITY IN CHILDREN

Maxwell, J., Masters, R., Hammond, J.
University of Hong Kong, Hong Kong

This experiment investigated the relationship between fundamental movement ability and implicit/explicit learning conditions in children. The experiment was conducted in two parts; the first consisted of assessing a large group of children with a battery of movement tests. For the second part of the experiment, children whose composite fundamental movement ability score fell in the upper or lower quartiles were invited to attend a laboratory session in which they learned a golf putting skill. A total of 261 primary school students (142 boys and 119 girls) aged 9-12 years (M = 9.74) from three Hong Kong primary schools were recruited for the first part of the study. Seventy-one children were subsequently asked to take part in the second part of the experiment, 45 agreed (25 boys, 20 girls, mean age = 9.80, SD = .59). Low and high ability children were assigned to either an implicit or explicit learning condition. Learning consisted of 300 shots follow-
ing errorless or errorful procedures validated by Maxwell, Masters, Kerr, and Weedon (2001). Following learning, all participants performed a 50 trial retention test, 50 trial secondary task transfer test, and a second 50 trial retention test. Based on previous research, it was predicted that errorful (explicit) learners would experience a drop in performance when required to perform a secondary task whilst concurrently performing the primary motor task. The performance of errorless (implicit) learners was expected to show no negative effects of secondary task load. Additionally, high ability learners were expected to outperform low ability learners in the errorful condition only, performance of high and low ability learners in the errorless condition was predicted to be equivalent. Finally, errorful (explicit) learners were expected to report more technical rules about how they performed the motor task than errorless learners.

The results supported these predictions, both low and high ability implicit learners were unaffected by the secondary task, as were high ability explicit learners. Low ability explicit learners suffered a drop in performance when required to perform the putting task and secondary task concurrently. The results suggest that implicit learning techniques should be applied to children, particularly those with low natural movement ability. Additionally, they suggest that the effectiveness of a variety of learning techniques may only be apparent when demands on attentional resources, particularly working memory, are at their greatest.

FREELY CHOSEN PEDAL RATE IS STEADY OVER MONTHS AND LARGELY INDIVIDUAL THAT CONTRIBUTES TO THE DESIGNATION AS A ROBUST INNATE VOLUNTARY MOTOR RHYTHM

Hansen, E.
Norwegian School of Sport Sciences, Norway

INTRODUCTION
Freely chosen pedalling during cycling represents a voluntary rhythmic movement as for example voluntary finger tapping. Suggestively, such rhythmic movements are largely influenced by central pattern generators that are rhythmically active neural networks located in the spinal cord (Zehr 2005). The steadiness of the freely chosen pedal rate over months is unknown. Therefore, the steadiness and individuality of the freely chosen pedal and finger tapping rates over 3 months was studied by comparing the inter- and intra-individual variation in these two diverse voluntary motor rhythms.

METHODS
Recrerationally active males (n=7, 29±3 years, 186±7 cm, 83±4 kg) who were accustomed to cycling, without being competitive cyclists, participated. All reported bimonthly, for 3 months. Each time, the participant with the index finger of the dominant hand performed 3 min unloaded tapping on the touch pad of a laptop PC and freely chosen tapping rate was calculated. Then, the participant performed a 5-min bout on an electromagnetically braked cycle ergometer. Work rate was 2 W/kg, which corresponds to about 60% of the maximal oxygen uptake. Freely chosen pedal rate was averaged over the last 2 min.

RESULTS
Average work rate during cycling was 167±8 W. Freely chosen pedal rate was constant over the 3 months (p>0.05), averaging 73±15 rpm. The degree of steadiness of each individual's pedal rate over the 3 months was indicated by an average 95% confidence interval (CI) across the participants of 8 rpm, ranging from 5-13 rpm. The individual pedal rates, averaged over the 3 months, ranged from 52-95 rpm. Expressed in percent of the overall average of 73 rpm, individual freely chosen pedal rates ranged from 71%-130%. Freely chosen finger tapping rate was also constant over the 3 months (p>0.05) with an average of 246±57 taps/min. The average CI across the participants was 13 taps/min, ranging from 8-16 taps/min. The individual finger tapping rates, averaged over the 3 months, ranged from 158-322 taps/min, corresponding to 64%-131% of the overall average of 245 taps/min. For both pedalling and tapping, the majority of the CI intervals did not overlap, underscoring the individuality of both motor rhythms.

DISCUSSION AND CONCLUSION
Freely chosen pedal rate was steady and at the same time largely individual over the 3 months, i.e. showing little variance within the participants while considerable variation between participants. This pattern was in striking resemblance to what was found for the freely chosen finger tapping rate. From this, and other results showing the freely chosen pedal rate to be unaffected by separate increases in cardiopulmonary and mechanical load (Hansen 2008), the freely chosen pedal rate is suggested to be a robust innate voluntary motor rhythm, likely under primary influence of central pattern generators.

MOVEMENT TIMING CONTROL IN ADOLESCENTS: EFFECTS OF TASK COMPLEXITY

Rodrigues, P., Barreiros, J., Vasconcelos, O., João de Deus, B.
Faculty of Sports, Porto University, Portugal

Time to initiate movement (TIM) in a coincidence-anticipation task involving different levels of movement complexity was investigated. Two age groups (13-15, 16-18 years) of male and female adolescents performed two serial hand pressing buttons tasks (simple and complex) in a platform coupled to a Bassin Anticipation Timer device. Six trials were recorded for each task. The order of presentation of tasks was counterbalanced across subjects. TIM was analyzed through a 2 (sex) x 2 (age group) x 2 (task) ANOVA. Results demonstrated a sex by age interaction on the complex task. While males tended to initiate movements faster than females in the 13-15 years group the reverse was observed for the 16-18 years group. Results also indicated that subjects took less time to initiate the movement in the more complex task. Individuals anticipated that they would need extra time to perform the task in the more complex condition and consequently reduced the time to initiate the action.
THE RELATIONSHIP BETWEEN THE PREACTIVATION OF LEG MUSCLES AND DROPPING HEIGHT

Takahara, T., Seki, K., Yamaguchi, H., Onodera, S.
Graduate School of Kawasaki University of Medical Welfare, Japan

Previous studies about a drop jump or hopping reported that the preactivation (PA) of a leg muscle expresses before foot contacts in landing phase. In the movement such as a drop jump or hopping jump, muscle contraction before passive muscle stretch keep much energy to elastic element of muscle-tendon complex. Previous studies consider that PA makes element of preparation for foot contacts and makes a contribution to the next motion. We previously cleared that the electromyographic (EMG) activity of the PA at the time of second landing phase decreased than that of first landing phase in the drop jump (DJ) from 0.3 m. In addition, the EMG activity was same in case of the dropping height of the second landing phase in DJ and landing was the same. These results suggest that the regulation of PA depends on the dropping height. It can be speculated if the DJ height was higher, EMG activity of PA is regulated appropriate for the dropping height. The purpose of this study was to compare the EMG activity of PA in the second landing of DJ using the vaulting board and that in the landing from the same height. Seven healthy males volunteered to take part in the experiments. Subjects performed from a platform onto vaulting board of 0.2 m. They had 10 drop jumps consisted the first landing phase (phase 1) and the second landing phase (phase 2) from a platform of 0.5 m (i.e. drop height was 0.3 m), and 10 landings (L-condition) from the platform of DJ height which was obtained by flight duration. The EMG activities of the m. gastrocnemius, m. soleus and m. tibialis anterior of the right leg were recorded. The EMG signals were recorded using bipolar surface electrodes fixed with a constant interelectrode distance of 20 mm. Joint angle was measured at the ankle using an electromiometer. The time of foot contacts was calculated using footswitch which was placed at sole. All analog signals were converted to digital signals in 1kHz and analysis on a personal computer. After the full-wave rectification of an EMG wave, Root Mean Square (RMS) values 100 ms before landing were calculated among phase 2 and L-condition as the muscle activity of PA. As for the values of RMS, no significant difference was observed between the phase 2 and the L-condition. It is suggested that the preparation by the nervous system for the shock of foot contacts was regulated appropriate for the dropping height. However, the values of RMS in phase 2 showed lower than phase 1 irrespective of the dropping height. It is considered that EMG activity in phase 1 included not only preparation for the foot contacts but also performing the next jump effectively. We considered that the descending input from the upper motor centers involved the regulation of PA. These data suggests that the feedforward adjustments control from the central nervous system at the time of voluntary movements might depend on the dropping height without next motion.

TO SKI OR NOT TO SKI: IS PREVIOUS SKIING EXPERIENCE BENEFICIAL IN FIRST TIME SNOWBOARDERS, AND VICE VERSA?

Cottyn, J., Vanhessche, C.
Katholieke Hogeschool Zuid-West-Vlaanderen, Belgium

Skiing and snowboarding are two popular winter sports, but young people are more attracted by the challenging, dangerous nature of snowboarding (Edensor & Richards, 2007). Nevertheless, youngsters are often advised to learn to ski first, before learning how to snowboard. In literature, there are no experimental studies reported investigating if previous experience in one discipline is transferable to the other. Therefore, 18 physical education students (mean age = 20 yr.), who were naïve to skiing and snowboarding, were divided in a Ski First group (N=9) that learned to ski first and then learned to snowboard or in a Snowboard First group (N=9), that learned to snowboard first and then learned to ski. Six 2-hour sessions in 3 days for each discipline were performed by all participants and performance was measured by the instructor after each session, using a standardized form card. For ski performance, a 6 (sessions) x 2 (group) analysis of variance (ANOVA) with repeated measures on the first factor revealed a significant interaction between sessions and group (F(5,12) = 8.27, p = 0.001, 95% CI = 0.7) and a significant increase in performance during the learning period (F(5,12) = 52.64, p < 0.001, 95% CI = 0.96). Post hoc analysis revealed that skiing performance was significantly better (p < 0.01) in the Snowboard First group after the first session, but no further significant differences between the other sessions were found. For snowboard performance, a similar 6 (sessions) x 2 (group) ANOVA revealed also a significant interaction between sessions and group (F(5,12) = 7.73, p < 0.01, 95% CI = 0.76) and a significant increase in performance during the learning period (F(5,12) = 35.76, p < 0.001, 95% CI = 0.94). The post hoc analysis revealed that the Ski First group performed significantly better after the second session (p < 0.05), but again no significant differences between the other sessions were found.

In summary, previous experience of skiing is beneficial in learning how to snowboard. Similarly, previous experience of snowboarding is facilitative in learning how to ski. However, at the end of a 6 sessions learning period, no significant differences between groups were found, indicating that the experience effect is only applicable in early stages of learning and that participants without experience in the other discipline are able to catch up at the end of the learning period. Therefore, first time snowboarders should not be advised to learn to ski first and vice versa.

TEACHING THE FRONT CRAWL STROKE BY KICKBOARD OR BY VARIOUS AIDS: A STUDY IN YOUNG CHILDREN

Scurati, R., Michielon, G., Longo, S., Inverznizi, P.
Faculty of Exercise Sciences - University of Milan, Italy

INTRODUCTION
There are contrasting opinions about the suitability of aids in teaching swimming. Authors state that there is no evidence of their effectiveness (1) instead of their influence when new stroke elements are taught (2). But whether aids are used, what sort of them has to be preferred? The purpose of this study was to compare the results of teaching the front crawl stroke by a number of aids or by the only kickboard.

MATERIAL AND METHODS
Two groups of seven 10 years old children, whom equal swimming abilities were previously verified, were taught during nine swim classes program to learn the front crawl swimming. One group (=VAG, Mean±SD, weight 33.1±10.7 kg, high 121.2±6.8 cm) practiced with various aids, such as pull-buoy, kickboard, tubes, gloves. The other group (=KBG, Mean±SD, weight 32.7±8.7 kg, high 125.6±5.9 cm) practiced only with the aid of the kickboard.
THE EFFECT OF TRAINING IN BILATERAL AND UNILATERAL REACTION TIME TASKS ON THE MOTOR CORtical ACTIVITY DURING BILATERAL AND UNILATERAL REACTION TIME TASKS

Shibai, K., Taniguchi, Y.
International Budo University, Japan

Introduction

When simultaneous bilateral movements are introduced in reaction time (RT) task or in strength exertion task, performances are reduced compared to that during single movement conditions. These phenomena were known as "bilateral deficit". The lateral specificity in the effect of bilateral and unilateral training is present in the resistance exercise (Taniguchi, 1997, 1998) but not in the RT task (Taniguchi, 1999). These mechanisms in the training have not yet been clarified. The purpose of this study was to investigate whether the cortical activity during the RT task would be changed with the effect of bilateral and unilateral training.

Methods

Before and after the training session, six right-handed subjects were measured simple RT tasks with isometric abduction of the index finger under three conditions: with the right hand, left hand, and both hands. Each response condition consisted of 2 blocks of 20 trials.

The order of the blocks was randomized. EEG activity was recorded on 21 locations using the 10-20 system. During the preparatory period, EEG was averaged, time-locked to the preparatory signal, under the three task conditions. Electromyographs (EMGs) were recorded with surface electrodes on the right and left first dorsal interosseous muscles. EMG-RTs were measured from the response signal to the onset of EMG. Isometric abduction forces were recorded by force transducers. Subjects were assigned to three groups: bilateral training group (BT), unilateral training group (UT), and control group (C). BT and UT continued the 2 blocks of 10 trials of each RT task, 3 days a week for 3 weeks. C did not train.

Results and Discussion

A two-factor analysis of variance, with two times (before and after) x two sides (right and left) demonstrated that significant reduce in EMG-RTs were found in UT subjects. No change was found in BT and C. It was concluded that the effect of training in RT was observed only for UT as shown in previous studies, but not for BT. The amplitude of contingent negative variation (CNV) on motor cortical area (C3 and C4) just before the response signal, as an index of motor preparation, tended to increase for UT but there are not consistent results. More studies are needed to clarify whether motor cortical activity during the RT task would be changed with the effect of bilateral and unilateral training.

IMPACT OF GUIDED AND OPEN LEARNING PROGRAMS ON MOTOR DEVELOPMENT OF MANIPULATIVE SKILLS

Mourão-Carvalhal, L., Xabregas, N.
Universidade Trás-os-Montes e Alto Douro, Portugal

The main objective of this research was to check the impact of guided teaching on the development and learning of manipulative skills (namely, throwing and kicking) in three- and four year old children attending preschool. The sample comprised 145 children, all attending preschool, who were divided into two groups: an experimental group and a control group. In the quasi experimental design that was used, both groups were subjected to a pre-test and a post-test. The experimental groups were subjected to experimental teaching units, aiming at the learning of manipulative skills with the ball, organized into 14 sessions of thirty minutes in two different learning contexts (guided and open), one lasting two months and the other one lasting four. The control group was subjected to no kind of teaching programme whatsoever. In order to compare the quantitative intra-group progress we used the t-test for independent paired samples. On the other hand, the Mann Whitney U-test was applied to compare the inter-group qualitative gains. For quantitative gains we used the t-test for independent samples. When the quantitative gains in both control and experimental groups were compared, no statistically significant differences were observed on throwing skill (t = 62; p = 0.532) and on kicking (t = 41; p = 0.158). Comparing the experimental groups qualitatively, there was progress in the three components of throwing: the actions of the foot; arm (anterior and posterior rotation); arm (humerus), as well as in the following components of kicking: torso and head; action of the leg and control. The results of this re-

IN ORDER TO VERIFY THE IMPROVEMENTS OF THE SUBJECTS, A COMPLETE FREE FRONT CRAWL STROKE IN THE FINAL PART OF EACH CLASS WAS VIDEO RECORDED AND SCORED THROUGH A MERS-F SCALE, JUDGING A NUMBER OF KEY ELEMENTS FOR THE STROKE. FOLLOWING ANALYSIS WERE CARRIED OUT: II INTRA-GROUP COMPARISON BETWEEN EACH CLASS AND THE NEXT; III INTRA-GROUP COMPARISON BETWEEN THE FIRST AND THE LAST CLASS; III COMPARISON BETWEEN VAG AND KBG IN EACH CLASS.

RESULTS

In each group significant improvements were found between the first and the last class: VAG, 2nd and 3rd (3.14±0.69 vs. 3.71±0.49 pts, p<0.05), 5th and 6th (4.34±1.27 vs. 7.03±0.85 pts, p<0.02), KBG, 1st and 2nd (2.57±0.53 vs. 3.43±0.53 pts, p=0.01), 2nd and 3rd (3.43±0.53 vs. 4.29±0.76 pts, p<0.03), 3rd and 4th (4.29±0.76 vs. 5.14±0.69 pts, p=0.03), 5th and 6th (5.57±0.79 vs. 6.83±1.44 pts, p<0.04).

In each group significant improvements were found between the first and the last class: VAG, 2nd and 3rd (3.71±0.49 vs. 7.63±0.44 pts, p<0.05), KBG 2.57±0.53 vs. 8.20±0.91 pts (p<0.05). No differences were found in the VAG - KBG comparison (iii) except after the 4th class (4.00±0.82 vs. 5.14±0.69 pts, p<0.05).

CONCLUSIONS

The main objective of this research was to check the impact of guided teaching on the development and learning of manipulative skills (namely, throwing and kicking) in three- and four year old children attending preschool. The sample comprised 145 children, all attending preschool, who were divided into two groups: an experimental group and a control group. In the quasi experimental design that was carried out: i) intra-group comparison between each class and the next; ii) intra-group comparison between the first and the last class; iii) comparison between VAG and KBG in each class.

**THE INFLUENCE OF CAFFEINE AND CARBOHYDRATE CO-INGESTION ON SOCCER PERFORMANCE**

Gant, N., Ali, A., Foskett, A.  
*The University of Auckland, New Zealand*

Independently carbohydrate and caffeine are known to improve certain aspects of athletic performance when ingested before and during prolonged exercise. However, less is understood about physiological and performance outcomes when these compounds are co-ingested during exercise. It is possible that carbohydrate and caffeine may provide additive ergogenic effects. Conversely, this combination could counteract any glycogen sparing benefit or lowered perception of effort. The aim of this study was to examine the influence of carbohydrate–caffeine co-ingestion on the physiological and cognitive aspects of prolonged simulated soccer activity.

Fifteen male competitive soccer players performed two 90-min intermittent shuttle-running trials (LIST), separated by 7 days. Using a randomised crossover design, participants ingested a 6% carbohydrate-electrolyte solution (CES), or a similar solution with 160 mg/kg of added caffeine (CAF). A volume of solution equivalent to 8 ml/kg body mass (BM) was ingested 1 h before exercise and a further 3 ml/kg BM was provided every 15 min during the protocol, a total caffeine dose of 3.7 mg/kg BM. Soccer passing skill (LPST) and countermovement jump height (CMJ) were quantified prior to exercise and every 15 min during the LIST. Sprinting performance, heart rate (HR), blood lactate concentration and the subjective experiences of participants were measured routinely throughout the protocol.

Mean 15-m sprinting time was faster during the CAF trial (P=0.04), over the final 15 min of exercise mean sprint times were CAF 2.48 ± 0.15 s vs. CES 2.59 ± 0.2 s. Explosive leg power was improved during the CAF trial (P=0.03) with CMJ height higher in CAF 52.9 ± 5.8 cm vs. CES 51.7 ± 5.7 cm. HR was elevated throughout the CAF trial (P<0.01), mean HR during the final 15 min of exercise was CAF 170 ± 7 beats/min vs. CES 166 ± 7 beats/min. Ratings of pleasure were significantly enhanced during the CAF trial and no differences were detected in RPE, thirst drive or felt arousal. There were no significant differences in passing skill, blood lactate concentration or BM losses between trials.

The addition of caffeine to the CES improved sprinting performance, countermovement jump height and the subjective experiences of players during 90-min of soccer-related exercise. Differences in performance were apparent during the maximal, self-selected components of the exercise protocol, and the addition of caffeine appeared to offset the fatigue-induced decline in these variables over time. Performance enhancements may have been mediated through caffeine’s central influence on the perception of effort, fatigue and pleasure. Caffeine ingestion did not influence the various components of soccer passing skill that were measured during this study. The addition of 160 mg/kg of caffeine to a well formulated carbohydrate-electrolyte solution may improve soccer performance, without detrimental to fluid balance and other key physiological and perceptual parameters.

**EFFECT OF MILK-BASED PROTEIN/CHO SUPPLEMENT TIMING ON THE ATTENUATION OF EXERCISE-INDUCED MUSCLE DAMAGE**

Cockburn, E., Hayes, P., Stevenson, E., St Clair Gibson, A.  
*Northumbria University, United Kingdom*

Exercise-induced muscle damage (EIMD) leads to decrements in muscle performance, increases in Creatine Kinase (CK) (Byrne and Eston, 2002), and delayed-onset muscle soreness (DOMS) (Nosaka et al., 2002). Protein/CHO supplements have been shown to attenuate EIMD (Byrne et al., 2007), possibly through changes in protein metabolism. The timing of protein/CHO ingestion is critical for changes in protein metabolism (Tipton et al., 2001). Therefore, the purpose of this study was to investigate the timing of milk-based protein/CHO supplementation on the attenuation of EIMD.

Four independent groups of 8 healthy males (age 20 ± 2 yrs, mass 78.5 ± 9.0 kg) ingested either a control (CON), milk-based protein/CHO immediately pre (PRE), immediately post (POST) or 24h post (P24) muscle damaging exercise. Participants completed 6 sets of 10 reps of eccentric/concentric leg flexions on each leg at 1.05 rad/s to induce hamstring muscle damage. Immediately prior and at 24h, 48h and 72h post EIMD participants completed a visual analogue scale to assess general and active DOMS, and performed 6 concentric knee extension/flexions. Venous blood samples were collected at the same time points for the analysis of CK concentrations. No significant differences were observed between groups for general DOMS, active DOMS, CK and peak torque (P>0.05). Effect sizes for DOMS and DOMS (non-dominant) effect sizes were 0.9, 1.6, 0.4, 0.5 and peak torque (non-dominant) effect sizes were 0.8, 0.6, 0.0 and 0.1, respectively.

The data indicates that although there were no significant differences, effect sizes demonstrated a trend towards the attenuation of EIMD with the consumption of milk-based protein/CHO immediately or 24h post muscle damaging exercise.

EFFECT OF ESSENTIAL AMINO ACID AND CARBOHYDRATE SUPPLEMENTATION ON MUSCLE TORQUE AND HYPERTROPHY FOLLOWING RESISTANCE TRAINING IN YOUNG MEN

Vieillefosse, S., Carpentier, A., Poortmans, J.R., Duchateau, J.
Institute for Motor Sciences, Université Libre de Bruxelles, Belgium.

Resistance training enhances muscle strength and power output in young individuals providing a sufficient nutritional supply of essential amino acids (EAA). In such condition, previous work pointed out an increase in muscle protein synthesis after training [1,2]. However, there is no data available on whole muscle mass increase under such conditions. The aim of the present investigation is to evaluate the increase in skeletal muscle mass and muscle strength following EAA supplementation combined to resistance training program. Twenty-five young active males (mean 24.6 ± 4) performed two sessions of resistance training per week during three months. They were divided into two groups, one group received placebo (PL) and the other group received an EAA supply (EAA). Both groups were further supplied with 15g and 30g of saccharose, respectively. Before training, food questionnaire was collected during 7 days, together with two 24h-urine collection. Maximal strength during squat and bench press exercise were tasked on an isotonic ergometer (Ariel CS 6000) before and by the end of training. Skeletal muscle mass was assessed by anthropometric measurements [3]. A linear regression was obtained between nutritional protein intake and nitrogen balance (P<0.001) together with a positive nitrogen balance of 1.09g protein intake per kg body weight. After training, the mean concentric strength for the two exercises increased by 9.8% (EAA group, p<0.05) and 8.9% (PL group, p<0.05), while the skeletal muscle mass increased by 2.9% and 1.7% respectively (p<0.05). No significant difference for the skeletal muscle mass but also for the strength (p>0.05) was showed between both groups When comparing the normalised strength (initial strength/skeletal muscle mass and the gain in strength, the EAA supplementation tend to be more effective in a “weaker” population [P =0.06]. Similarly, a linear regression tendency (P = 0.06) between the nitrogen balance (g/kg body weight) and the gain in skeletal muscle mass (%) increase was also observed in the PL group.

In conclusion, our study pointed out an increase in skeletal muscle mass in an PL and EAA groups, with no statistical difference between groups. However, the increase in skeletal muscle mass under EAA supplementation appears to be more effective in subjects with an lower initial muscle torque and a lower (or negative) nitrogen balance.

ASSESSMENT OF SUPPLEMENTS INTAKE AMONG POLISH TRIATHLONISTS

Szygula, Z., Kazimierzak, K., Schiegel-Zawadzka, M.
University of Physical Education, Krakow, Poland.

The aim of this study was to recognize the way of supplements and nutrients ingestion as well as drinks intake among triathletes.

Methods: The study was conducted in the north of Poland on the group of 34 triathletes (Athletes A) and 34 non-athletes (Control Ci. Both groups were characterized concerning subjects’ age and sex. The study was a case control study. In each group there were 7 females and 27 males aged 15-25 (average 20 ±5 ±4). Such information as amount and type of meals and supplements intake was collected with usage of questionnaire.

Results: The main reasons for physical activity among athletes were keeping the physical condition (71%) and remaining healthy and fit (44%), while non-athletes pointed physical fitness (67%) and health keeping (38%). Most of subjects used to have only two main meals during the day (A-53%, C-56%). 21% of triathletes and 27% of non-athletes used to have three meals during the day. 32% of athletes declared to have special diet and 57% of them consulted it with their coach. The rest of athletes compiled their diet on their own (29%) or with friends’ help (14%). The most common drink in gr. A was mineral water (86% of athletes drank 3-5 glasses/day), subjects from gr. C tended to drink one glass twice a day (57% of females and 58% of males) (p=0.0001). Subjects from gr. C used to drink much gaseous beverages than those from gr. A (p=0.004). 14% of females from gr. C admitted to drink about 3-5 glasses of gaseous beverages per day, while females from gr. A. A claimed to drink them occasionally (43%) or never (57%). Energetic drinks were more commonly drank by men from gr. A (1-2 glasses/day) comparing to non-training men, who drank them occasionally or rarely (p=0.0044). In gr. A the mostly used nutrients were muscle building nutrients - 52% of males and 29% of females athletes admitted to use supplements. Females intake mainly fat burning supplements, which were to help them in ideal silhouette achieving (71%) and only 29% of men did so as well (p=0.001). 80% of examined subjects from the gr. preferred to intake supplements twice or three times a week especially after the training (90%). Type of supplement was consulted with coach in 88%, 50% of subjects read about the supplement in different sources and 35% heard about it from friends or doctor. 71% of athletes have noticed supplements influence on their health, physical condition and endurance.

Conclusions: Supplements intake among the athletes is different and depends on athletes’ sex. With a view to frequency of supplements intake they should be considered while composing athletes’ diet, which should consist of four meals.

NSI CHECKLIST AND BMI IN THE ASSESSMENT OF THE NUTRITIONAL STATUS OF ALZHEIMER’S DISEASE PATIENTS

Ramos, L., Vale, F.
(1) Clinical Hospital of the Faculty of Medicine of Ribeirão Preto, Ribeirão Preto, SP, Brazil; (2) Foundation of Superior Education of Passos, University of the State of Minas Gerais, Brazil

Background. Alzheimer disease (AD) is commonly associated with nutritional disorders which may impair the general health. Efforts should be directed to understand, and assess the nutritional status of demented patients by using simple, non-invasive, easy to administer, patient-friendly, non-expensive screening tools. Objective. To evaluate the Nutrition Screening Initiative (NSI) checklist and body mass index (BMI) in the assessment of the nutritional status of AD patients. Methods. This study included 45 patients (64.4% women, mean age 75 ± 8 ±4 years and mean Mini-Mental State Examination (MMSE) score 12 ± 7 ± 5. Nutritional status was assessed by the NSI checklist and the age-related BMI. Dementia severity was assessed through Clinical Dementia Rating (CDR) and MMSE. Fisher’s exact test was performed to analyze differences among groups. Regarding to dementia severity, 42.2% of patients were rated as CDR 1, 33.3% as CDR 2 and 24.4% as CDR 3.
HYDRATION STRATEGY ON ROMANIAN NATIONAL FOOTBALL TEAM

Ionescu, A., Apostol, A., Reinaldo, P., Vasilescu, M.
UNIV. OF MEDICINE CAROL DAVILA, BUCHAREST, Romania

AIM
To evaluate the sweating rate and fluid intake habits of the Romanian Football Team players in order to know their hydration behaviors and helps their recovery and performance.

MATERIALS and METHODS
Eighteen players of the Romanian Soccer Team were evaluated by the Gatorade Sports Science Institute (GSSI) during training session before a match for 2008 Europe Championship qualification

Experimental design: The sweat test was performed on September 3 2007, in Bucharest. The average heat index stress (HIS), an indicator of environment stress (radiation, humidity and temperature) was moderate (19.9°C). The total time of testing was 75 minutes, but a group of 5 players finished earlier (45'). During training there was about 2-3 hydration breaks per player. Sweat loss was estimated considering body weight changes before and after training, monitoring fluid intake (Gatorade and water) from the bottles given to each player, and fluid loss through urine. Initial hydration status was tested through urine specific gravity of urine sample taken before exercise. Electrolytes loss in sweat was measure using specific patches.

RESULTS
Thirteen players provided urine samples to evaluate their urine specific gravity. On average the group evaluated presented USG values of 1.020. The sweat rate was 0.7 l per hour, considered a low sweat rate. The players replaced 57% of their fluid loss. Some do not drink and others over drink. In general, players finished their practice with a relative low level of dehydration (0 – 4%). It was also observed that fluid intake was bit higher during than after exercise (452 vs. 300 ml). This is a good hydration habit because potentially helps athletes perform better during training and they become used to drink during exercise. On average, Gatorade intake was higher than water fluid intake was bit higher during than after exercise (452 vs. 300 ml). This is a good hydration habit because potentially helps athletes perform better during training and they become used to drink during exercise. On average, Gatorade intake was higher than water.

EFFECT OF RADIX SALVIAE MILTIORRHIZAE (DANSHEN) ON CHANGES IN BONE FORMATION MARKERS AND HORMONE PROFILES DURING A 15-DAY CYCLING TOUR

Chang, CM., Chiang, C., Ku, S., Chiu, Y., Hung, W., Wu, C., Chang, C.
Taiwan Sport University, Southern Taiwan University of Technology, Taiwan

The potential functions of Radix salviae miltiorrhiza (Danshen) include to enhance procollagen synthesis and fracture healing. In addition, Danshen has been used as an alternative medicine in the treatment for various diseases such as cardiovascular diseases, acute pancreatitis, and cancer. Over the past two decades, multi-day cycling tour has become one of the most popular forms of physical activity. Long-term regular physical activity, especially weight-bearing types, has been shown to increase bone mass. On the other hand, acute unaccustomed exercise may have negative effect on bone metabolism. The information regarding multi-day endurance exercise on bone metabolism in previously untrained subjects is still lacking. In addition, it has been shown regular resistance training could increase testosterone and dehydroepiandrosterone sulfate (DHEAS). However, the changes of these hormones during endurance training are still unclear. The aims of this study were to investigate the effect of Danshen on bone formation markers, osteocalcin (OC) and amino-terminal propeptide of type I collagen (PINP), during a 15-day cycling tour in previously untrained subjects. In addition, the effect of Danshen on testosterone and DHEAS will also be examined. Twenty-eight male subjects who participated in Cycling Taiwan 2007 were randomly divided into placebo or Danshen group with 14 in each. The Danshen group consumed 4 pills containing Danshen extracts daily during the tour. The control group consumed the equal amount of pills containing starch. The 2 groups were similar in age, height, and body weight. The tour covered approximately 1100 km in 15 days with 80-120 km per day in most of the days. All subjects were in a free feeding style during the tour. Fasting blood samples were collected in the early morning on day 1 (D1), 5 (D5), 10 (D10), and 15 (D15) during the tour and 7 days after completing the tour (P7). The data was analyzed by 2-way repeated measurement ANOVA. There was significant time effect on testosterone and dehydroepiandrosterone sulfate (DHEAS). The results of this study indicated that Danshen may not have effect on the changes of bone metabolism, testosterone, and DHEAS in during a multi-day cycling tour in previously untrained subjects.
EFFECT OF RADIX SALVIAE MILTIORRHIZAE (DANSHEN) ON CHANGES OF ANTIOXIDANT STATUS DURING A 15-DAY CYCLING TOUR

Lu, GY., Chiang, CW., Ku, SH., Chiu, YC., Hung, W., Wu, CL., Chang, CK.
Taiwan Sport University, Southern Taiwan University of Technology, Taiwan

The potential functions of Radix salviae miltiorrhize (Danshen) include the elimination of oxygen free radicals and prevention of oxidative stress. It has been suggested that regular exercise could enhance antioxidant defense system. On the other hand, unaccustomed intensive exercise may increase free radical production. Multi-day cycling tours have been gaining significant popularity in recent years. However, changes in antioxidant status during multi-day endurance exercise were still unclear in untrained recreational participants. In addition, most studies on exercise effects only measured the parameters before and after exercise with little or no information on the changes during the training period. The aims of the present study were to investigate the effect of Danshen on changes in activities of antioxidant enzymes and total antioxidant status (TAS) during a 15-day cycling tour in untrained healthy subjects. Twenty-eight male subjects who participated in Cycling Taiwan 2007 were randomly divided into placebo or Danshen group with 14 in each. The Danshen group consumed 4 pills containing Danshen extracts daily during the tour. The control group consumed the equal amount of pills containing starch. The 2 groups were similar in age, height, and body weight. The tour covered approximately 1000 km in 15 days with 80-120 km per day in most of the days. All subjects were in a free feeding style during the tour. Fast blood samples were collected in the early morning on day 1 (D1), 5 (D5), 10 (D10), and 15 (D15) during the tour and 7 days after completing the tour (P7). The data was analyzed by 2-way repeated measurement ANOVA. There were significant time and group effects on glutathione peroxidase (GPX) activity. In the placebo group, GPX activity was significantly lower in D10 comparing to D1. GPX activities remained unchanged during the race in the Danshen group. Both groups showed a significant decrease in GPX activity in P7 comparing to D1. There was a significant time effect on glutathione reductase (GR) activity. In the placebo group, GR activities during and after the tour were similar to D1. In the Danshen group, GR activity was significantly higher in D5 comparing to D1, then return to basal level in D10 and P7. The time effect was also significant on TAS. TAS remained constant throughout the tour but was significantly increased in P7 comparing to D1 in both groups. The results of this study suggested that Danshen may help to prevent the decrease in GPX activity during the multi-day endurance exercise in previously untrained subjects. However, it may not have an effect on GR activity and TAS levels.

UTILISATION OF AN ARMBAND DEVICE FOR MONITORING OF ENERGY EXPENDITURE AND ACTIVITY IN RUNNING AND CYCLING ATHLETES

Koehler, K., Braun, H., de Marées, M., Mester, J., Schaanen, W.
German Research Centre of Elite Sports, Cologne, Germany

INTRODUCTION: Correct quantification of energy expenditure (EE) is of essential importance in the evaluation of an athlete's nutrition status. In the laboratory setting, indirect calorimetry (IC) has been well established as the method of choice for determination of EE. However, portable IC and other methods have - in part severe - limitations regarding its applicability in field settings. The SenseWear Pro armband is a portable device, which combines biaxial accelerometer with measuring skin and near body temperature and galvanic skin response. Due to its simple and inexpensive usability, the armband seems well suited for high-resolution activity monitoring of athletes.

The aim of the present study was to compare the SenseWear armband to other measures of EE both in laboratory and field situations in well-trained athletes.

METHODS: Fifteen male triathletes (30 ± 6 y, 80.7 ± 6.2 kg) wore the SenseWear Pro3 armband (BodyMedia, Pittsburgh, USA) over a period of seven days. Within this time, the athletes performed two standardized exercise bouts, consisting of (a) a treadmill running test with increasing velocity until exhaustion, and (b) bicycle ergometry with increasing power output until exhaustion. During these exercise bouts, VO2 and VCO2 were measured with a Zan 600 (Oberthulba, Germany) spirometer. EE was calculated from IC data using standard equations. Besides these two controlled exercise bouts, athletes were free to train as they desired except for swimming.

Additionally, all subjects filled out a standardized activity protocol (AP) for assessing activity and sleep patterns and approximation of EE.

RESULTS & DISCUSSION: During the running exercise test, armband data was highly correlated to IC data in all subjects (mean r-squared = 0.87 ± 0.05). However, EE approximated by the armband was significantly lower for all running speeds (2.4 to 4.8 m/s; p < 0.01). During the stationary cycling test, there was also a high degree of correlation (mean r-squared = 0.84 ± 0.12), but armband EE was lower than IC data for all steps (140 to 380 W; p < 0.01). Overall daily EE measured with the armband (3607.2 ± 422.8 kcal/d) and calculated from AP data (3433.5 ± 298.9 kcal/d) did not differ (p = 0.21).

As indicated by the much lower EE values during the cycling exercise, the difference between armband and AP values was negatively associated with daily cycling time (p < 0.01). Both sleep and lying time as recorded by the armband were correlated with sleep time from AP (p < 0.01), but only lying time did not differ from self-recorded sleep time (p = 0.39).

The present data indicate that the armband is suitable for use in activity monitoring of athletes in in-field settings. However EE monitoring during exercise - especially with regard to running at great speed or cycling with high power output - seems to require exercise-specific calibration.

USE OF NUTRITIONAL SUPPLEMENTS BY GERMAN ELITE JUNIOR ATHLETES

German Research Centre of Elite Sports, Cologne, Germany

INTRODUCTION: Despite the fact that there is little to no scientific evidence on beneficial effects, the use of nutritional supplements (NS) is widespread in the athletic community. Among athletes, the prevalence of supplement use varies greatly depending on age, sport, and level of competition.

Data on NS use among adolescent athletes has been mostly assessed in high school and college athletes. However, this group is not comparable to elite junior athletes, who compete on national and/or international level. To our knowledge, scientific data on prevalence of and motives for NS use by elite junior athletes is lacking. Therefore, the present survey was designed to assess the rate of NS use among a wide spectrum of German elite junior athletes with respect to age, gender, and type of sport. Additionally, the motives for NS use and sources of information and products as well as the awareness of NS contaminations were asked for.

METHODS: A five-page questionnaire was used to assess information regarding the past and present use of NS. The listed supplements included vitamins, minerals, carbohydrate, protein, and fatty acid preparations, sport beverages, other ergogenic aids, isolated com-
pounds, and plant extracts. All junior athletes participating in the monitoring programme of the German Research Centre of Elite Sports were handed the questionnaire. Data from 167 athletes (16.5 ± 3.0 y) was included into the present data analysis.

RESULTS & DISCUSSION: Overall, 133 athletes (74 %) reported the use of at least one NS. Supplement use was significantly higher in older athletes (11-14 y: 75 %, 15-16 y: 76 %, 17-18 y: 75 %, 18-25 y: 97 %; p < 0.05). Among NS users, minerals (84 %), vitamins (75 %), sport and energy drinks (69 %), and carbohydrate preparations (64 %) were most frequently used. Only a small number of athletes reported the use of protein/amino acid preparations (29 %), caffeine (16 %), creatine (6 %), carnitine (6 %) or other ergogenic aids. Major reasons for NS use were health related (77 %), whereas performance enhancement (28 %) and recommendation by others (22 %) were less stated motives. Primarily supplements were obtained from parents (43 %) or by athletes themselves (34 %). NS were mainly purchased in drug-stores (62 %), supermarkets (18 %), and health food stores (17 %). Among all athletes, only 41 % were aware of the problem of supplement contaminations.

These figures demonstrate that NS use is common and widespread among German junior elite athletes, which strongly contradicts recommendations by leading sport federations against supplement use by athletes under 18 years of age. Identification of the spectrum of NS use and motives, and sources of products and information may be helpful in proper nutritional and medical education of these potential future elite senior athletes.

EFFECT OF CONJUGATED LINOLEIC ACID SUPPLEMENTATION ON BODY COMPOSITION IN WOMEN SUBMITTED TO AEROBIC TRAINING

Dodero, S., Trindade, M., Cyrino, E., Tirapegui, J.
University of São Paulo, Brazil

Conjugated linoleic acid (CLA) is a group of positional and geometric isomers of linoleic acid commonly found in beef, lamb and dairy products. Although recent studies with CLA have been reported to reduce adiposity in animal models, the effects of CLA on body composition in humans are still contradictory. The objective of the present study was to investigate the effects of CLA supplementation associated with aerobic training on body composition. The sample was constituted by 34 female university students, from 17 to 30 years old and BMI > 25 kg/m². Anthropometric measures of body mass, stature, waist and hip circumferences and body composition were obtained before and after eight weeks of conjugated linoleic acid supplementation (3,2g/d) or placebo (4g/d olive oil). The dual-energy X-ray absorptiometry was used to determine body composition and bioelectrical impedance was utilized to measure total body water. Aerobic training was performed in a treadmill, with a frequency of 3 times per week and duration of 30 minutes. For statistical treatment the analysis of variance (ANOVA two-way) for repeated measures was used followed by the post hoc of Scheffé when P < 0.05. There was no statistical significance in BMI, %body fat, fat free mass, bone mineral component and total body water between moments and groups. Both groups reduced significantly waist circumference and waist-to-hip ratio. Even though there was significant reduction of body mass (78,4±7,6 kg vs. 77,5±7,0 kg, P=0,048) and fat mass (34,8±4,9 kg vs. 33,8±4,81 kg, P=0,027) on the CLA group throughout time, there was no significant difference in the change of these parameters between groups. Thus, the supplementation of conjugated linoleic acid did not showed additional effects in the reduction of the body mass and fat mass in young women after eight weeks of study.

THE EFFECTS OF EASTER HOLIDAYS ON BODY COMPOSITION MEASURES IN OBESE GREEK WOMEN

Jamurtas, A., Tsitsiou, G., Sakellarious, G., O’ Sullivan, K., Koutedakis, Y.
Institute of Human Performance and Rehabilitation, Greece

The purpose of this study was to assess possible body composition changes over a two weeks period during Easter holidays. Twenty five overweight and obese women (BMI = 30.1 ± 0.8 kg/m²) were assessed for body composition changes 5-7 days prior to and a week after Easter day. Body composition measures included body weight, body mass index (BMI), waist circumference, hip circumference, waist to hip ratio and percent body fat. Subjects reported to the lab in the morning, in a fasting state. The measurements were made with the subjects being lightly dressed and by the same trained technician. All measurements appeared elevated after Easter but significant increase (p<0.005) was found in waist (2.0± 2.73 cm) and hip circumferences (1.6± 2.39 cm). Body weight (0.280 ± 1.07 kg), BMI (0.104± 0.418 kg/m²), the percent body fat and the waist to hip ratio (0.140 ± 0.994 % and 0.0055 ± 0.0267) increased following the two weeks of holiday. Seventeen out of the twenty five women (68%) increased their body weight (1.0 3.3 kg), seven women (28%) decreased their body weight (-0.04 -0.85 kg/m²) whereas in one woman (4%) the body weight did not change. The mean increase in the body weight of the women who increased their body weight was 0.79 kg whereas nine of them (36% of the total population) increased their body weight by more than half a kilogram. The mean increase in women that gained more than half a kilogram was 1.23 kg. Seventeen out of the twenty five women (68%) increased their BMI (0.04 1.32 kg/m²), seven women (28%) decreased their BMI (-0.04 -0.85 kg/m²) whereas in one woman (4%) the BMI did not change. Eighteen out of the twenty five women (72%) increased their waist circumference (1 7 cm), three women (12 %) decreased their waist circumference (-1 -3 cm) whereas in four women (16%) the waist circumference did not change. Sixteen out of the twenty five women (64%) increased their hip circumference (1 8 cm), three women (12 %) decreased their hip circumference (-1 -2 cm) whereas in six women (24%) the hip circumference did not change. Fifteen out of the twenty five women (60%) increased their percent body fat (0.5 2 %), four women (16 %) decreased their percent body fat (-1 -2 kg) whereas in six women (24%) the percent body fat did not change. These results indicate that a short period of holidays can result in significant alterations in body composition. Taking into consideration that weight gains during holidays are normally retained [Yanovski et al. 2000], body-weight-control strategies should be introduced to prevent such unwelcome changes.

MAGNESIUM DIETARY DEFICIENCY REDUCES ANTIOXIDANT ACTIVITY IN THE MUSCLE OF RATS UNDERGONE A MODERATE PHYSICAL TRAINING

Amorim, A., Tirapegui, J., Pires, I.
University of São Paulo, Brazil

INTRODUCTION: Marginal magnesium (Mg) dietary deficiency is a common problem worldwide, mainly after the inclusion of industrialized foods in the diet. Many studies suggest the effect of Mg deficiency on the increased susceptibility to oxidative stress. However, there
is little information in literature about the antioxidant capacity of skeletal muscles in Mg deficient organisms doing regular physical exercise. OBJECTIVE: Evaluate the activity of antioxidant enzymes and the lipid peroxidation in the muscle tissue of animals undergone physical exercise and dietary Mg deficiency. MATERIALS AND METHODS: Male Wistar rats (initial weight of 280 g) were divided into control (CON, n=6), exercised control (CONEX, n=6), sedentary Mg deficient (DEF, n=6) and exercise Mg deficient (DEFEX, n=6). The control diet was prepared according to the recommendations of AlNRM (500 mg/Mg/kg of ration) and the Mg deficient diet contained 200 mg/Mg/kg of ration. The animals were fed ad libitum during 6 weeks of experiment and swam 1 hour per day during 5 days every week. The removal of the gastrocnemius muscle took place 24 hours after the last exercise session. The cytosolic and mitochondrial activities of superoxide dismutase (SOD), catalase (CAT) and glutathione peroxidase (GPx), besides the concentration of malondialdehyde (MDA) were determined in this muscle. RESULTS: in the cytosolic portion of the gastrocnemius muscle, SOD and CAT activities were significantly higher (p<0.05) in the EX group (10.3±.2.5 USOD/mg protein and 1.1±0.3 UCAT/mg protein) compared to the DEFEX group (5.8±0.8 USOD/mg protein and 0.6±0.1 UCAT/mg protein), whereas GPx activity presented no significant difference between the groups. In the mitochondrial portion, SOD and GPX activities were significantly higher (p<0.05) in the exercised animals compared to SED and MARG groups. No significant differences in MDA concentration in the gastrocnemius muscle of animals in the EX and DEFEX groups 10.07±0.01 and 0.6±0.02 μmol MDA/mg protein, respectively) were observed. CONCLUSIONS: the consumption of dietary Mg below the recommended levels reduced the antioxidant defenses of the studied muscle, although it did not increase the lipid peroxidation in the exercised animals.

ENERGY INTAKE AND APPETITE FOLLOWING EXERCISE IN GIRLS

Dodd, C., Watson, J., Hardaker, R.
Northumbria University, United Kingdom

Introduction
Recently, an elevation in hunger, fullness and desire to eat, immediately following exercise challenges at 75% peak oxygen uptake has been demonstrated in young girls (Dodd, 2007). This is in contrast to the acute 'exercise-induced-anorexia' commonly reported for adults immediately following similar exercise (King & Blundell, 1995). Enhanced appetite in the girls was not reflected by an elevation in energy intake (EI) at meals offered at least 30 min after exercise. This implies that any exercise-induced factors influencing subjective sensations of appetite in children, may be directly related to the period immediately following exercise. The present study aimed to examine the onset of food intake, EI and appetite immediately following exercise in 9-10 y girls.

Methods
Six girls (Age 10.4±0.4 years, BMI 19.6±3.5 kg/m2, 24.4±9.8% body fat) conducted an initial FLEX heart rate test to plot regression of HR vs VO2 and estimate subsequent energy expenditure (EE). This incremental cycle test was extended to peak oxygen uptake to predict HR intensities and exercise durations corresponding to 75% peak oxygen uptake and ~0.75 MJ EE. In a counterbalanced fashion, participants were then randomly assigned to a school-based treatment day, incorporating cycling at 75% peak oxygen uptake (EX), or sedentary activities (SED). A maintenance breakfast was served at 0830 and exercise commenced at 1200. An ad libitum lunch was provided in excess immediately following the exercise or control period and food was covertly weighed before and after meals. The girls were asked to eat whenever they felt hungry and onset of eating was recorded along with EI. Ratings of hunger, fullness and desire to eat were recorded using visual analogue scales immediately before, during and after exercise and then every 10 min for 60 min. EE was assessed from 0830 until the end of the hour-long lunch period. Lunch EI, EE (0830–13:55) and appetite ratings were compared using mANOVA.

Results
Energy expenditure was significantly higher (p<0.05) in EX compared to SED (2.2±0.7 MJ vs 1.8±0.7 MJ). Neither time of eating onset nor EI at lunch (4.1±1.2 MJ, EX vs 4.6±2.1 MJ, SED) were significantly different between conditions (p>0.05). For hunger, fullness and desire to eat, there was a main effect for time (p<0.001), but no interactions between time and condition (p>0.05).

Discussion/Conclusion
9-10 y girls did not increase their EI at an ad libitum lunch offered immediately following exercise. There was no impact of exercise on self-reported hunger, fullness and desire to eat during or after cycling, compared to a sedentary control period.

PEDAGOGIC EXPERIENCES IN THE INITIAL FORMATION INVOLVING SPORTING PROJECTS

Teixeira, R., Teixeira, D., Vieira, J., Vieira, L
Universidade Estadual de Maringá, Brazil

Introduction: Brazil develops countless sporting projects whose larger objective is to give conditions that kids of having opportunity their dreams of better times and be far away from the delinquency. Allied this search, it can stand out the subject that sport is directly related with a concept of health and quality of life. Specifically in the case of the State University of Maringá - UEM, several projects are developed in this extent, as the Project “Sporting Formation in the Handball” that counts with the partnerships of the General office of Sports, Leisure and Recreation of the state district of Maringá, the Handball Association of Maringá and with the patronage of Unimed/Maringá for the children’s service with age among 9 to 12 years, in state or public schools and sporting centers. Objective: this project has as objective stimulates the learning of this sport practice, besides making possible the academics of the Course of Physical education professional practices aiding their initial formation. Methodology: the methodology is divided in the organization and systemization of the contents and methodological strategies centered in global games and recreational activities under the teacher’s of the department orientation. They are also used support texts involving subjects of racism, individualism, and violence. Results: initially, in the year of 2003, 1 Center of
existsences was instituted, assisting 40 children approximately. During 2004 they were instituted more 5 Centers (150 children). In 2005 we elevated for 7 Centers (250 children) and in 2006 we arrived to 14 Centers that assist 440 children approximately.

**Perspectives:** The goal for 2008 is arrive to 20 Centers, and we are at this moment with lives 4 Centers in implantation. These new Centers will elevate the number of assisted children significantly. This project have discovered sporting talents and they plows directed goes specialized training centers and in conditions of supporting these children/athlete offering scholarship, feeding and plans of health.

**PHYSICAL EDUCATION TEACHERS, ATHLETES AND SPECTATORS’ OPINIONS ON DEVELOPMENT OF TURKISH HANDBALL: A CASE STUDY IN ESKİSEHIR**

Celiksoy, S., Celiksoy, M., Akn, E.
Anadolu University, Turkey

Handball is a popular sport which has a lot of spectators in many parts of the world. This popularity makes it an important part of physical education classes.

Although handball has been federated since 1976, it is one of the sport branches that has not been in a better position yet. Previously, handball had been in a good process but recently there have been appreciable decreases in every aspects (clubs, spectators, etc.) Some factors, such as decreasing of the number of supporters, being uninterested in handball, physical education teachers’ tendencies to other sport branches, not spreading the basic handball training, not giving news about handball in mass media sufficiently, can be seen as a handicap to develop handball.

In this research, the following question was considered. What are the individuals’ opinions about development of handball in Turkey? Hence, a survey was prepared by the specialist researchers and then a piloting was carried out on 15 individuals. In this process some items were revised and the duration of answering the items was fixed. Finally, the survey was carried on handball coaches, athletes, spectators and others (total 100) in 2006.

In analyzing process the demographic characteristics of the participants were evaluated as follow: % 50 of them were male, % 50 of them were female, % 74 of them were single, % 23 of them were secondary school students, % 77 of them were graduate students, % 55 of them were in 21-30 age group, % 47 of the individuals’ monthly incomes are 400 or under 400 dollars. According to demographic characteristics, a great many of participants are educated, more than half of them are young and single, nearly half of them have low incomes and many of them are students, teachers, and coaches.

Principal Component Factor was used in order to group, to classify and to deviate to main factors of the 24 variants. According to analysis of results, there were five factors which indicated restrictions in handball. The primary factor was mini handball which emphasized the importance of mini handball training, facilities, equipments and other factors were seen to have great effects for handball. As a result, it could be said that some factors such as mini handball training, media, institutionalization, advertisement and organization have great importance for the development of handball and several projects should be carried out urgently.

ANOVA test was used to reveal the differentiation of attitudes with regard to the factors affecting handball and demographic characteristics. The findings of the research revealed that there were significant differences between the institutionalization which was one of the factors affecting handball and profession groups. As a result, educators implied that General Directorate for Youth and Sports, province delegates, clubs and schools should consider club activities and provide sponsors’ support.

**DEVELOPMENT OF MOTIVATION IN THE CONTEXT OF SUSTAINABLE EDUCATION IN SPORT CLASSES IN BASIC SCHOOL**

Gerina, N.
Daugavpils University, Latvia

Economical, social and culturological mechanisms of a contemporary society significantly influence all spheres of person’s life and motivation as well. Significant attention needs to be paid to these mechanisms because motivation depends on these mechanisms.

In this article motivation is analyzed in basic school and in the context of education for sustainable education. The article analyzes factors with respect to their professional competence, their expectations for advancement opportunities and the ongoing development/recycling.
THE SCOPE OF THE PROFESSIONAL OCCUPATIONS IN THE OUTDOOR ACTIVITIES

Carvalhinho, L., Rodrigues, J., Serôdio, A.

Sport Sciences School of Rio Maior - Polytechnic Institute of Santarém, Portugal

This study was carried-out, in the field of outdoor activities and the objective was to study the opinion of the technicians in Orienteering, Mountain-Bike, Climbing, Mountaineering, Canoeing, Diving and Paragliding with respect to their professional occupations carried out in the various sport organizations.

In agreement with some studies (Priest & Gass, 1997; Sarmento, Rosado & Rodrigues, 2000), it was possible to identify to the departure the following occupations: Manager, Instructor, Main Technician and Auxiliary Technician.

The sample was made-up of 830 individuals (149 Managers, 75 Instructors, 194 Main Technicians and 412 Auxiliary Technicians), divided according to their professional occupation.

To obtain the data we used a questionnaire [Carvalhinho, 2006], built and validated for the effect. In dealing with the data, we used descriptive statistics as well as comparative statistics to verify the significant differences among the various groups in the sample. In this case, we used the Kruskall-Wallis and Mann-Whitney U statistical techniques.

In the most of professional occupation we verified there are significant differences among the groups. The main results were: Manager (0,002«P«0,039); Main Technicians (0,014«P«0,025) and Auxiliary Technicians (0,002«P«0,011). However, in the occupation of ‘Instructor’, there are no significant differences among the groups in the study.

In general, it is possible to find quite different realities, with very own cultures of development and of values that constitute reference for its sport technicians, particularly for those that have the power of decision and the responsibility to develop this sport sector. On the other hand, the Instructors presented more consensual opinions, what can reveal some conscience and stability in the acting of the respective occupation.

In highest, the technicians of outdoor activities agree with the existence of different professional occupations, in that these should be associated to very defined attributions that allow to know them the context of the intervention, the competences and the autonomy in the professional field.

THE E-LEARNING CHALLENGE FOR THE COACH EDUCATION: A PRELIMINARY STUDY ON HANDBALL COACH

Sequeira, P., Frazao, H., Rodrigues, J., Santos, A.

Sport Sciences School of Rio Maior, Portugal

Introduction

Coaches play an important role in introducing people to sport and in helping children, players and athletes to improve and achieve success. Coach education programmes have the purpose to equip coaches with the competences (skills and expertise) to do the job. The formal of coach education programmes traditionally included theoretical and practical sessions. Some also included supervised practice and seminars. The Portuguese Handball coach education programs take place in specific dates (vacations, long weekends) with the consequence that they are usually very concentrated and take place only in one or two moments of the season. The main goal of e-learning is to overcome barriers of learning styles. Using video, audio, active learning, simulations, and electronic advances in the teaching-learning process can overcome problems encountered by learners who do not adapt to just one learning style. E-learning also helps to overcome barriers of place and time.

Aim of the study

The aim of this study is the validation of e-learning in the coach education.

Methods

Our sample was composed by 304 handball coaches (level 2) from the 2007/2008 season and 1 teacher. The coaches participated in a e-learning module of 50 hours. The subject of the course was: handball training processes. The learning management system that we used in this study was the STABOS e-learning platform. We used the forums, the SCORM reporting and the internal portal/course statistics to analyse the individual progress. We used the method of content analysis that allows inferences about the production conditions of the interactions, based on quantitative indicators and others.

Results

The teacher posted one topic of discussion in every forum (4 topics, in total). 109 new topics were created by the coaches. The 113 topics generated 1616 post messages. All the 304 coaches interacted between them through the forum and the different topics. Coaches average time online at the platform: 10h43m36sec. As result, 79,28% of the coaches were approved in this course. Only 21,72% weren't approved.

Discussion/Conclusion

Concerning the results we identified that the e-learning promoted and improved interactions between the coaches (among themselves, as well as with the teacher). We suggest research on this topic with the increase of the number of coaches, days of education, subjects and in other sports.

THE IMPORTANCE OF SOCIAL SUPPORT FOR THE ELDERLY: A STUDY OF THE PROJECT SEM FRONTEIRAS

Marconcin, P., Vendruscolo, R.

Federal University of Paraná, Brazil

Demographic data points to a change in the population distribution. According to Garcia (2000), the twenty-first century may be considered as the century of the elderly. In this context, the physical education is understood as a fundamental field of knowledge able to pro-
vide a new way to face life in this population by the practice of physical activities, such as sports. The present study aims to describe the proposed theoretical methodology of the project Sem Fronteiras, that means No Frontiers, which is characterized by being a program of sports for the elderly that occurs in the facilities of the Federal University of Parana, and it shows clearly the importance of social support between the participants. The methodology of the study, qualitative in nature, occurred at two points: first, through the analysis of the documents containing the proposed project and annual reports for assessment of it, and a second time through interview applied to the elderly enrolled in the project. The researchers state that the project is supported theoretically on the principle of continuing education, which covers the education of adults and elderly, but is not limited to a specific period of life and aims to contribute to the cultural renewal, in order to bond personal satisfaction and social participation (Néri and Cachioni, 1999). Thus, the methodological procedures of the project do not support a program with leisure activities, which in most cases does not lead to greater reflection by the participants. So, too, away from the biomedical perspective, more widespread in physical education, and return to the reflection of how important we make, creative and meaningful, the years ahead. If the elderly are enrolled in creative activities, they are supposed to be more connected to the outside world, being more able to adapt to its changes.

There is also the idea that this project is considered a place where the elderly can enhance their network of relationships, which can lead to the well being of social support, as they have opportunity to share good and bad experiences and feelings.

DIVERSIFIED PROFESSIONALISM OF PRIMARY SCHOOL PE TEACHERS IN HONG KONG
Sum, K., Ha, A., Chan, W., Dimmock, C.
The Chinese University of Hong Kong, Hong Kong

This study set out to investigate the professional lives of primary school physical education teachers (PSPETs) in Hong Kong. It carried out through the inductive development of a theory, based on grounded theory methods, of how Hong Kong PSPETs manage their professional lives. The central objective of this study was to find out how PSPETs go through the socialisation and professionalisation process as they experience changes to their personal and professional identity in their work places and in society.

The researchers employed theoretical sampling in order that data collection be purposively directed towards informants and towards situations thought likely to provide data that promised to be relevant to and able to develop and build the emergent theory. PSPETs in Hong Kong have been defined by the researchers as professionals who specialize in teaching physical education in primary schools in Hong Kong. Through snowball sampling, the researchers identified suitable participants for study. Participants for this study were from a variety of backgrounds and were able to enrich the contexts for analysis. Eleven PSPETs were interviewed. Participants ranged in age from 25 to 59, with 6 males and 5 females. Their years of experience as PSPETs were between 2 and 30 years. The ratio of males to females varied slightly depending on the response and availability of the PSPETs: In addition, data collection ceased upon data saturation, which was when nothing new could be added to the data.

The researchers used semi-structured interviews, together with documentary sources (diaries) for conducting data collection. They were conducted over a 10-month period. The transcribed interviews were analysed using open coding, axial coding and selective coding procedures. Member checks, audit trails and triangulation were used to ensure trustworthiness.

With the ever switching work lives and interplaying identity which embedded into PSPETs’ profession and their socialization experiences, a main concern: diversified professionalism was discovered in this study with the following categories [criteria]:
1. Organizational sensitivity
2. Source of Satisfaction (from students’ achievement)
3. Critical incident and personnel
4. Organizational positioning (Marginalization of a subject, not a person)
5. Educational reforms as a significant factor of socialization
6. Preferred roles (not PE teacher)

The results revealed that PSPETs were not marginalised in terms of their multiple roles particularly in the organisational culture of Hong Kong primary school. On the contrary, PSPETs played major roles working as 1) various subjects teacher such as English, Mathematics, Chinese, Information Technology; 2) disciplinarian teacher; 3) coach; 4) administrator; and 5) manager of various sport teams as the same time which enabled them being organisational and professional socialized diversely.

PE TEACHERS’ PERCEPTION OF A GRADING SYSTEM AND THE NOTION OF ABILITY
Redelius, K.
Swedish School of Sport and Health Sciences, Sweden

More than ten years ago now the Swedish school system underwent a comprehensive reform. At the core of this reform were a) a decentralisation of decision-making and responsibilities from the state to the municipalities and the local schools, b) a shift in the steering documents from regulation by content to regulation by goals, c) a greater emphasis on learning in all subjects, and d) an emphasis on issues of health and a physically active lifestyle in the subject of Physical Education. The new grading system is goal-related (in contrast to the former, norm-related system which means that student achievement is or should be assessed in relation to the goals stated in the course syllabi). The basic idea is that there should be a close relationship between the goals the pupils are supposed to reach, the knowledge they are expected to acquire and the assessment criteria used for grading.

The overall aim of the study is to investigate how teachers both perceive and use this new grading system. Central questions are: How do they feel about grading pupils in PE? Are they familiar with the criterion-referenced grading system? What kind of grading criteria are teachers guided by when assessing pupils? In the light of the teachers’ answers, one aim is to discuss the consequences that teachers’ grading criteria may have for pupils’ notions of ability and what seems to be important knowledge in PE. The study draws on empirical data from questionnaires answered by 61 PE teachers working in secondary school. The responses to the questions have been analysed in both a quantitative and a qualitative way. The results indicate that the majority of teachers either find it very difficult or difficult to grade their pupils. They state that they are familiar with the new grading system, but the analysis of the way they say they grade their pupils indicates that they do not seem to have grasped the assumptions underlying the grading system. Achieving a pass grade in PE is dependent on participation, being active and positive and doing one’s best, although these criteria are not acceptable in a criterion-referenced system according to the National Agency of Education, since grades should always be given in accordance with the stipulated
JOINT ACTIONS PROJECT: THE EUROPEAN MOVEMENT TOWARDS INCLUSIVE PHYSICAL ACTIVITY FOR CHILDREN AND YOUNGSTERS WITH DISABILITIES

Dobreva-Faria, I., Djibova, S., Vancoppenolle, H.
Catholic University-Leuven, Belgium

An educational kit and promotional CD-ROM, called Count Me In, were created in the framework of the European project Sports and Physical Activity for Persons with a Disability Awareness, Understanding and Action. In this project, a group of representatives from 17 European countries strived towards a common goal - to endorse the full inclusion and participation of children and youngsters with a disability into sport, leisure and physical activity.

The purpose of the products Count Me In is double: to educate teachers, parents, coaches and volunteers in the field of inclusive physical activity and secondly to promote sports, leisure and physical activity for children with a disability.

The educational kit is a practical guide for all people with little knowledge on inclusion, physical activity or disability that can be used as a first-line tool in the learning process. The kit consists of a book and a DVD. The user can find the basic information on the concepts of Adapted Physical Activity (APA) and inclusion. Furthermore, the guide outlines a series of practical and versatile adaptation/inclusion strategies. The user is stimulated to actively search for creative solutions with these basic information in mind, when organising inclusive settings. As an additional motivational tool, a series of examples of good practice are illustrated in the final chapter. These examples are also illustrated in the accompanying DVD. The educational kit is mainly distributed as a life-long learning and distance learning tool. The strength of this educational kit is that it combines visual material and a handbook.

Secondly, a promotional CD-ROM was created to stimulate children with a disability to take part in physical activity. The CD-ROM consists of 8 movie compilations in which a wide range of activities is presented. In each movie, children with different levels of abilities are presented, so every child watching the CD-ROM should be able to identify with one or more children in the videos. The CD-ROM can be explored in 16 different languages.

The CD-ROM is user-friendly and can also be used in schools, sports clubs and organisations as a tool to motivate children with disabilities to participate in sports and physical activity.

Both products were disseminated in 17 European partner countries through special schools, mainstream sports organisations and adapted sports organisations; disability support systems and universities.

PRIMARY SCHOOL PUPILS’ ATTITUDES TOWARDS SPORT HEALTH

Nowoczen, J.
Josef Pilsudski University of Physical Education in Warsaw, Poland

The aim of the research was to seek answers to 3 problem questions: 1) How does health oriented education affect the attitudes of school pupils towards health? 2) Is their knowledge about health care reflected in their choices and behavior conducing to health care? 3) What are the attitudes of school pupils towards sport as means providing a chance to sustain and improve health condition? A pedagogical experiment was the method of the research. The essence of the experiment was to compare, within the time span of 2 years, schools which carried out a programme of health oriented education with traditional schools and observe their attitudes towards health and sport. A PROZET scale and computer programme STATISTICA were used in the research. Pupils from 12 elementary schools, out of which 6 were experimental schools, were studied. A total of 1652 school children aged 11-13 were subject to the investigations. Girls accounted for 58% of them and boys accounted for 42% of the total.

The results demonstrated that the majority of school pupils had a positive attitude towards sport. 47,8% defined it as enthusiastic, 36,4% as moderate, 15,3% demonstrated an indifferent attitude and 0,5% were negative towards sport. The programme of Health oriented education and sex affect statistically significantly (p<0,05) the attitudes of school pupils. A higher level of attitudes is observed by pupils who are following a health oriented education and by boys. The place of living does not affect statistically the studied groups as far as the frequency of taking up sport activities. The statistic analysis demonstrated that girls prefer mainly esthetic forms of sports (p<0,01), whereas boys prefer sport games.

When analyzing the values of the calculated indexes for each of the components of health oriented attitudes, no statistically significant changes in them were observed. This means that in experimental schools pedagogical endeavors in the area of health oriented education do not as strong as to affect pupils’ attitudes towards health when comparing to pupils from traditional schools.

1. Attitudes of pupils towards sport undergo positive changes in the course of health oriented education.
2. Attitudes of pupils towards health do not undergo favorable changes as a result of school education.

In some communities even a fall in the index values of those attitudes, along with the extension of time spent in school, was observed. The knowledge possessed by school pupils regarding health and factors determining its condition, did not translate directly into the development of school pupils’ positive attitudes towards sport.

THE IMPROVEMENT OF THE STRATEGIES OF SELECTION AND ORIENTATION IN AEROBICS

Dobrescu, T., Raveica, G., Márza-Dnil, D.
The University of Bacu, Romania

The aerobic gymnastics registers spectaculars evolutions reaching a high development level, having exercises that impresses by the difficulty of the elements, of the combinations and the virtuosity. This presumes in the same time a continuous activity for discovering new elements, new preparation and appreciation systems, a diversification of the approached methodology. Studying the present degree of the research development it finds out that the aerobic gymnastics, as a young branch in performance sport (1995), with some few bibliographical specialty resources, has no specific model of selection and orientation elaborated on scientific bases.

Research methods that were used are: the documentation, the observation, the experiment, the measurement and testing, the shaping method, the mathematic-statistic method and the graphic one.

PP-PE03 Physical Education 3

13TH ANNUAL CONGRESS OF THE EUROPEAN COLLEGE OF SPORT SCIENCE
The purpose of this research is to determine experimentally the model of selection for the performance aerobic gymnastics, which serves as a working instrument in this continuous process, to orientate the talented elements with a basic preparation from the artistic, guaranteed the development of the sports-life of those which, thanks to some psychometrical or medical factors, haven’t registered yet any progresses in the way to the great performance. This experiment identifies the essential elements the model of selection for the sportsmen with previous experience, being made up by important indicators in the selection of talents from the specific clubs from the country and their orientation, in the way of capitalization of the performance potential, to the aerobics.

Results and conclusions The elaboration of the selection model it’s an instrument with real diagnosis functions and also an instrument of prognosis of the sportsmen availabilities resulted from the artistic gymnastics for an fast evolution to the high performance in the aerobic gymnastics. We consider that the results obtained in this experiment constitute certainties to determine on the basic information’s, on the structure of the model of selection and orientation from the aerobic gymnastics, identified by the anthropometric, functional, psychological and performing parameters of the motor and psychomotor skill decade model at the old juniors.

IS IT ALWAYS THE RIGHT PERSON THAT WINS? RELIABILITY AND VALIDITY IN JUDGING SPORTS

Johansson, A.
Umeå university, Sweden

Is it always the right person that wins? In competitive sports the difference between winning and loosing can be very marginal but still the result will have a big impact. To finish second, even if it is an Olympic Game, can be felt like a failure for an athlete or team. Rules- and judging systems are defining who will be the winner and how well those measurements and judgements are defined and used has a big importance for the results and outcomes of games and competitions. In the light of this the quality of the measurements and the judgements in sports are an extremely important issue both for the individuals involved but also for the credibility of the sport. In order for the right person or team to be able to win it is important the measurements and judgements defining the results are of high quality. In my licentiate dissertation, consisting of two separate reports and one summary report, the freestyle discipline, acroski (Johansson, 1998) and the gymnastic discipline, rhythmic gymnastics, RG, (Johansson, 2001) where studied with a focus on the rules and judgements in the sports. The reliability and validity of the rule and judging systems were analysed together with changes in the rule and judging systems. Reliability as the judges ability to interpret the rules and judge in a consistent way, and validity of the judgements in the sense that the judges and the rules, where in accordance with the idea of the sport. Information was gathered from rulebooks, judging manuals, meeting protocols, historical documents and from interviews with two coaches, two judges and four athletes from each of the two sports. The studies showed both sports had gone through major changes in the rule and judging systems. Many of the changes were focused on increasing the reliability of the judgements and a problem could be seen when that the validity deficient. Reliability and validity interact with each other but validity is the most important of these factors. Finding the balance between making the judgements as objective as possible, without loosing the idea of the sport, together with the quick evolution of the sports, seemed to be the main challenges with the rule and judging systems of acroski and RG. This study clearly points at the importance of constant work with both reliability and validity questions in judgements and measurements if the results are going to be fair and the right person going to be able to win.

INNOVATIVE RESPONSE TO CURRENT EUROPEAN CHALLENGES - JOINT MASTER PROGRAMME IN ADAPTED PHYSICAL ACTIVITY FOR ELDERLY

Djibova, S., Dobreva-Fario, I., Van Coppennelle, H.
National Sports Academy, Bulgaria

Numerous research projects have demonstrated that the health benefits of planned physical activities (PA) for elderly are indisputable. The number of ageing people and ageing people with a disability in Europe is rapidly increasing. Therefore the topic of ageing has been recognised, more than ever, as a top theme on the European agenda. The Eurostat data estimate that by the end of 2040 the severely impaired adults will be 6.5% of the total population in Europe, or 24.5 million people. Regular physical exercise is the best antidote to many of the effects of aging. As older adults are the fastest growing age group, attention needs to be given to them as a special population with specific needs in the area of exercise and sport. Qualified professionals in the area of adapted physical activity (APA) for the elderly have to be prepared now, so they can meet the new demands of the future.

The development of joint degrees was set as an aim for the European Higher Education Area in the Prague Declaration in May 2001. In the Berlin Communiqué of 19 September 2001, the ministers responsible for higher education in the countries participating in the Bologna Process decided ‘to actively support the development and adequate quality assurance of integrated curricula leading to joint degrees’. In response to these two perspectives, a multidisciplinary team from THENAPA II developed a European Joint Master programme APA for elderly. It aims achieving a common educational model in the domain of APA for elderly and at provoking educational changes and improvements in the area of APA, sport and exercise for the elderly. The methodology included a research aiming to identify the extend to which the topic of APA and sport for elderly is included in the academic curricula. The results show that only two universities provide a separate module that includes ageing, disability and PA. Ageing and PA were covered together in 45% of the European countries, and disability and physical activity in 39 %. In most countries ageing, disability and physical activity are presented as separate subjects. Qualitative approach was applied for defining the best practices in order to combine the existing knowledge in one master programme. The curriculum is developed following the guidelines of the International Society for Ageing and Physical Activity and consists of 14 modules, 11 theoretical, 2 practically oriented and one module related to the master thesis. It offers a state-of-the-art on research and teaching methodology in APA for elderly with a disability and the elderly persons in general, as well as comprehensive training and adequate knowledge in the many aspects of APA. The social, pedagogical and technical aspects of physical activity, disability and ageing are the theoretical foundation. This program is a response to the EU efforts of raising the qualification profile of physical activity service providers but more efforts in the educational field are necessary.
SURFING: DIDACTIC AND METHODOLOGICAL CONCEPTIONS

Correia, M., Rosado, A., Mesquita, I.
Human Movement Faculty, Technical University of Lisbon; Sport Faculty, Oporto University, Portugal

The aim of this study was to determine specific features about the expert knowledge concerning coaches’ conceptions and didactic methodologies, as well as, the way they proceed when organizing curricular contents on surfing. The intent of the present investigation was to ask expert surfing coaches about the design of learning experiences and movement tasks related to specific content on surfing. According to Grossman (1990) and Rink’s (1993) model, this study was based in a qualitative methodology. A structured interview was used with eleven surfing expert coaches, with open-ended questions about content development on surfing. Content development on surfing was revealed, taking into consideration the progression (extension), depth and application dimensions of Rink’s Model.

The source of coaches’ specialized knowledge comes from the experience in competition and coaching, as well as, their academic education, judging courses and self-study. The practical experience as athletes (experience in competition) was the main source of the specialized knowledge named.

The coaches’ conception about the specific knowledge of an expert surfing coach is convergent, it should embrace knowledge, with special incidence in particular disciplines, such as, Pedagogy, Training Methodology, Psychology and Oceanography. The specific knowledge of surfing is also appointed as fundamental. This specific knowledge comes from the competitor’s and coach’s experience, conducting to a clear awareness of space and material arrangements to establish proper learning experiences.

The skills on each level of practice were established. Coaches distinguished 3 levels of practice: Introductory, Development and Competition level. There was no total agreement among coaches about the learning sequence of the skills, however they made a clear distinction between basic skills and advanced skills.

Organizational arrangements for tasks were described, with special emphasis on space and equipment arrangement. The choice of the location (beach) and the type of board, together with the specific conditions (wind and waves), decide the quality of the learning experience. The coaches integrate opportunities for their athletes to apply their skills (application) in meetings with other surf schools and competition simulations. This investigation, used to examine coaches’ expertise, lead to the characterization of the didactic-methodology conceptions on surfing.

TEACHING INVASION GAMES IN PHYSICAL EDUCATION LESSONS: THE RELATIONSHIP BETWEEN TEACHER BELIEFS, AND TEACHING BEHAVIOUR

Tallir, I., Valcke, M., Musch, E., Lenoir, M.
Ghent University, Belgium

In the past educational research studies could be catalogued as process-product studies (Brophy & Good, 1986). More recently the study of teacher behaviour has evolved toward a focus on teacher thinking and as a result teachers’ beliefs have become a central concept in research about teaching and teacher behaviour (Clark & Peterson, 1986). The present study was conducted to explore the nature of teaching and learning behaviour in invasion game lessons and the relationship with teachers’ beliefs and self-perceived behaviour. A sample of 241 physical education teachers (123 female, working in primary (n=78) and secondary education (n=163) in Flanders, the Dutch speaking region of Belgium participated in this study. Teaching experience ranged from 0 to 37 years within this group (Mean = 13.88, SD=10.42) and 72 % of the PE teachers attended in-service trainings about invasion games on a regular basis (on average 1.4 in-service trainings per school year). The participants completed a general educational beliefs scale, and a newly designed physical education related beliefs scale. A sub-sample (N=82) was involved in a semi-structured interview to obtain self-descriptions of their instructional approach during invasion game lessons. Further, the teaching and learning behaviour was observed during an invasion game lesson of these teachers. Descriptive results of the beliefs’ scales indicated that higher levels of constructivist beliefs are observed. The real time observations of the PE lessons revealed that the average distributions of percentages of time spent on either traditional cognitivist or constructivist teaching and learning behaviour were comparable. Further, a strong correlation was found between the general and the physical education related belief scale. The interviews revealed that most teachers described their teaching behaviour as rather traditional cognitivist oriented compared to the mixed cognitivist-constructivist orientation. Constructivist teaching approaches were according to the teachers adopted to a much lesser extent. Stepwise linear regressions revealed that constructivist beliefs predicted constructivist teaching and learning behaviour, while traditional physical education beliefs predicted cognitivist teaching and learning behaviour. In general, the results of this study point at the complex nature of the relationship between teacher beliefs and their teaching behaviour.

POSTURAL CONTROL AND BALANCE ASSESSMENT IN CHILDREN WITH HEARING DEFICIENCY

Barros, J., Monteiro, A., Monteiro, B.
Universidade de Brasilia, Brazil

The balance is the process of maintenance the center of pressure (COP), projection of the gravity center in the soil, inside the base of support area of the body. This study describes the postural control in children with hearing deficiency and compares the results with the control group, using the displacement parameters of the COP. It is a transverse analytical study where forty children were distributed equally in two groups denominated study group (GE) with medium age of 8,88 ± 1,22 years, and control group (GC) with medium age 9,34 ±1,00 years old. All the individuals were submitted to the stabilometry and they accomplished four different static tests, with two feet support on the force platform, varying the base of support and the vision, for 25 seconds each. The parameters root mean square, mean velocity, sway area and mean frequency of COP were analyzed. For data treatment was used the inference statistics ANOVA (variance analysis) and the no-parametric test Kruskal-Wallis. The results showed that children with hearing loss presented more instability in the
orthostatic posture when compared to the control group in relation to the stabilometric parameters associated to the postural control efficiency. Like this, was observed that the parameter sway area of the COP, was the most sensitive to detect significant differences among children with hearing deficiency and the normal ones. Therefore, these results supported the idea that the children with hearing loss of this sample presented a deficit of sensorial organization that justifies future interventions.

PHYSICAL ACTIVITY, MOTOR COMPETENCE AND HEALTH STATUS OF CHILDREN IN DEPENDENCE OF SOCIAL STATUS
Holzweg, M., Ketelhut, K.
Humboldt University Berlin, Germany

Introduction
In the last years the health status of children in Germany declined and the number of psychologically conspicuousness children also increased. According to the KIGGS study children from socially deprived areas are hit from this development the most (compare Opper et. al, 2007). Holzweg (2006) and several other studies allocate a decline of the level of activity and the motor competence of young children in Germany (compare Woll, 2007 for an overview). In this study physical activity, motor competence and health status of children with different social backgrounds (privileged vs. deprived) are assessed.

Method
A sample of 172 3-5 year old children was included in this study. While 80 children lived in a deprived area 92 children lived in an affluent area. The children were testes with the KMS 3-6 and the MOT 4-6. Height, weight and Body Mass Index (BMI) were also assessed. In a questionnaire for the parents’ social status, activity level, television consumption, participation in sport clubs and sport activity of the family were assessed. The social status was collected by profession and income of both parents and according to the social structure atlas for Berlin. The analysis of the assessed data was carried out with SPSS 15 (ANOVAs).

Results
Regarding coordination (SHH: F(3,9)=16.51, p<.05; eta²=.085), TBT: F(3,9)=14.28, p<.05; eta²=.075) and flexibility (F(3,9)=20.14, p<.05; eta²=.102) significant differences between the two groups could be shown. With the data of the questionnaire significant differences between the two groups relating to television consumption (F(3,9)=44.87; p<.05; eta²=.238), participation in sport clubs (F(3,9)=22.6, p<.05; eta²=.132), outdoor activities (F(3,9)=6.37, p<.05; eta²=.041), as well as sport activity of the family (F(3,9)=17.35; p<.05; eta²=.104) could be identified.

Discussion / Conclusions
The study showed that comparable to obesity and health status also motor competence is decisively influenced by the social status of the children. The results of this study additionally indicated differences of the level of activity in dependence of the social background. Therefore it seems to be necessary to offer affirmative intervention programmes especially in Kindergartens and Primary Schools in socially deprived areas.

MEANS AND PROCEDURES OF THE PEDAGOGY IN SPORT’S TAINING - AN EXAMPLE IN JUDO
Lopes, H., Fernando, A., Vicente, A.
University of Madeira and University of Beira Interior, Portugal

Centering the pedagogical procedure on the student / sportsman, favouring mainly learning, implies adjustments to the methodology used as well as the adoption of knowledge to the utilization form. The teacher / trainer has to help solve problems in this personalized training and therefore needs to know the variables and if possible, the indicators which allow the control of the evolution.

Our study falls upon the relation between procedure and means in the intervention using Judo grips as an example. The grip is a means: 1) of communication receiving and transmitting signals; 2) of attack applies force; 3) of defense limiting the opponent’s possibilities. There is interaction between Judo players, a dialogue which occurs in the grip through the force which is applied. A dialogue which (like any other type of dialogue) may be learnt by a) memorizing a pair of expression or with another strategy, b) learning to interpret the signals, consequently understanding the opponent’s intentions. In a) the widening of knowledge is through the rise in the number of controlled expressions. In b) through the capacity of generalizing knowledge (understanding the function) so as to adapt to new situations. In a) it is important to memorize many forms of doing, selecting the most favourable and repeating them to become stronger and quicker. It is automizing the gesture. The way it is done may be transmitted by the trainer and the sportsman will be the receptor / adaptor. No matter how wide the acting selection is, the number of answers will always be limited to some case.

In b) however, it will adapt the answer to the specified problem at hand. The training consists in optimizing the attack and not only its form of execution. How?

Just like x+y=z allows us to define z in the functions of the premises x and y, whatever the value of x or y, if the premises are controlled. In a Judo combat for example, it is possible to make various combinations but also verify which is the most favourable in relation to the situation. Instead of memorizing solutions, strategies are set up.

In relation to the grip which is used as an example, it is important to define the communication, the attacks and the defense which is desired and achieved. For this methodology to be possible the description of the doing is necessary to understand how it works, that is, having adequate knowledge of the acting form.

Our presentation will demonstrate how the training of a judo grip may be done in situations a) and b), and will analyze the advantages of each case.

It is evident that from a pedagogical point of view, we have two different procedures and results. In pedagogical terms the option is clear.
DANCE IN PHYSICAL EDUCATION AND TEACHER NEEDS
Oliveira, M., Januário, C.
Military College of Belo Horizonte, Brazil

The study has been framed under the perception of a small-minded on teaching Dance in the schools. Knowing that Dance is not an exclusive content of Physical Education (PE) cultural area, that was inserted and systematized in Brazilian curriculum and schools and present in PE teachers initial training, we consider meaningful: a) identify what are the needs of teachers to deal with this content; b) identify continued education that teachers have searched at the last three years. The sample is composed by 38 PE teachers of Belo Horizonte municipal net of education. The study is descriptive and exploratory, and data collection had two phases: a) we used a questionnaire about perceived needs and continued education searched; b) we used an interview to six teachers. Data from the questionnaires were submitted to statistical analysis and interviews explored by content analysis, enabling the identification of needs and recognized the main issues to be envisaged on the attempt to improve teaching Dance content into PE. From questionnaires was possible to extract that 95% of teachers had the content of Dance or similar in their initial training. Continued education is restricted to small extend courses and mostly on general educational area; only 7.9% of teachers sought some continued education in dance area. All training areas were considered necessary or very necessary for more than 60% of teachers. Content Knowledge, Development and Diversity, Management and Motivation, Communication, Planning and Instruction, Student Evaluation, Reflection, Technology, and Collaborative Work, with emphasis for Development and Diversity. From 42 functions or teaching skills presented in the questionnaire, only one function (F4) was considered as non important or less important by more than 50% of teachers. This function relates to know and to apply physiologic, biomechanics, anatomical and psychological contents for teach dance in schools, and it’s more a skill linked under ‘sportive orientations’. Data from the interviews were organized by three themes: 1 - Dance orientations, 2 - Dance in the context of initial training, 3 - Dance in the school context; and 4 - From education to practice. One of the conclusions that arise from crossing all data is that teacher needs are directly related to exposed PE ‘sportive orientations’, experienced by them at graduation. Another is that the initial training is more focused on learning to dance than how to teach this content in PE lessons.

TEACHERS’ VIEWS ABOUT SPORT EDUCATION WITHIN PHYSICAL EDUCATION PROGRAMS IN PUBLIC SCHOOLS OF ALAGOAS-BRAZIL
Costa, M., Graça, A., Albuquerque, A., Moreira Jr., R.
Universidade do Porto, Portugal

This study analyzes the factors that guide the pedagogical practice of physical education teacher related to sports education in public school. Twelve physical education teachers from three basic public schools of Maceió, State of Alagoas, Brazil volunteered to participate in a semi-structured open-ended interview focused on the factors that favour and make difficult the development of sports education in the PE programs. Data resulting from the verbatim transcriptions of interviews were content analyzed based on descriptive, data-generated categories (Sousa, 2005). In teachers’ views sport constitutes the primary activity of physical education curriculum. Teachers acknowledge that indoor soccer is the students’ favourite activity. For the majority of the teachers, imparting information about the general risks and benefits of sport practice were a key element of their instruction. As such, they value theoretical lessons as a complement to practical activities. Teachers state that teachers and methods of sport instruction should promote cooperation and enduring commitment to sport practice. The good acceptance of sports education by teachers and pupils makes easier the attainment of the educational goals of the program.

PHYSICAL ACTIVITY AND MOTOR COMPETENCE OF CHILDREN IN DEPENDENCE OF SOCIAL STATUS
Holzweg, M., Ketelhut, K.
Humboldt University of Berlin, Germany

Introduction
In the last years the health status of children in Germany declined and the number of psychologically conscious children also increased. According to the KIGGS study children from socially deprived areas are hit from this development the most (compare Oppen et al, 2007). Holzweg (2006) and several other studies allocate a decline of the level of activity and the motor competence of young children in Germany (compare Woll, 2007 for an overview). In this paper we discuss factors that may influence the physical activity motor competence of children from different social backgrounds (privileged vs. deprived) are assessed.

Method
A sample of 172 3-5 year old children was included in this study. While 80 children lived in a deprived area 92 children lived in an affluent area. The children were tested with the KMS 3-6 and the MOT 4-6. Height, weight and Body Mass Index (BMI) were also assessed. In a questionnaire the children's social status, activity level, television consumption, participation in sport clubs and sport activity of the family were assessed. The social status was collected by profession and income of both parents and according to the social structure atlas for Berlin. The analysis of the assessed data was carried out with SPSS 15 (ANOVA).

Results
Regarding coordination (SHH: F(3,9)=16.51, p<.05; eta²=0.85), TBT: F(3,9)=14.28, p<.05, eta²=0.75 and flexibility (F(3,9)=20.94, p<.05, eta²=0.82) and flexibility (F(3,9)=20.94, p<.05, eta²=0.50) significant differences between the two groups could be shown. With the data of the questionnaire significant differences between the two groups relating to television consumption (F(3,9)=44.87, p<.05, eta²=0.88), participation in sport clubs (F(3,9)=22.6, p<.05, eta²=0.92), outdoor activities (F(3,9)=6.37, p<.05, eta²=0.41), as well as sport activity of the family (F(3,9)=17.35, p<.05, eta²=0.94) could be identified.

Discussion / Conclusions
The study showed that comparable to obesity and health status also motor competence is decisively influenced by the social status of the children. The results of this study additionally indicated differences of the level of activity in dependence of the social background. There-
fore it seems to be necessary to offer affirmative intervention programmes especially in Kindergartens and Primary Schools in socially deprived areas.

THE PROFILE OF OUT-OF-SCHOOL PHYSICAL ACTIVITIES AMONG PRESCHOOL CHILDREN
Vandervorst, F., Cools, W., De Martelaer, K., Bertels, J., Vandaele, B.
Vrije Universiteit Brussel (VUB), Belgium

Introduction: Several studies (Cardon & De Bourdeaudhuij, 2007, Biddle et al, 2004) reveal that the majority of the population is not enough physical active. This inactive lifestyle can increase risk factors on several disorders, such as cardio-respiratory diseases, cancer, obesity and diabetes. Moreover, research results (Department of Health, 2004) show us that for example children who are highly engaged in physical activities, have more developmental potential of physical, psychological, social and health-related advantages. In view of national economic and social prosperity on the long-term, it is needed to set up physical interventions to increase the physical activity of those children. Recent studies suggest (Loucaides et al, 2003, Michaud-Tomson et al, 2003, Vincent & Pangrazi, 2002) that focusing on the out-of-school-environment to increase their own physical activity level, is effective.

Objectives: This study aims to look at the profile of out-of-school physical activities of preschool children between 4 and 6 years old.

Methods: Two rural and two urban preschools participated in the study. The study was conducted in Flanders, the Northern part of Belgium. 81 (53,3%) out of 152 parents provided informed consent for participation in the study. 32 preschool children in rural area preschools (16 boys and 16 girls) and 48 preschool children in urban area preschools (23 boys and 25 girls) participated in the study. Data is collected in autumn, winter and spring. Each period consists of four full days of follow up: two schooldays and two weekend days. Registering starts at waking up, step counts are recorded at the beginning and end of each school day and at bedtime. The Yamax Digiwalker pedometer type SW-200 was used to register step counts. Data are analyzed using SPSS for Windows.

Results and conclusions: Preliminary results on the first test period (autumn 2007) show that preschool children have comparable average step counts during week- (11 301 +/- 4016) and weekend days (10 563 +/- 3167). On weekdays average out-of-school physical activity step counts are 6312 +/- 2572. These results show that more than half of the physical activity among preschool children happens out of school. Recommended daily step counts of 12000 for girls and 15000 for boys (Tudor-Locke et al, 2004) are not met by most of the children.

INTRAMUSCULAR METABOLISM DURING LOW-INTENSITY RESISTANCE EXERCISE WITH BLOOD FLOW RESTRICTION
Hokkaido University, Hokkaido University, Japan

Background: Muscle hypertrophy and strength gain can be achieved by high-intensity resistance training usually with greater load than 65% of one repetition maximum (IRM) (1). However, unconventional studies have reported that low-intensity resistance training with blood flow restriction could lead to marked increases in muscle size and strength, and result in adaptations equal to those of high-intensity resistance training (2,3). The researchers suggested that the supplementation of low-intensity training with blood flow restriction might have provided the intense stress in the skeletal muscle, but the exact scenarios were not clarified. In the present study, we investigated the intramuscular metabolism during a single bout of low-intensity resistance training with blood flow restriction and compared it with that of high- and low-intensity resistance exercise without blood flow restriction by 31P-magnetic resonance spectroscopy (31P-MRS).

Methods and Results: Twenty-six healthy subjects (men/women: 13/13, age: 22 ± 4 yr) participated in this study. Subjects performed dynamic plantar flexion exercise (30 times/min) for 2 min. Experimental protocols were as follows: low-intensity exercise condition (L) using the load of 20% of one-repetition maximal (IRM), L with blood flow restriction (LR), and high-intensity exercise using 65% of IRM (H). Intramuscular phosphocreatine (PCr), diaphragm inorganic phosphate (H2PO4) and pH during rest and exercise were obtained by 31P-MRS. The depletion of PCr, increase of H2PO4 and decrease of pH during LR were significantly greater than those in L (p<0.001); however those in LR were significantly lower than those in H (p<0.001). The recruitment of fast-twitch fiber evaluated by inorganic phosphate (Pi) splitting was only 31% of the subjects in LR, compared to 70% in H. No significant gender difference was found.

Conclusions: These results suggest that the metabolic stress in skeletal muscle during low-intensity resistance training was significantly increased by applying blood flow restriction, but did not generally reach that during high-intensity resistance training. This new method of resistance training needs to be further examined for optimization of the protocol.

RESPONSES TO OVER-THE-COUNTER ANALGESIC CONSUMPTION ON TREADMILL RUNNING: A PILOT STUDY
Muendel, T., Bryant, M., Walters, M., Edge, J., Morton, R.
Massey University, New Zealand

Analgesics are commonly consumed by athletes to prevent or better tolerate pain associated with training and/or competition (Wagner et al. 1989), particularly runners due to the large eccentric component involved. Perceived exertion at lactate threshold appears to be lower during track-running (Garcin et al. 2005) as does muscle soreness and decline in muscle function following eccentric exercise (Hasson et al. 1993) following consumption of analgesics.

The aim of the present study was to compare consumption of two commonly available analgesics with a placebo prior to treadmill running in order to identify any possible physiological or perceptual effects.

Eight trained male runners [mean values ± SD, Age = 28 ± 8 yrs; VO2peak = 60 ± 7 ml/kg-1/min-1] completed 5-minute stages on a treadmill corresponding to 30, 60 and 80% velocity at VO2peak. Measures of heart rate, ventilation, lactate and perceived exertion were recorded during the final minute of each stage. On the day of their trial, subjects consumed Paracetamol (PAR), Ibuprofen (IBU) or placebo (PLA, calcium carbonate) equal to the manufacturer’s recommended limit at 4-hourly intervals prior to treadmill running. Trials took place at 18:00h, were randomized, administered in a double-blind fashion and separated by at least 7 days for wash-out.

Heart rate, ventilation, O2 uptake, lactate concentration and perceived exertion increased with an increased running velocity (all P < 0.05), however there were no effects of treatment on any of the variables measured.

We conclude that consumption of analgesics per se has no effect on physiological or perceptual responses to treadmill running at or below the anaerobic threshold.

EFFECT OF HYPOXIA ON THE INDICATORS OF COMPUTERIZED ELECTRIC - PUNCTURE DIAGNOSTICS
Sukhov, S.
National Research and Practical Centre of Physical Culture, Kazakhstan

Introduction
At examining athletes in the conditions of mountain elevations one should take in account the fact that the findings may differ from the standards used on flat country. Goal of the study was to assess the effect of hypoxia on the indicators of computerized electric-puncture diagnostics.

Methods
To register electric - physiological characteristics of biologically active points (BAPs), there was used the Electric-Puncture Diagnostic System (EDS) developed as a set of hard- and software. EDS allows measuring in several algorithms. The study findings were expressed in conventional units (c.u). There were taken measures at 40 control (c) BAPs of all arm and leg meridians on both sides of the body. Along with measuring individual BAPs, there were determined the indicators proposed by us: sum of all BAPs, sum of arm meridians cBAPs, sum of leg meridians cBAPs, sum of heart and lung meridians’ cBAPs, sum of cBAPs of meridians of nervous and endocrine systems, and the ”upper/lower” ratio which reflects the balance between the upper and lower parts of the body. Ten mountain - climbers (of age 19.5±0.2 body mass 69.5±2.5 kg, height 176.3±1.7cm, VC 5.0±0.2 l) were examined twice, with one day interval. During the first examination the athletes breathed atmospheric air, while in the second one, there was used gas mixture with 11.2% of oxygen that corresponds to the altitude of 5,000 m. Examination was performed in the rest and after a maximum aerobic load.

Results
It was established that at breathing of ambient air the physical load resulted in a slight growth of the sum of cBAPs of all meridians, sum of cBAPs of arm meridians, and led to significant increase of the sum of cBAPs of meridians of heart and lungs (356±5 and 377±4, respectively, P<0.05) and the sum of cBAPs of nervous and endocrine systems (355±5 and 382±5, respectively, P<0.05). There was mentioned significant growth of the ”upper/lower” ratio in comparison with the resting state (0.93±0.01 and 0.96±0.009, respectively, P<0.05) that evidenced to the improvement of balance between arm and leg meridians, and is considered as a favorable factor. At breathing the hypoxic mixture, there was noted just a slight increase of the sum of cBAPs of heart and lung and the ”upper/lower” ratio. All the rest indicators did not change. Thus, hypoxia in the physical load causes unidirectional change of all indicators of electric-puncture diagnostics towards their reduction. Such reaction demonstrates its substantial effect on the results of the given type of diagnostics.

Conclusion
At using computerized electric-puncture diagnostics in the conditions of decreased partial pressure of oxygen, there is no clear reaction of electric-puncture diagnostic indicators to the physical load, the fact which should be taken into consideration at interpreting the data collected in such conditions.

CHANGE OF AUTOGENIC INHIBITION AT LONG ISOMETRIC CONTRACTION
Gorodnichiev, R., Smirnova, L.
Velikie Luki State Academy of Physical Education and Sport, Russia

At studying of physiological mechanisms of regulation of person’s voluntary movements the principles attention is given to processes of fatigue of those or others neuronal networks of the central nervous system. Only few works are directed on revealing of participation of different kinds of inhibition on management of motor activity (T. Robertson, D.M. Koceja, 2007). In this connection the purpose of our research was to study the role of autogenic inhibition of a spinal - motoneurons in regulation of isometric contraction of different size.
18 long-distance runners aged 19 to 22 years took part in the research. The subjects carried out the isometric muscular contraction (plantar foot bending) size in 25, 50, 75 and 100 % of maximum voluntary load (IV) within 30 seconds (except for 100 % of load) in sitting position in dynamographic system Biodex (Biodex Medical System, USA). In a special series of researches they kept a static load in 75 % MVC before voluntary refusal. The expressiveness of autogenic inhibition of a spinal - motoneurons was estimated indirectly on duration of the silent period in m.gastrocnemius medialis and m. tibialis anterior, caused by electrostimulus to the field of a popliteal fossa (R. Person, 1985). The EMG investigated muscles was registered by superficial bipolar electrodes with the help of electromyograph Neuro-MEP-8® (Neurosoft, Russia, 2006).

It is revealed, that duration of the silent period of m.gastrocnemius medialis decreases with 79.9±6.5 ms (25 % of MVC) to 11.3±3.4 ms (100 % of MVC), with the increase of force of isometric contraction and the amplitude of the H - reflex has increased from 1.3 to 4.4 mV correspondingly. There were no reliable changes of duration of the silent period during 30 seconds of keeping load, i.e. the expressiveness of autogenic inhibition practically remained invariable at this period.

It is revealed, that duration of the silent period increased a little more in m. tibialis anterior. These changes were accompanied by decreasing of amplitude of H-reflex. Thus, autogenic inhibition participates in regulation of isometric muscular contraction. The expressiveness of autogenic inhibition of a spinal - motoneurons at the person increases at fatigue development.

STUDYING OF MOTOR-EVOKED POTENTIALS PARAMETERS OF SKELETAL MUSCLES DURING ISOMETRIC CONTRACTIONS

Petrov, D.
Veikliye Luki State Academy of Physical Education and Sports, Russia

Motor-evoked potentials (MEP) parameters of skeletal muscles under transcranial magnetic stimulation (TMS) characterize changes in functioning of control structures of the nervous system during muscular contractions and allow to study adaptive cortico-spinal mechanisms at sustained isometric efforts (Taylor et al, 1996, 2007; Gandevia, 2001; Enoka).

The purpose of the present research was to study motor-evoked potentials parameters and the EMG silent period of skeletal muscles under transcranial magnetic stimulation (TMS) in the process of isometric muscle contraction (IMC), and revealing of differences of MEP parameters in athletes adapted to work of a different specialization.

7 ski-racers and 7 sprinters took part in researches. All the subjects were informed about conditions of the research and gave a written consent to participation, and it conformed to the Helsinki Declaration.

The subjects performed 10 isometric contractions (plantar dorsiflexion), making 80 % of maximal voluntary contraction (MVC) to task failure. The interval of rest made 1 minute between contractions. Contralateral MEP of m. gastrocnemius med., m. soleus and m. tibialis anterior were registered.

It was established, that during 10-fold performance of isometric effort excitability of cortical neurons in the investigated groups of athletes increased. So, MEP threshold of m. soleus in rest made 60 % of the magnetic stimulator output, after the 1st attempt - 56 % (p<0.05), and after the 10th - 54 % (p<0.05) in the ski-racers.

It was revealed that the MEP amplitude of the skeletal muscles is higher at the end of contraction in comparison with that at the beginning and it is significantly higher than that at rest. The MEP amplitude of m. gastrocnemius med. in the group of ski-racers in 10th attempt at the beginning of contraction made 3.9, in the end - 4.6, which is by 279.3 % (p<0.000) and 348.3 % (p<0.000) higher than that at rest.

It was determined, that the duration of the EMG silent period at the end of a single isometric effort was longer, than that at the beginning of performance. Furthermore, the researched parameter decreased during 10-fold sustained contractions. So, the EMG silent period of m. soleus in the group of ski-racers in 1st attempt made 177.7±7.1 ms at the beginning of effort, it was 198.5±5.5 ms at the end, in 10th - 165.5±5.1 ms (p<0.05) and 180.4±5.3 ms (p<0.05), correspondingly.

The received results can possibly be explained by a change of cortical neurons' properties and their increased influence on the spinal structures, that provide more powerful current of efferent impulses to the skeletal muscles, and also by a modification of intracortical inhibition processes.

BLOOD PRESSURE RESPONSES AFTER REPEATED SPRINT CYCLING: DIFFERENCES BETWEEN BOYS AND MEN

Bogdanis, G., Papaspyrou, A., Theoς, A., Maridaki, M.
National & Kapodistrian University of Athens, Greece

Repeated high intensity exercise, in the form of five 30 s bouts results in an increase in systolic blood pressure (DBP) during recovery in men (1). However, little is known about the possible differences in hemodynamic changes after repeated sprint exercise between adults and children. The purpose of this study was to compare the blood pressure responses after ten maximal cycling sprints between boys and men. Twelve preadolescent boys (age: 11.8±0.2 y, height: 152±2 cm, body mass: 44±2 kg) and nine men (age: 21.7±0.8 y, height: 175±2 cm, body mass: 74±2 kg) performed ten 6s sprints separated by 24s of passive recovery on a modified friction-loaded cycle ergometer, against a load corresponding to 50% of the optimal resistance as determined by a force-velocity test. SBP and DBP were measured before and for 12 minutes after the test (3, 4, 6, 9.5, 12 min) while the participants remained seated. Differences between the two groups were analyzed using two-way ANOVA with repeated measures on one factor. Results are presented as mean ± SE. Post warm-up SBP was higher in men compared to boys (135±4 mmHg vs 123±3 mmHg, p<0.05) and peaked on the 3rd min of recovery, with the increase being greater in men than in boys (45 vs 16 mmHg, reaching 181±8 and 139±5 mmHg, respectively, P<0.05). SBP in boys returned to pre-exercise levels on the 4th min and fell below that on the 12th min of recovery (112±2 mmHg, p<0.05). However SBP in men was elevated until 9.5 min into recovery, when SBP returned to the resting value and remained unchanged thereafter. The pattern of DBP changes was similar in boys and men. DBP was higher than the resting value on the 3rd min of recovery, while a drop below the resting value was observed after the 6th min (men: 56±2, boys 57±2 mmHg) and was maintained until the end of the recovery period. It is concluded that repeated short sprints on a cycle ergometer cause an increase in SBP during the recovery period that is almost 3 times higher and lasts longer in men compared to boys. However, DBP drops below the resting value after 6 min of recovery, with changes being similar in boys and men. The different changes of SBP in boys and men may be explained by the combination of a higher cardiac output and a greater peripheral resistance in men compared to boys. This may be related to a higher metaboreflex due to the greater metabolic disturbances in men than in boys.

FATIGUE AND STEADINESS OF DOMINANT AND NON-DOMINANT HUMAN QUADRICEPS FEMORIS MUSCLES DURING VOLUNTARY ISOMETRIC CONTRACTIONS

Williams, M., Ponte, J.
University of Chichester, United Kingdom

BACKGROUND: Dominant and non-dominant legs have been investigated with respect to unilateral postural control (Hoffman et al. 1998), torque of quadriceps muscles (Guette et al. 2005) and muscle fatigue (Martin & Rattey, 2007). Fatiguing isometric contractions at low intensities are characterized by a progressive increase in amplitude of the force fluctuations (i.e. deterioration of muscle steadiness). PURPOSE: To examine fatigue and steadiness of dominant (D) and non-dominant (ND) quadriceps during voluntary isometric contractions. METHODS: Leg dominance was based on the subject’s preferred kicking leg. Subjects were 13 healthy, physically active, subjects (3 females, 10 males; age: 20±2 yr; body mass: 73.3±11.6 kg; height: 1.76±0.11 m; mean ± SD). Subject’s upper body was firmly restrained and hip and knee joint angles kept at 90°. Subject’s ankle was connected with a chain to a force transducer (model 616, Tedea-Huntleigh, Cardiff, UK) sampling frequency 1000Hz. Maximal voluntary isometric force (MVIF), steadiness during 20%MVIF until task failure and MVIF 20 seconds after completion of the 20%MVIF, for calculation of the fatigue index, were measured. Steadiness or amplitude of the force fluctuations was calculated as the coefficient of variation (CV)=SD/mean x 100) during the first (0-10%), middle (45-55%) and last (90-100%) time period of total endurance time. RESULTS: Dominant and non-dominant quadriceps had similar MVIF. D: 655.8±162.5 N; ND: 637.1±156.0 Nl and similar endurance times during 20%MVIF: D: 374.8±174.2 s; ND 384.5±149.3 s. However, dominant quadriceps had a 7.8% higher fatigue index than non-dominant quadriceps (D: 38.6±16.7%; ND: 30.8±16.5%; Student t-test, P=0.007). Steadiness increased over time (two-way ANOVA, P<0.05) but there were no differences in similar time periods of endurance time for dominant and non-dominant quadriceps (0-10%; D: 2.63±0.68%, ND: 2.68±0.61%; 45-55%; D: 4.06±1.71%, ND: 4.00±1.46%; 90-100%; D: 10.71±4.91% ND: 9.97±2.96%). CONCLUSIONS: Dominant quadriceps femoris muscles experienced larger fatigue from submaximal 20% sustained isometric contractions suggesting that the occurrence of central fatigue may be related to leg dominance. However, differences in fatigue were not associated with differences in muscle steadiness in dominant and non-dominant quadriceps femoris muscles.

THE EFFECTS OF RESISTANCE TRAINING ON SYMPATHETIC NEURAL ACTIVITY RESPONSE DURING FATIGUING STATIC HANDGIP EXERCISE

Saito, M., Hachiya, T.
Toyota Technological Institute, Japan

Muscle contraction elicits increased muscle sympathetic nerve activity (MSNA) caused by central neural activity (central command) and muscle reflex. The MSNA response during muscle contraction is reduced after endurance training. However, there has been inconsistent results of the MSNA response after resistance training; the response was attenuated(1) or not changed(2) during isometric handgrip. On the other hand, an increase in muscle strength after short-term resistance training is due to an improvement of neural drive from higher center to the muscle rather than the alteration of muscle properties(3). Thus, we hypothesized that if central neural drive to the muscle increased after resistance training, this may influence the autonomic nervous system. The aim of the study was to investigate if resistance training influenced the MSNA response during muscular contraction. MSNA, heart rate (HR) and blood pressure (BP) response to two-min isometric handgrip (IHG) and fatiguing isometric handgrip exercise (FTG) at 33% of maximal voluntary contraction, followed by post-exercise circulatory occlusion (PECO) were compared before and after resistance training. MSNA was recorded from the tibial nerve and represented as burst frequency per min. HR counted from ECG and BP from Finapres were determined. Eighteen healthy subjects, with mean age of 23 years, took part in this study. All subjects gave informed written consent and the study had TTI Ethical Committee approval. Ten subjects were assigned to training group (TG) and other nine subjects were allocated to control group (CG). TG trained a non-dominant arm. The training regimen was consisted of three sets of ten maximal 10-s static handgrip repeated 10 s interval, 4 days per week for four weeks. Maximal handgrip force increased by 23% in TG after training but remained constant in CG. MSNA increased during handgrip and PECO from the resting control in IHG as well as FTG. MSNA response during handgrip and PECO in IHG presented no significant change after training. During fatiguing handgrip, extent of MSNA response during handgrip increased by 29% was greater after training compared to before training while unchanged during PECO. In CG no significant difference in MSNA response during IHG as well as FTG between before and after training was found. HR and BP response in IHG and FTG were unchanged after training. This study demonstrated that short-term strength training may influence on MSNA response during fatiguing muscle contraction, while MSNA response during PECO was obtained insignificant effects. These different responses may be related to volitional factor rather than muscle reflex.

Glucagon growth hormone and insulin-like growth factor-1 responses to two heavy resistance training with different rest intervals between sets

Seyed, N., Senobar, T.

University of medicine science, Iran

Resistance training is a powerful stimulus for acute increase in the concentration of anabolic hormone. At present, little data are available on changes in the levels of IGF-I and GH following different rest intervals between sets in resistance training. Therefore, in order to examine the effects of different rest intervals on the sets on acute GH and IGF-I responses, different rest intervals resistance trained men served as subjects (Mean SD, age=22 ± 2 years, body mass=84 ± 8 kg). Subjects performed two heavy-resistance training protocols that were similar with regard to the total volume of work (1), but differed with regard the length of rest between sets (1 vs. 3-minutes). Both protocols included 5 sets of 10 RM bench press and squat that performed on two randomized separate sessions. Blood samples were collected before immediately and 1-hour after the protocols for determination GH, IGF-I and blood lactate concentration. Two way analysis of variance with repeated measures demonstrated that both protocols led to the greater acute increases (P<0.05) in serum GH concentrations. However, the GH response was significantly larger in short rest than long rest interval between sets protocol, and IGF-I didn’t significantly change between protocols. Blood lactate concentrations increased more in short rest than long rest interval between sets protocol (P<0.05). Results of this study support rest interval length as a strategy for increasing GH and IGF-I serum concentrations, which is believed to enhance and stimulate greater strength and hypertrophy adaptations.

Decrease in running economy following downhill running

Chen, T., Nosaka, K., Chen, H., Lin, M., Wu, C.

National Chiayi University, Taiwan

Several studies have investigated the effects of exercise-induced muscle damage (EIMD) on running economy (RE), but controversy exists whether EIMD affects RE significantly. Some studies reported no significant effect of EIMD on oxygen consumption (VO2) during sub-maximal treadmill running (55-75% VO2max) following lower body resistance exercises with free-weight (Scott et al. J Strength Cond Res 2003), a downhill running (DHR) (Harmill et al. Int J Sports Biomech 1991), or a maximal eccentric exercise of the knee extensors on an isokinetic dynamometer (Paschalis et al. Int J Sports Med 2005). On the other hand, Braun & Dutto (Eur J Appl Physiol, 2003) and Chen et al. J Sports Sci, 2007) showed that RE during sub-maximal treadmill running (65, 75, and 85% VO2peak) was significantly reduced for 3 days following DHR. It appears that exercise and the level of muscle damage, characteristics of subjects, and protocol to assess RE are factors contributing the different findings. To confirm the findings of our previous study (Chen et al. 2007), this study used untrained subjects to induce greater muscle damage than the previous study, and included a higher intensity of running to assess RE. Twelve untrained male students (19-23 yrs) performed a 30-minute DHR at a gradient of -16% at the intensity of their pre-determined 70% VO2max. Maximal isokinetic concentric strength at 30°/s, isometric strength of the knee extensors, muscle soreness (SOR), and plasma creatine kinase (CK) activity were measured before, immediately after, and for 5 consecutive days after DHR. RE was assessed by VO2, minute ventilation (VE), respiratory exchange ratio (RER), heart rate (HR), ratings of perceived exertion (RPE), and blood lactate concentration (LACT) during a 5-minute running on a treadmill at the intensities of 70%, 80%, and 90% VO2max (randomized order, 10 min between the intensities) before, and 2 and 5 days after DHR. Changes in the measures following DHR from baseline were analysed by a one-way ANOVA, and changes in the RE measures following DHR were compared amongst the intensities using a two-way repeated measure ANOVA. DHR resulted in significant (P<0.05) development of SOR, decreases in muscle strength (17-22%), and increases in plasma CK activity (390-660%), which lasted for 5 days after DHR. All RE parameters showed significant (P<0.05) increases from baseline for 5 days following DHR at the 80% and 90% running intensities, but this was not the case for the 70% intensity. The results of the present study confirmed that RE is reduced after DHR. It appears that the magnitude of muscle damage induced by the DHR in the present study was greater than that of the previous study (Chen et al. 2007), and the effect of EIMD on RE was also greater for the present study. It may be that the greater decrease in RE at the high intensity running was associated with the damage to fast twitch fibers, which might have been occurred to a greater extent for the untrained subjects.

Physiological and metabolic characteristics associated with the preferred transition speed in trained racewalkers

Ziv, G., Rotstein, A.

The Zinman College for Physical Education and Sports Sciences at the Wingate Institute, Israel

Purpose: Human terrestrial locomotion is characterized by either walking or running. The preferred transition speed (PTS) at which humans change their gait was found to be lower than their energetically optimal transition speed (EOTS). However, this phenomenon was not examined in racewalkers. The purpose of this study was to evaluate the PTS and EOTS in trained racewalkers compared to a control group. Methods: Eleven racewalkers and thirteen control subjects participated in this study. Subjects arrived at the lab on three separate occasions. Visit I: walk-run PTS determination: subjects were required to walk at a slow walking speed and the treadmill’s speed was increased by 0.2 km/hr every 30 s until the subject felt it was easier to walk. Run-walk PTS determination: subjects were required to run at a speed which was above their ability to walk and the treadmill’s speed was reduced by 0.2 km/hr every 30 s until the subject felt it was easier to run. PTS was defined as the average of the walk-run PTS and the run-walk PTS. Plantar and dorsi flexion isokinetic dynamometer (Paschalis et al. Int J Sports Med 2005). On the other hand, Braun & Dutto (Eur J Appl Physiol, 2003) and Chen et al. J Sports Sci, 2007) showed that RE during sub-maximal treadmill running (65, 75, and 85% VO2peak) was significantly reduced for 3 days following DHR. It appears that exercise and the level of muscle damage, characteristics of subjects, and protocol to assess RE are factors contributing the different findings. To confirm the findings of our previous study (Chen et al. 2007), this study used untrained subjects to induce greater muscle damage than the previous study, and included a higher intensity of running to assess RE. Twelve untrained male students (19-23 yrs) performed a 30-minute DHR at a gradient of -16% at the intensity of their pre-determined 70% VO2max. Maximal isokinetic concentric strength at 30°/s, isometric strength of the knee extensors, muscle soreness (SOR), and plasma creatine kinase (CK) activity were measured before, immediately after, and for 5 consecutive days after DHR. RE was assessed by VO2, minute ventilation (VE), respiratory exchange ratio (RER), heart rate (HR), ratings of perceived exertion (RPE), and blood lactate concentration (LACT) during a 5-minute running on a treadmill at the intensities of 70%, 80%, and 90% VO2max (randomized order, 10 min between the intensities) before, and 2 and 5 days after DHR. Changes in the measures following DHR from baseline were analysed by a one-way ANOVA, and changes in the RE measures following DHR were compared amongst the intensities using a two-way repeated measure ANOVA. DHR resulted in significant (P<0.05) development of SOR, decreases in muscle strength (17-22%), and increases in plasma CK activity (390-660%), which lasted for 5 days after DHR. All RE parameters showed significant (P<0.05) increases from baseline for 5 days following DHR at the 80% and 90% running intensities, but this was not the case for the 70% intensity. The results of the present study confirmed that RE is reduced after DHR. It appears that the magnitude of muscle damage induced by the DHR in the present study was greater than that of the previous study (Chen et al. 2007), and the effect of EIMD on RE was also greater for the present study. It may be that the greater decrease in RE at the high intensity running was associated with the damage to fast twitch fibers, which might have been occurred to a greater extent for the untrained subjects.
EFFECTS OF MODERATE ALTITUDE ON PULMONARY FUNCTION OF PHYSICAL EDUCATION STUDENTS

Ozlem, O., Atesoglu, U., Cetin, E., Oz, E., Ertas, B.
Gazi University, Turkey

INTRODUCTION: The effects of different altitudes (low, moderate or extreme) on vital functions are well documented. Again, it's known by the recent researches that no statistically meaningful changes occur on pulmonary functions up to 1500m although there may be changes at velocity of air currents, and again it's adaption ratio to the altitude differs according to sex. The purpose of this study is to determine the effects of moderate altitude (1800m) on pulmonary functions among PE students.

METHOD: In the study, 19 apparently healthy subjects (10 male, 9 female) from Gazi University School of Physical Education and Sports students voluntarily participated. The age, height and weight measurements (mean±SD) of the male and female subjects are 21.22±1.71 year, 167.11±4.96 cm, 53.77±4.89 kg and 22.20±1.75 year, 175.00±4.38 cm, 71.00±10.48 kg respectively. COSMED PFX desktop Spirometer used in this study. All pulmonary tests which are FVC, FEV, FEF, VC and MVV measured 3 times: First day(I) and after 5 days(II) at altitude(1800m Ilgaz Mountains). The last one(III) applied in city 10 days later(850m). The data were analyzed with Repeated Measure Analysis of Variance (ANOVA) by SPSS statistical software.

RESULTS: According to the results, there is no significant differences within the groups both female and male students in all tests. However, as compare the male and female student groups, the results showed that FVC, FEV, PEF, VC and MVV were significantly different (P<0.05 P<0.01).

DISCUSSION & CONCLUSION: Muza et al; reported that; women, who stayed at 4300m for two weeks, showed faster adaptation than men. Forte et al; determined that increasing at the FEV1 and a little decreasing of the FVC and 20% increasing at the MVV at high altitude. On the other hand, we found on the moderate altitude, pulmonary functions did not significantly effect within all groups. Although, as compare female and male subjects pulmonary functions parameters were significantly different in all tests.

EFFECT OF EXERCISE AND DIET MODIFICATION INTERVENTION ON ENDOTHELIAL DYSFUNCTION AND INSULIN RESISTANCE IN A RAT MODEL OF DIET-INDUCED OBESITY

Touali, S., Meziri, F., Devaux, S., Barhoumi, T., Regnard, J., Berthelot, A., Laurant, P.
University of Franche-Comté, UFR STAPS, France

This study was designed to examine whether abnormalities that comprise the metabolic syndrome (obesity, insulin resistance, hyperlipidemia, endothelial dysfunction and hypertension) are reversible by physical exercise with/o without diet modification in a rat model of diet-induced obesity.

Male Sprague-Dawley rats were placed on either a high fat (HF) or control diet (CI). After 12 weeks, HF rats were separated into 4 groups: sedentary obese group (OB), exercise trained (motor treadmill 5 days/week, 60 min/day for 12 weeks) obese group (OB/EX), modified diet (high fat to control diet) group (HF/C) and exercise trained with modified diet group (HF/C/EX). Body weight and blood pressure were measured weekly. Retropertioneal and epididymal fat mass, plasma lipids and glucose levels, and vasorelaxant response in isolated aorta were measured in all groups after 24 weeks.

Body weight, retropertioneal and epididymal fat mass were significantly higher in OB rats. Exercise significantly decreased these parameters in OB/EX and HF/C/EX rats. Plasma total and LDL-cholesterol and glucose levels were significantly higher in OB rats while plasma HDL-cholesterol was significantly lower than control group. Exercise improved lipids and glucose concentrations in the OB/EX and HF/C/EX rats. The vasorelaxation response to acetylcholine was significantly impaired in the aorta from the OB rats compared with the control rats. However, the endothelium-dependent response to acetylcholine was restored in aorta from the OB/EX and HF/C/EX rats. There were no differences in the vasorelaxation response to sodium nitroprusside between groups. The relaxation responses to insulin were significantly attenuated in the OB group compared to the control group. In the same manner than acetylcholine, the endothelium-dependent relaxation to insulin was markedly restored in aorta from the OB/EX and HF/C/EX groups.

Our findings suggest that exercise is able to reverse the metabolic syndrome in rat fed a high fat diet, to improve the cellular response to insulin and to restore the endothelium- and NO-dependent vasorelaxation. These results demonstrate that metabolic syndrome induced by an inappropriate diet is reversed by exercise without necessary diet modification. Finally, it is concluded that exercise may be a potential non-pharmacological treatment for multiple simultaneous cardiovascular risk factors.

EFFECTS OF EXERCISE TRAINING AT DIFFERENT HYPOBARIC HYPOXIC CONDITIONS ON CARDIOVASCULAR ADAPTATIONS

Futoshi, O., Nishiwaki, M., Kawakami, R., Tamaki, H., Tanaka, T., Saito, K.
National Institute of Fitness and Sports, Japan

Introduction
Recently, we have reported that aerobic exercise under a hypobaric hypoxic condition could more effectively reduce total peripheral resistance (TPR) and blood pressure (BP), compared to the exercise under a normal condition (Ogita 2007). The reduction of TPR was partly attributed to an enhancement of vasodilative capacity. Furthermore, the adaptation seemed to be brought by a hypoxic stimulus which cause vasodilation through several metabolites such as nitric oxide and adenosine. In this study, we therefore examined the effects of exercise training at different hypobaric hypoxic conditions on cardiovascular adaptations, especially during exercise.

Methods
The subjects were 22 healthy adults (25±4 yrs). They were matched for physical fitness level into three groups and then randomized to normobaric normoxic exercise group (N; n=6) and 2 hypobaric hypoxic exercise groups (H1; n=10, H2; n=6). The aquatic exercise training was done in swimming pool located in a chamber where atmospheric pressure could be regulated. The exercise was performed at the intensity of around 50%VO2max for 30 minutes/training session, 4 days/week, for 4 weeks. H1 and H2 had the exercise in the hypobaric conditions corresponded to 1200m and 2000m above sea level, respectively, and were exposed to the hypoxic condition for 2 hours/session. Before and after the training period, VO2max and cardiovascular responses, such as heart rate (HR), stroke volume (SV), cardiac output (CO), and systolic (SBP), diastolic (DBP) and mean blood pressure (MBP) during cycling exercise at the intensity of 50%VO2max, which was determined before the training, were measured. In addition, the diameter of the popliteal artery was measured at rest and during reactive hyperemia after release of 5-minute arterial occlusion.

Results
After the 4 weeks of training, VO2max did not change significantly in all groups. In cardiovascular responses during the moderate exercise, no significant changes were observed in N, and only DBP significantly decreased in H1. On the other hand, SV and CO in H2 significantly increased. Furthermore, DBP (pre: 68±8; post: 55±4 mmHg) and MBP (pre: 94±4; post: 91±4 mmHg) significantly decreased (P<0.05). The diameter of popliteal artery at rest did not change significantly in all groups, however, peak diameter during reactive hyperemia significantly increased only in H2 (pre: 6.6±0.6; post: 7.0±0.8 mm) (P<0.05).

Discussion/Conclusion
These findings suggest that exercise in hypobaric hypoxic condition more effectively reduces TPR and BP with an increase in SV compared to the exercise under normal condition but that hypoxic stimulus corresponding to 1200 m above sea level would not be strong enough to induce such cardiovascular adaptations.

COMPARISON OF ELECTRICAL AND MAGNETIC STIMULATIONS TO ASSESS KNEE EXTENSOR MUSCLE FUNCTION

Verges, S., Mauffiletti, N., Kerherve, H., Decorte, N., Wuyam, B., Millet, G.

Joseph Fourier University and Grenoble University-Hospital, Grenoble, Schultz Clinic, Zurich, Switzerland, Jean Monnet University, Saint-Etienne, France

This study aimed at (i) comparing electrical and magnetic stimulations to assess knee extensor (KE) muscle function and (ii) assessing whether the ratio of the second twitch of paired stimulations at 10 and 100 Hz (T210:100, Yan et al. 1993) is equivalent to the low-to-high frequency force ratio obtained during tetanic contractions (F10:100). Twenty-two healthy subjects performed i) supramaximal electrical femoral nerve stimulation (ENS), ii) supramaximal magnetic femoral nerve stimulation (MNS) and iii) submaximal transcutaneous electrical knee muscle stimulation (EMS) in a random order at 1 Hz (single stimulation), 10 Hz and 100 Hz (paired stimulations), followed by 0-5 s tetani at 10 and 100 Hz with EMS. KE force and electromyographic responses were recorded during each stimulation. For 10 subjects, measurements were also performed before and after a 30-min downhill run (slope -20%, speed 10kmh-1) on a motorized treadmill. Peak forces during single and paired stimulations were comparable with EMS and MNS, but smaller with EMS (H1: 151±25 N vs. 147±26 N; H2: 129±19 N vs. 127±21 N, P<0.05), and MNS (H1: 133±12 N vs. 129±16 N; H2: 121±15 N vs. 118±17 N, P<0.05). M-wave characteristics were similar with EMS and MNS. F10:100 did not correlate with T210:100 measured with EMS (r²=0.19), MNS (r²=0.01) or EMS (r²=0.18) before exercise. We conclude that electrical and magnetic stimulations of the femoral nerve provide similar neuromuscular assessment of the KE. However, T210:100 and F10:100 ratios are not equivalent to assess low-to-high frequency force of the KE muscle in vivo.

ELECTRICAL STIMULATION SENSORY THRESHOLD IS RELATED TO SUBCUTANEOUS FAT THICKNESS

Mauffiletti, N., Morelli, A., Sartorio, A., Duclay, J., Billot, M., Martin, A.

Schultz Clinic, Zurich, Switzerland

We recently demonstrated lower electrical sensory thresholds in women than in men (1), i.e., female subjects perceived electrical stimulation with lower current amplitudes than their male counterparts (r=-43%). Interestingly, the lowest sensory currents were observed in those subjects with the largest skinfold thicknesses (women), therefore suggesting a link between subcutaneous adipose tissue mass and sensory excitability. To confirm these observations, in this study we compared detection-threshold stimulation levels between men and women having wide ranges of subcutaneous fat (i.e., obese individuals). Moreover, since skinfold thickness does not provide an accurate assessment of the quantity of subcutaneous fat, we quantified thigh subcutaneous fat thickness using B-mode ultrasound (2), and attempted to relate this parameter to sensory threshold.

Thirty adult obese individuals (15 men and 15 women; BMI: 41±6 and 42±8 kg/m², respectively) were enrolled in this study. B-mode ultrasound images were obtained from the lateral aspect of the vastus lateralis muscle at half of femur length, while the subject was seated with an angle of 90° at the hip and knee joints. In the same position, the quadriceps femoris muscle was stimulated at 50 Hz with a portable electrical stimulation unit and two surface electrodes. Electrodes were placed 5 cm below the femoral triangle and at half of femur length, over the vastus lateralis muscle belly. The investigator progressively increased current amplitude (mA) from zero to sensory threshold, i.e., when the subject indicated initial lowest perception of stimulus sensation. Subcutaneous fat thickness and sensory threshold data were the average of 2-3 trials per thigh (both thighs were tested).

Subcutaneous fat thickness was significantly larger in women (24.8±7.5 mm) than in men (12.7±3.6 mm). Sensory threshold was significantly lower in women (2.33±0.75 mA) than in men (3.80±0.70 mA). The lowest sensory thresholds were observed in those subjects with the largest fat thicknesses and vice versa (r²=-0.77, P<0.001; fat thickness=0.58×sensory threshold+3.62).

In line with our previous investigation, the present findings allow us to speculate that the number and/or sensitivity of cutaneous and subcutaneous receptors activated by detection-threshold current could differ between men, both obese (this study) and nonobese (1). Considering that these low electrical stimulation levels would predominantly activate large-diameter A-beta afferents, sex differences could exist in the properties of encapsulated nerve endings (such as Pacinian corpuscles and Merkel disc). The choice of optimal current amplitudes is paramount to the effectiveness of electrical stimulation treatments (e.g., for TENS). We therefore recommend that practitioners consider that women may present lower sensory thresholds than men.
ALTERATION OF NEUROMUSCULAR FUNCTION IN SQUASH

Girard, O., Micallef, J.P., Noual, J., Millet, G.
University of Montpellier, France

Introduction: Racquet sports are increasingly popular, but in these sports, exercise-induced neuromuscular fatigue has received little attention until recently (Girard and Millet, 2008) and has been limited to the game of tennis (Girard et al. 2007). The aim of this study was therefore to identify the central (i.e., reduction in motor units recruitment; decreased central drive) and peripheral (i.e., decrease in muscle fiber contractility) mechanisms that contribute to the decline in muscle strength (i.e., knee extensors) after a squash match play.

Methods: Before and immediately after a 1-h squash match, maximal percutaneous electrical stimulations (model DS-7, Digitimer Stimulator, UK) were applied to the femoral nerve of 10 trained squash players. To examine potential impairment in central drive, changes in EMG activity of vastus lateralis (VL) and vastus medialis (VM) muscles normalized to M-wave amplitude (RMS/M) as well as muscle activation (VA) were quantified during maximal voluntary contraction (MVC) of knee extensors. Peripheral fatigue was assessed by examining the characteristics of the M-wave and twitch contractile properties following single stimuli. The torque and EMG data (MP30, Biopac, CA) were recorded (2000 Hz).

Results: MVC declined (280.5 ± 46.8 vs. 233.6 ± 35.4 Nm, -16%; P< 0.001) and this was accompanied by an impairment of central activation, as attested by decline in VA (76.7 ± 10.4 vs. 71.3 ± 9.6%, -7%; P< 0.05) and raw EMG activity of the two vasti (-17%; P< 0.05), whereas RMS/M decrease was lesser (VL: -5%; NS and VM: -12%; P= 0.10). In the fatigued state, no significant change in M-wave amplitude (VL: 11.6 ± 4.6 vs. 10.6 ± 4.9 mV, -9%; VM: 8.8 ± 4.0 vs. 8.2 ± 3.3 mV, -5%) or duration were observed. Following exercise, the single twitch was characterized by lower peak torque -20%; P < 0.001 as well as shorter half-relaxation time -15%; P < 0.001 and reduced maximal rate of twitch tension development -23%; P < 0.001 and relaxation 17%; P < 0.05. Finally, handgrip force did not change (28.2 ± 6.2 vs. 28.7 ± 6.3 kg).

Discussion/Conclusions: A 1-h squash match play caused peripheral fatigue higher than the one observed after 3-h of tennis (MVC: -9%; Girard et al. 2007) by impairing excitation-contraction coupling, whereas sarcolemmal excitability seems well preserved. Our results also emphasize the role of central activation failure as a possible origin of the alterations in neuromuscular function observed. The highly intermittent nature of squash and the high effective playing time (squad: 50-70% vs. tennis: 20-30%, Girard and Millet, 2008) explain the differences observed with tennis.

EFFECT OF TWO DIFFERENT EXERCISE INTENSITIES ON THE CONCENTRATION OF STEROID HORMONS IN THE SALVIA OF HIGH SCHOOL STUDENTS

Budde, H., Pietraßyk-Kendziorra, S., Voelcker-Rehage, C.
Institute of Sport Science, Humboldt University Berlin, Germany

Introduction
In young individuals few data are available on hormonal response to exercise-related stress (Boisseau & Delamarche 2000). It is well known that physical activity can influence the secretory processes of many endocrine tissues, and, in particular, acute physical exercise is known that physical activity can influence the secretory processes of many endocrine tissues, and, in particular, acute physical exercise is able to also sharply increase the serum concentrations of steroid hormones (SH) (Smilios et al., 2003). These responses are influenced by sexual steroids. It is well

Results revealed that the cortisol level of the high intensity group was significantly increased after training (T2) and still elevated after heavy-intensity training. After a high intensively exercise the levels of both SHs rose compared to the control and the low intensity group.

CAN OBESITY AFFECT DAILY LIVING ACTIVITIES ENERGY EXPENDITURE IN CHILDREN?

Foina, M., Magnoni, D., Sassone, M., Casolo, F., Galvani, C.

1Motor Science, 2Istituto di medicina e scienza dello sport, 3ASI, Italy

Differences between obese and non-obese children have been already measured by indirect calorimetry for resting energy expenditure (REE). On the contrary no study investigated on the variation of activity energy expenditure (AEE) other than walking and running. The aim of the present study was to determine the REE and the AEE of 11 common physical activities in overweight or obese (OI) and non-obese (CG) children.

21 volunteer children participated in the study (G1: N=10, age, 9.5±1.6 yr; BMI, 23.6±1.7 kg/m2; VO2max, 33.6±1.6 ml/kg/min; G2: N=11, age, 9.4±1.6 yr; BMI, 16.5±1.6 kg/m2; VO2max, 45.6±1.6 ml/kg/min). Subjects were classified as overweight, obese and non-obese according to international reference values (Cole, 2000). Two sets of activities were performed in two separate days by each subject. Activities ranged from cruyoning to running and rope skipping and were divided according to the actual intensity (<3 METS, 3-6 METS, >6 METS). Oxygen consumpation was measured continuously with a portable metabolic system (K4b2, Cosmed, Italy).

REE was higher, even if not significantly, in G1 in comparison with G2 (REE: G1 1204.7±549.8 kcal/d, G2 1046.3±303.2 kcal/d). No significant differences were detected between G1 and G2 in AEE, even if the same trend that REE was observed for moderate and vigorous activities (AEE <3 METS: G1 58.5±23.5 kcal/d, G2 63.2±22.3 kcal/d, AEE 3-6 METS: G1 180.8±65.2 kcal/d, G2 170.1±54.9, AEE >6 METS: G1 353.7±101.6 kcal/d, G2 312.9±97.3 kcal/d).

These data indicate that REE and moderate and vigorous AEE are energetically more expensive for overweight and obese children than for non-obese children, even if this difference is not statistically significant. These data confirm that obese children show a trend to a higher energy expenditure, the mechanical power being equal. Devising a physical activity program in which children train together with non-obese children could be useful and effective in the treatment of overweight or obesity.

MORPHOLOGICAL AND FUNCTIONAL CHANGES OF THE HEART DURING DETRAINING PERIOD IN MALE ATHLETES

Kneffel, Z., Varga-Pintér, B., Horváth, P., Pavlik, G.

Semmelweis University, Faculty of P.E. and Sport Sciences, Hungary

In order to evaluate the influence of detraining on cardiovascular re-adaptations, 43 male (22.5 ± 6.8 years) athletes were examined during the training and within 2 months of detraining period (usually caused different kind of injuries). We used two dimensionally guided M-mode picture to detect the morphological changes (left ventricular wall thickness, end-diastolic diameter, left ventricular muscle mass) and used Doppler echocardiography to detect functional changes (cardiac output, stroke volume, VCF). For data analysis we used t-test for dependent samples with help of STATISTICA for Windows 8.0 program. After the detraining period the wall thickness decreased by 3.1% (14.47 vs. 14.02 p<0.0065), left ventricular mass decreased 3.23% (88.07 vs. 85.22 p<0.05), but the end-diastolic diameter did not reduce significantly. However, functional changes showed stronger difference between the active and the non-active period as the cardiac output value elevated by 16.3% (1.92 vs. 2.23 p<0.0012), the stroke volume value high by 5.52% (33.63 vs. 35.49 p<0.024), in the VCF value increased by 6.73% (1.13 vs. 1.2 p<0.008) and the resting heart rate by 7.1% (57.88 vs. 61.99 p<0.03). In accordance with other authors it seems that morphological changes appear markedly only after 60 days detraining. Functional characteristics of the heart are dominancy causes higher values in the functional characteristics of the heart.

STUDY OF VALIDITY AND RELIABILITY OF NON-EXERCISE TEST & GAS ANALYSIS TO ESTIMATE VO2MAX IN FEMALE BASKETBALL PLAYERS

Fallah, O., Gaini, A., Ziaee, N., Barmaki, S., Farshidi, Z.

university of tehran, Iran

The purpose of this study was to investigate the validity and reliability of Houston non-exercise test & gas analysis for estimating vo2max in female basketball players. For this reason, 30 female basketball players (age 21±3.33 yr old, height 167±3.5 cm, weight 60±7.72 kg) who experienced in super league competition in Tehran were selected.

For estimating vo2max, subjects were invited to physical fitness assessment center of national Olympic academy. Their vo2max were measured by gas analysis using Brouce protocol on treadmill (vo2max 41.21±3.8 ml.kg⁻¹.min⁻¹). The Houston non-exercise test included first measuring body fat percent (%BF) and second measuring body mass in dex. The subject's body fat percent was measured by skin fold method with caliper and the body mass index was measured by body mass analyzer (in body).

To determine physical activity rate a questionnaire were developed and distributed among subjects. Then the intended variables were put in equation of Houston non-exercise test, and estimated of vo2max and the subject's vo2max was predicted in an indirect way (vo2max = 0.76, SEE = 3.75, P = 0.00).

Further, the result showed that proved the reliability of vo2max obtained from non -exercise test and gas analysis system. Ir = 0.76, SEE = 3.75, P = 0.00).

We concluded that the N-EX models provided an accurate estimate of vo2max for female basketball players who had a vo2max less than 55 ml/kg·1·min⁻¹.

Key words:
Non-exercise test, gas analysis, Vo2max

It has been shown that an acute unfamiliar bout of downhill running (DHR) may induce delayed onset muscle soreness (DOMS) and decrease running economy (RE). Eighteen physically active subjects (9 men, 9 women) were divided into two groups based on their maximal oxygen consumption (VO₂max) and gender (equal number of both sexes in both groups). The downhill group (DHG; n = 10, age 26 ± 4 years and VO₂max 49 ± 10 ml/kg/min) and the control group (CG, n = 8, 29 ± 5 years and 51 ± 9 ml/kg/min) both performed two 30 min treadmill exercise bouts (E₁ and E₂, respectively) with 48 h recovery in between. In DHG the first 5 min was run on a level treadmill, then 20 min with 10 % downhill (DHR-phase) and again the last 5 min on level treadmill (both in E₁ and E₂). In CG both exercise bouts were performed on level treadmill. Treadmill velocity in both groups was 70 % of that attained in a progressive VO₂max-test (performed 2-4 weeks earlier). Oxygen consumption (VO₂) and heart rate (HR) were measured continuously during E₁ and E₂. Step length (SL) and frequency were determined after 4, 14, 24 and 29 min of running. Blood samples were taken for blood lactate and serum creatine kinase activity (CK). Squat jump, counter movement jump and maximal hopping power were measured before and after the bouts. The subjects also evaluated DOMS of their thigh muscles daily for 7 days after E₁ (scale 0-6). The results showed a decrease in RE in DHG during E₁ (VO₂ increased from the first 5 min to the last 5 min; 34 ±/− 5 vs. 38 ±/− 5 ml/kg/min, 9.2 ±/− 4.7 %, p < 0.01). VO₂ also increased from the first 5 min in E₁ to the first 5 min in E₂ (36 ±/− 4 ml/kg/min) and the control group (CG) increased VO₂ by 4.7 ±/− 5.5 % in DHG (p < 0.05), but no increase in DHG or in the last 5 min was observed. During E₂, and in CG at any phase of the study, no changes in RE were observed. HR was higher in DHG during the first 5 min in E₂ (154 ±/− 11 bpm) than in E₁ (150 ±/− 11 bpm, 3.1 ±/− 4.0 %, p < 0.05). SL was longer in DHG during DHR-phase (1.18 ±/− 0.21 m) than in level running (1.13 ±/− 0.18 m, p < 0.05) and also longer than during DHR-phase in E₂ (1.14 ±/− 0.19 m, p < 0.05). No changes in the jumping performance were observed in either group. Significant increases in CK and DOMS were only found in DHG. The results of this study suggest that unfamiliar DHR may induce muscle damage that decreases RE, especially in level running. The absence of decrease in RE during the second DHR bout may be explained, at least in part, by the ‘repeated bout effect’, i.e. fast adaptation to eccentric exercise resulting in less muscle damage in the second exercise bout (McHugh et al. 1999).

**Comparisons of VO₂ Kinetics in Walking and Running at the Gait Transition Speed**

Sentića, D., Vucetic, V., Rakovac, M.

Faculty of Kinesiology, University of Zagreb, Croatia

**Background**

Walking and running, as two distinct patterns of locomotion, may be considered as the most natural forms of physical activity in humans. It is surprising, therefore, that no attempts have been made, to our knowledge, to compare the VO₂ kinetics in walking and running. The aim of this study was to examine VO₂ kinetics during walking and running at the preferred gait transition speed (PTS).

**Methods**

Twenty-two physical education students (21.4 ± 2.4 y, 182 ± 7 cm), performed treadmill tests for determination of the aerobic gas exchange thresholds for walking, ATw, and running, ATr, VO₂max and PTS. Thereafter, they completed two square-wave 30-minute walking (W30) and running (R30) tests at the PTS, VO₂ was determined breath-by-breath, and computerised non-linear regression techniques were used to describe either a mono-, bi-, or exponential or exponential-linear VO₂ response. ANOVA for repeated measurements was used to test for differences between walking and running parameters.

**Results**

The PTS had the same average value as ATw and ATr (7.1 ± 0.4 km/h). The time constant for the fast VO₂ component (" tau") in the 30-minute tests was significantly smaller for running than for walking (29 ± 8 ± 4 s vs 33.0 ± 8 ± 2 s, p < 0.01), while the amplitude of the primary VO₂ response (A1) was smaller in the walking test (10.9 ± 1.6 vs 15.7 ± 2.1 ml O₂/min/kg). The parameters of the VO₂ slow component did not differ significantly between tests, although the VO₂ slow component was greater (170 ± 94 ml/min vs 132 ± 25 ml/min) and more often present (19/22 vs 6/22) during running. The time delay for the slow component (t2) was greater for walking (343 ± 220 s vs 194 ± 116 s, p < 0.05). The mean time to achieve stable state (tss) and the aerobic energy cost (Css) were significantly lower for walking (tss = 316 ± 306 s and 586 ± 419 s, Css = 157 ± 20 ml O₂/kg/km and 218 ± 20 ml O₂/kg/km, for W30 and R30, respectively). In W30, the aerobic energy cost centered at the 3rd minute of exercise (C3 = 153 ± 18 ml O₂/kg/km) and Css did not differ significantly (p > 0.05), while in the R30 test, C3 was significantly lower than Css (C3 = 197 ± 21 ml O₂/kg/km, p < 0.05), although explaining effectively the variability of Css (r² = 0.93).

**Conclusions**

Oxygen uptake kinetics (" tau") are significantly faster in running compared to walking at the preferred gait transition speed in young healthy subjects. Although all tests were equally distributed within the moderate and heavy intensity domains, walking at the PTS is characterized by a monoexponential VO₂ response, while a VO₂ slow component is present during running at the PTS, in most subjects.

**The Effects of Two Consecutive Downhill Running Exercise Bouts on Running Economy**

Pullinen, T., Erojärvi, V.

University of Jyväskylä, Finland

The aim of this study was to examine VO₂ kinetics during walking and running at the preferred gait transition speed (PTS). Thereafter, they completed two square-wave 30-minute walking (W30) and running (R30) tests at the PTS; VO₂ was determined breath-by-breath, and computerised non-linear regression techniques were used to describe either a mono-, bi-, or exponential or exponential-linear VO₂ response. ANOVA for repeated measurements was used to test for differences between walking and running parameters.

**Results**

The PTS had the same average value as ATw and ATr (7.1 ± 0.4 km/h). The time constant for the fast VO₂ component (" tau") in the 30-minute tests was significantly smaller for running than for walking (29 ± 8 ± 4 s vs 33.0 ± 8 ± 2 s, p < 0.01), while the amplitude of the primary VO₂ response (A1) was smaller in the walking test (10.9 ± 1.6 vs 15.7 ± 2.1 ml O₂/min/kg). The parameters of the VO₂ slow component did not differ significantly between tests, although the VO₂ slow component was greater (170 ± 94 ml/min vs 132 ± 25 ml/min) and more often present (19/22 vs 6/22) during running. The time delay for the slow component (t2) was greater for walking (343 ± 220 s vs 194 ± 116 s, p < 0.05). The mean time to achieve stable state (tss) and the aerobic energy cost (Css) were significantly lower for walking (tss = 316 ± 306 s and 586 ± 419 s, Css = 157 ± 20 ml O₂/kg/km and 218 ± 20 ml O₂/kg/km, for W30 and R30, respectively). In W30, the aerobic energy cost centered at the 3rd minute of exercise (C3 = 153 ± 18 ml O₂/kg/km) and Css did not differ significantly (p > 0.05), while in the R30 test, C3 was significantly lower than Css (C3 = 197 ± 21 ml O₂/kg/km, p < 0.05), although explaining effectively the variability of Css (r² = 0.93).

**Conclusions**

Oxygen uptake kinetics (" tau") are significantly faster in running compared to walking at the preferred gait transition speed in young healthy subjects. Although all tests were equally distributed within the moderate and heavy intensity domains, walking at the PTS is characterized by a monoexponential VO₂ response, while a VO₂ slow component is present during running at the PTS, in most subjects.

EFFECTS OF CARDIAC RESPIRATORY RHYTHM INDUCED BY DIFFERENT EXERCISE PATTERNS IN HUMANS

Tajima, T., Tadano, C., Shimose, R., Yona, M., Naito, Y., Seki, H., Muro, M.
Toho University School of Medicine, Japan

Purpose: Cardiac respiratory coupling (CRC) is defined as a temporal proportion between cardiac and respiratory frequency (f). Several studies have reported that cardiac (HR) and respiratory frequency ratio (CR-ratio) appears at 3:1 and 4:1 at rest in humans. However, the physiological role of CRC during exercise is unknown. The aim of this study was to test the effects of CR-ratio induced by different patterns of exercise in humans.

Methods: Eighty healthy subjects (30.9 ± 10.4 yrs) participated in this study. Pedaling exercise was carried out on a ramp and at two constant loads. The work-load was fixed at 90 % of AT level and was kept constant at 60 rev/min. The pattern of exercise was step exercise (SE) and ramp exercise (RE) for 4 minutes, and interval exercise (IE) with three repetitions for a minute. Subjects repeated each protocol two times. Measurement items were gas, ECG, and EMG at rest and during pedaling exercise.

Before the experiment subjects performed an incremental test using a bicycle ergometer to determine the anaerobic threshold (AT) level. For the results, CR-ratio was calculated for different types of trends with a time course of response in heartbeats and respiratory frequency.

Results: In the incremental test, the average f was smaller in INC than that in STE at rest and AT (p<0.05). CR-ratio was lower in INC than in STE at AT (p<0.05). However, HR, VO2, VCO2, and VE were not significantly different. The intensity of 90 % AT level was 103.8 ± 28.68 w in INC and 93.7 ± 30.7 w in STE and both loads were not significantly different.

CR-ratio during SE and IE showed different responses, compared with INC and STE. This change of CR-ratio depended on f response during both exercises in INC group. In contrast, CR-ratio in STE was not changed by means of gradual increase with f response. However, VO2, VCO2, and mV-EMG in INC were lower than in STE.

Discussion: In the present study we might be able to classify two types of CR-ratio from cardiac and respiratory frequency components.

Change of the gradual CR-ratio with exercise could be related the decline of CRC since respiratory sinus arrhythmia (RSA) appears to be a strong modulatory effect of HR due to respiratory rhythm. These results in the responses of INC suggest that efficiency of pulmonary gas exchange is increased due to the decline of CRC. CRC could be changed by the control of neural adaptation including some outputted central command during exercise. In contrast, STE group showed lower efficiency of gas exchange while CRC increased due to high neural drive.

We conclude that the role of coupling in cardiac and respiratory control (CRC-ratio) needs to be more widely investigated during different patterns of exercise.

DEVELOPMENT OF A MEASURING SYSTEM FOR PERFORMANCE DIAGNOSTIC IN SCUBA DIVING

Dräger, T., Dalecki, M., Hoffmann, U.
German Sport University Cologne, Germany

Physical fitness in sport scuba divers is a necessary requirement for safe diving. However, at this point in time, classical standardised procedures such as cycle ergometer tests only provide an assessment of general physical performance levels, whereas a special test of performance capacity with regard to the particular environmental conditions of diving does not exist. We therefore developed a new measuring system to examine scuba divers in their specific underwater environment. In the present work we utilised this system in a first field test, to investigate the validation of the recorded data.

Material and Methods: The developed measuring system included a swimboard with a commercial datalogger, an impeller sensor and a telemetric system to detect heart rate (HR). Moreover, the oxygen uptake (VO2) ventilation and airway resistance were recorded with pressure differential sensors inside the breathing loop of a closed circuit diving apparatus. In this first field test, subjects performed a swim step-test with a speed of 0.4 and 0.6 m/s and duration of 4 minutes each in 5m depth. Thereby, we recorded HR and VO2 [n=5], and the ventilation and airway resistance (n=9). The inspiratory and expiratory phases were recorded separately.

Results: Increasing physical strain during the step test was reflected by all measured parameters. HR increased from 116 ± 20 b/min to 152 ± 15 b/min, the oxygen uptake from 1.65 ± 0.37 l/min to 2.8 ± 0.42 l/min. Similarly, the expiratory volume heightened from 1592 ± 188 ml to 2624 ± 573 ml, and the inspiratory volume from 1765 ± 295 ml to 3013 ± 691 ml (all mean ± SD).

Conclusions: Results of this first standardized field test prove, that our new measuring system is able to validly record parameters like HR, VO2, and VE during scuba diving.

USE OF RUNNING COMPUTER AND STRIDE SENSOR IN 12-HOUR HALL RUN COMPETITION

Petäkoski, K., Suvilaakso, M.
Fysio-Sport Petäkoski Oy, Polar Electro Oy, Finland

K-clymphak12-hour running competition was held in February 11th, 2007 in Lohja, Finland. Measurements were done in 3 male runners before and during the running. The mean age (+/-SD) of the group was 46.0(6.1) years, body weight 66.4(4.6) kg, height 177.8(6.1) cm and body mass index 21.0(1.1) kg/m². The aim of this study was to investigate the feasibility and accuracy of Polar RS800sd Running Computer and WearLink® textile transmitter in long-lasting running competition and to validate Polar s3 stride sensorTM W.I.N.D. speed, running cadence (RC), stride length (SL) and distance measurements during the race.

The s3 sensor was calibrated before the race on 1000 meter distance. The running competition took place in an indoor parking hall on 200 meter long concrete covered track. During the race the runners did change their running direction every 2 hours. Temperature during the competition was 12 °C. Heart rate (HR), speed, RC, SL and distance measurements were evaluated at 2 hours intervals.

The group mean (+/SD) of maximum oxygen uptake predicted with Polar Fitness Test with RS800sd before the race was 53.8 (7.8) ml/kg/min, the resting HR 58(6) bpm and the predicted maximum HR 174(14) bpm. The mean HR (% maximum HR) during the 12-hours race was 84.3 % (148 bpm). Both the HR as well as running velocity did decline during the race linearly from 89.4 % (145bpm) to 81.6 % (140bpm) and 10.5 km/h to 9.8 km/h, respectively. The mean speed did also decline from 5.18 min/km to 6.06 min/km. Compared to the values taken at 0-2 h to those taken at 10-12 hours RC did decline -1.1 % (from 90 to 89 rpm) and SL did decline -9.4 % (from 102 cm to 93 cm).
The group mean of official distance achieved during the race was 113,440 km (range 98,991-132,876 km) and the distance measured by Polar s3 was 116,470km (range 102,717-134,344 km). The winner of the race did run 146,296 km. The mean difference in the distances was 2.7% (3,026 km). Statistically the distances did not differ (t = 0.996 p< 0.001). In 2 hours lap times the mean error in the running distance measurement by Polar s3 compared to the official distance was 3.5% (range 0.7-5.6%) corresponding to 0.636km (0.149-0.990km) with high agreement (r = 0.990 p< 0.01). Distances measured by Polar s3-sensor were longer than official running distances. This difference is explained by the fact that movements during the running brakes (e.g. eating and toilet-visit) are included into Polar distance figures.

According to the subjects the s3 sensor was easy to calibrate, unnoticeable to wear and did not disturb running. The transmitter was evaluated to be comfortable and it did not cause any skin abrasions. Based on the study we conclude that the Polar RS800sd Running Computer and its s3 stride sensorTM W.I.N.D. accessory are feasible and valid to be used in ultra-long running performance.

THE EFFECTS OF A 12 WEEK WALKING INTERVENTION ON HEALTH IN ADULTS NOT MEETING THE PHYSICAL ACTIVITY RECOMMENDATIONS

Gray, S., Baker, G., Wright, A., Fitzsimons, C., Mutrie, N., Nimmo, M.
University of Strathclyde, United Kingdom

Purpose
Thirty minutes of moderate intensity physical activity (PA) on 5 days of the week is a major component of current physical activity recommendations. Recent evidence has suggested that motivated individuals can be encouraged to increase PA, specifically walking, via targeted interventions (Ogilvie et al, 2007) yet many of the approaches investigated in the review remain to be convincingly demonstrated. The aim of the current study, therefore, is to investigate if a 12 week walking intervention results in any health benefit in an adult population currently not achieving the minimum recommended levels of PA.

Methods
Recruited from the West of Scotland community 79 volunteers (63 females and 16 males) were randomised to either a control (n=40) or intervention group (n=39). The control group were instructed to maintain their normal walking for the 12 week study period. The intervention group received a PA consultation and pedometer feedback with individualised step-count goals graduated to achieving an additional 3,000 steps/day, 5 days/week from week 7 onwards. In 76 volunteers (63 females and 13 males) health outcomes were measured (n=59 in the control group and 37 in the intervention group) at baseline and 12 weeks, were body mass, waist:hip ratio, percentage body fat, blood pressure and resting heart rate in 66 volunteers (55 females and 11 males) a fasting blood sample also taken (n=34 in the control group and 32 in the intervention group) at both time points was analysed for glucose, insulin, total cholesterol and HDL-cholesterol. The Homeostasis model assessment for insulin resistance was calculated as fasting plasma insulin (mU.l-1)*fasting plasma glucose (mmol.l-1)/22.5. Analysis was performed on intention to treat basis, using 2(group) by 2(time) mixed factorial repeated measures ANOVAs. Data are presented as mean (S.D.)

Results
In the intervention group, average daily step count increased (P<0.001) from 6802 (3212) steps/day at baseline to 9977 (4669) steps/day at 12 weeks. The average daily step count of the control group at baseline was 6924 (3201) steps/day and did not change (P=0.618) during the 12 week period. None of the health outcomes measured changed (P>0.05) between baseline and 12 weeks for the intervention group.

Conclusion
A progressive increase in walking, in this population, over a total of 12 weeks had no effect on any of the anthropometric and metabolic health outcomes measured in the present study.

ALTRATION OF SERUM LIPOPROTEINS AFTER AEROBIC AND ANAEROBIC ACTIVITY IN MALE ATHLETES

Shahsavaran, A., Pourvaghar, M.
Islamic Azad University of Tehran Garb, Iran

Several long-term, aerobic exercise and anaerobic exercise, studies have been conducted with healthy individuals to measure the effect of increased physical activity on serum lipoprotein concentrations. Lipoproteins are transport vehicles in the circulation plasma that are composed of various lipids such as cholesterol, phospholipids, triglycerides and proteins known as apoproteins. Since fat can’t mix with water, which is the main ingredient of blood, cholesterol's most important job is to help carry fat through your blood vessels. Before cholesterol can enter the bloodstream it is coated with a protein. These cholesterol-protein packages are referred to as lipoproteins. Triglyceride is the most common type of fat in the body. Many people who have heart disease or diabetes have high triglyceride levels. Normal triglyceride levels vary by age and sex. A high triglyceride level combined with low HDL cholesterol or high LDL cholesterol seems to speed up atherosclerosis, which is the buildup of fatty deposits in artery walls that increase the risk.

In this research we use scientific and experimental methods. In this study, 14 students were participated. They were students of physical education. The means and standard deviations of their height, weight, age and body mass index (BMI) were respectively: 175±5.9, (68.27±9.89), (20.07±1.44), (22.11±2.47). The purpose of this study was to find out changes of cholesterol and triglyceride in their blood serum after aerobic and anaerobic activities. Blood samples were used to measure cholesterol and triglyceride, one sample before the activity and the other after it. The analysis of data by SPSS software and paired-sample t-test showed that the decrease in the cholesterol level and increase in the triglyceride level of their blood.

The observed difference between the two samples for triglyceride were significant (p = 0.045). However, this difference for cholesterol was non-significant (p = 0.88). This shows that aerobic and anaerobic activities do influence level of triglyceride.

This can be due to the time of physical exercise secretion of catecholamine which facilitates release of free fatty acid (FFA) from body tissues. Also the result indicated that aerobic and anaerobic activities have no influence on the cholesterol in the blood. This can be explained in terms of the normal of cholesterol of the participants.
HORMONAL RESPONSE TO A CONCENTRIC AND ECCENTRIC STRENGTH TRAINING SESSION

Timon, R., Tomas-Carus, P., Olcina, G., Muñoz, D., Toribio, F., Raimundo, A., Maynor, M.
Sport Sciences School. University of Extremadura. Spain

High intensity strength training provokes changes in steroid hormones concentrations. It could be altered by the kind of muscle contractions: eccentric or concentric.

Purpose. The aim of this study is to compare the urinary steroid profile after two different strength training sessions: eccentric or concentric, both of them with same total work.

Methods. 17 males (mean SD years: 24.1 [8.6]; height: 1.75 [0.6]; weight: 72.05 [8.3]) performed two different trials on an isokinetic dynamometer (BIODEX III) training both quadriceps muscles, right and left, in different days. Trial 1(CON-CON): 4x10 Concentric knee extension + relax knee flexion, speed 60°/sec; rest 90 seconds between each series and 4 minutes between each leg. Trial 2(CON-EXC): 4x5 Concentric knee extension - Eccentric knee flexion in similar conditions. Urine samples were taken before the exercise and one hour after finishing it. Testosterone, DHEA, Androstenedione, Androsterone, Etoiocholanolone, Cortisol, Cortisone, Tetrahydrocortisol and Tetrahydrocortisone values were determined by using GC/MS/MS techniques.

Results: No significant differences were achieved in the following strength parameters: Total Work Concentric (mean SD) right knee extensors: 6345.2 [587.3] J; left knee extensors 6303.2 [620.5] J. Eccentric right knee extensors: 6297.2 [620.5] J; left knee extensors 6553.8 [701.5] J and Average Peak Torque Concentric right knee extensors: 199.95 [31.2] Nm, left knee extensors: 196.75 [27.4] Nm; Eccentric right knee extensors: 249.4 [58.3] Nm, left knee extensors 224.8 [63.5] Nm. This was in accordance with no changes in steroid profile before and after trials or comparing CON-CON and CON - EXC trials.

Conclusions. Strength training sessions similar to those performed in this study, are not as intense in order to produce urinary hormonal alterations. As well, in these kind of exercises, eccentric contractions do not provoke different hormonal changes than concentric contractions.

EFFECTS ON THE H-M RECRUITMENT CURVE AT REST AND V-WAVE RESPONSES DURING INCREASED %MVC WITH SKIN COLD STIMULATION

Yona, M., Tadano, C., Tajima, T., Shimrose, R., Seki, H., Naito, Y., Sakamoto, M., Muro, M.
Tokyo University of Pharmacy and Life Science, Japan

(Introduction) We have demonstrated that the decrease in skin temperature with skin cold stimulation effects motor units (MUs). This result suggests that the cutaneous afferent of cold receptor has connections with the MUs in the spinal cord. However, there are few studies on the effects on the motoneuron with cooling by using electrical stimulation. The purpose of this study was to investigate the effects of skin cold stimulation on the motoneuron in the spinal cord using electrical stimulation. (Methods) Eleven healthy adults who volunteered for this study. All measurements were taken from right leg muscles. Subjects were examined in the sit position with the hip, knee and ankle joints at 90 degrees. Measurement muscle was used m. soleus. The electric signals were picked up by surface electrodes (a diameter of 5mm) on the belly of the right SOL. The force of the isometric contraction and twitch were established by a force transducer attached to the apparatus. The EMG and mechanical signals were digitized on-line and stored for analysis. This experiment was performed under two conditions that consisted of control (skin temperature about 33 degrees), Control and skin cold stimulation (skin temperature 26 degrees, cooling). The skin temperature was reduced gradually from control temperature to 26 degrees with a cold pack for 5min. Before each trial, 2 maximal voluntary isometric contractions (MVC) for 2 seconds were performed at the control temperature. The force of every 10%MVC was calculated using control MVC. H-M recruitment curve was taken at rest under both conditions. V-wave responses of every 10%MVC were obtained using a supramaximal stimulus under both conditions. (Results and Discussion). There was no significant difference in Mmax and M-superimpose between the conditions. Cooling did not induced significant changes in the H-M recruitment curve. Four subjects showed clear increases H-M recruitment curve with skin cold stimulation, five subjects showed obvious decreases, whereas no clear change was observed in the remaining two subjects. The amplitude of V-wave increased gradually with increased %MVC in both conditions. With skin cold stimulation the amplitude of V-wave increased in the latter half of the %MVC more than control. The present study found that there was no significant difference between control and cooling in the faster half of the %MVC. Furthermore, the silent period in skin cold stimulation after superimposed stimulation was shorter than that in control in the later half of the %MVC. Twitch force during %MVC in cooling decreased in the faster half of the %MVC more than control. These results suggest that the increased V-wave and reduced silent period in skin cold stimulation might be related to the elevated motoneuron excitability and an enhanced neural drive.

EFFECTS OF SINGLE DOSE ARGinine SUPPLEMENTATION ON LACTate THRESHOLD AND PERFORMANCE

Yavuz, U., Demirel, A., Turnagöl, H., Ahin, Z.
Hacettepe University, Turkey

This study has been designed to investigate the possible effects of pre-exercise acute arginine supplementation on lactate threshold and lactate metabolism in male wrestlers. Nine volunteer male wrestlers who were wrestling in Turkatish Greco-roman 1st league participated to the study. Test- retest protocol was done on the same subjects. After 12 hours fasting (during the night) venous blood samples were taken before the exercise protocol for determining the plasma amino acid profiles and arginine levels. Incremental exercise protocol was applied and oxygen consumption was measured during the exercise, heart rate and plasma lactate levels were measured during the exercise and recovery. Exercise protocol started at 90 watts on bicycle ergometry and the load was increased 30 watts in every 3 minutes. Exercise was continued till the subjects can not go on cycling at the desired working loads or the subjects wanted to stop. Plasma amino acid profiles were also determined after the exercise protocol. Study has been conducted by using cross over design. Half of the subject took 1.5 gram /10 kg body weight L-arginine while other half were taking same amount of wheat bran before the first exercise.
and same amount of L-arginine before the second exercise protocol. Results showed that in the same working loads there was no difference for the mean lactate levels between arginine and placebo groups (p>0.05) while there was a right shift on working load-lactate graphic. There was no difference for maximum oxygen consumption (arginine 52.47±4.01, placebo 52.07±5.21) and maximum heart rates (arginine 181.09±13.37, placebo 185.89±7.38) (p>0.05). Time to exhaustion was longer with L-arginine supplementation (1368.8±59.8 sec) compared to placebo (1315±90.8 sec). Plasma arginine, ornithine and citrulline levels before and after the exercise were found higher with L-arginine supplementation. These results suggest that L-arginine supplementation can have beneficial effects on exercise performance but can not explain the metabolic pathways which are responsible for these effects.

**BREATHING STRATEGY DURING HEAVY CONSTANT LOAD EXERCISE IN YOUNG AND MASTER ATHLETES WITH EXPIRATORY FLOW LIMITATION**

Kippelen, P., Bolger, C., Devereux, G., Ayres, J. 
University of Aberdeen, United Kingdom

Significant limitation of expiratory flow has been observed in highly fit healthy individuals at maximal exercise. The presence of flow limitation may cause reflex inhibition of the hyperventilatory response and/or an alteration in operational lung volumes (1,2). This study examined whether differences in breathing strategy exist between young flow-limited and non-flow-limited athletes during heavy constant load exercise. As the age-related decline in lung elastic recoil increases the likelihood for flow limitation (3) master athletes were studied as well.

20 young endurance athletes (28+/−6yr, VO2max 60+/−5 ml/kg/min) and 10 master athletes (57+/−5yr, VO2max 50+/−5 ml/kg/min) performed an 8min treadmill test at 90% of maximal aerobic speed. Throughout the test cardio-respiratory parameters were continuously monitored and tidal volume (Vt) loops were plotted into the maximal flow-volume loop measured at rest. End-expiratory lung volume (EELV) was estimated at the end of each minute by measuring expiratory reserve volume relative to forced vital capacity (ERV/FVC). All young athletes showed greater than 10% of flow limitation (FL, 48+/−18 %) and the remaining 10 constituted a non-flow limited group (NFL, 14+/−11%). All master athletes (MA) presented moderate-to-severe flow limitation (50+/−19%). Expiratory flow limitation rose in all subjects from the first to the final minute (P<0.01): the mean increase was 24% in FL, 10% in NFL and 15% in MA, with a plateau reached at mid point. Ventilation also rose significantly, reaching a value of 127+/−15L/min in NFL, 129+/−20L/min in FL and 122+/−12L/min in MA at 8min (time effect P<0.001; group effect NS). This was due to an increase in both breathing rate and Vt up to the third minute of the test. Therefore the increase in VE was exclusively explained by an increased breathing rate. EELV significantly increased in the first half of the run in all athletes (P<0.001). However all values remained well below baseline, even in MA who breathed at slightly higher lung volumes (P<0.05).

We conclude that young and master healthy athletes adopt very similar breathing strategies whilst performing at a constant workload near maximal intensity regardless of their degree of expiratory flow limitation.

**EFFECTS OF PALATINOSE VS. HIGH FRUCTOSE CORN SYRUP-INDUCED SUBSTRATE AND METABOLITE AFTER SUBMAXIMAL EXERCISE IN OBESE MEN**

Kim, MK., Okuno, M., Matsu, T., Kim, MJ., Suzuki, K., Tanaka, K. 
University of Tsukuba, Japan

Background: Palatinose (PAL) which are composed of glucose and fructose is a disaccharide present in hone, which is slowly digested, resulting in a slow availability for absorption. These different patterns of digestion and absorption may affect substrate and metabolic changes from ingestion after exercise in human. Objective: The present study was to determine whether dietary PAL vs. high fructose corn syrup (HFCS) intake after submaximal exercise would affect substrate and metabolic changes in obese men. Methods: Ten obese middle-aged men (age 46.0 ± 2.3; weight 79.4 ± 2.8 kg, body mass index 27.1 ± 1.0; peak oxygen consumption 32.0 ± 1.2 ml/kg/min, mean ± SDI participated in a randomized, double-blind, cross-over study. After an overnight fast, participants were performed with a cycle ergometer for 60 min at 50 % VO2peak and then consumed HFCS-55 (55 % fructose, 1.0 g/kg body mass, 500 ml) or Non-Calorie diet (sweet placebo, 500 ml) respectively. Substrate utilization with rates of fat and carbohydrate oxidation was measured by indirect calorimetry and blood samples were simultaneously obtained from an antecubital vein before exercise and 0, 10, 20, 30, 60, 90, and 120 minutes after consuming the carbohydrates. Results: During exercise, energy expenditure was not different among 3 experimental condition. The concentration of plasma glucose, insulin and C-peptide following PAL and Non-Calorie ingestion markedly were lower than those of HFCS (P < 0.05). The non-esterified fatty acids were higher with PAL and Non-Calorie diet (sweet placebo) compared with HFCS (P < 0.05). However, plasma epinephrine and norepinephrine concentrations were not significantly different across three trials. PAL and Non-Calorie ingestion markedly showed increased fat oxidation compared with HFCS (P < 0.05). Conclusions: The impaired effect of suppressed fat oxidation of HFCS is more than those of PAL ingestion without reference to changes of circulating catecholamine. The present data suggests that the use of HFCS as beverage of postexercise may be undesirable, particularly for obese men. PAL may be a suitable replacement sugar in terms of substrate utilization in postexercise recovery (i.e., negative energy balance).

**CARDIOVASCULAR RESPONSES TO PROLONGED APNEA IN RESTING IMMERSED BREATH-HOLD DIVERS**

Perini, R., Gheza, A., Moia, C., Ferretti, G. 
1 Università di Brescia, Italy and 2 Centre Medical Universitaire, Geneve, CH, Italy

The cardiovascular responses to prolonged immersed apnoea were evaluated in 7 breath-hold divers (mean age: 31±4 yrs). The subject rested head-out immersed in a pool (water temperature: 27 °C) for some minutes for control measurements, then he/she held the breath and immersed the face assuming a prone position below the surface of the water up to volitional end. Blood pressure profile was continuously recorded (Portapres) from the hand kept outside the water on the edge of the pool. Beat to beat values of systolic and dia-
stolic pressures (Ps and Pd), heart rate (HR) and stroke volume (SV) were obtained (Beatscope®). Mean pressure (Pm), cardiac output (Q') and total peripheral resistance (TPR) were calculated. Apnoea ranged from 166 s to 299 s (mean: 236.8±50.8 s). In all subjects HR decreased from 81±9.8 to 59.5±9.8 bpm within the initial 30 s of apnoea (phase I). No further change in HR occurred throughout the apnoea. PS decreased in the initial 5 s of apnoea by 20 mmHg (p<0.05), then returned to control (137±25 mmHg) at the end of phase I. No change in Pd occurred in phase I. Both Ps and Pd remained unchanged in the following 92±29.8 s (phase II), then linearly increased in the successive 122±45.8 s (phase III). At the end of apnoea Ps and Pd were, respectively, 224±50 mmHg and 117±23 mmHg. Pm was significantly increased by 18 mmHg above control (95.1±12.7 mmHg) at the end of phase II and further increased to 152±30.2 mmHg during phase III. For the entire apnoea, SV was unchanged compared to control (93.0±32.7 ml), whereas Q' was 30% lower (p<0.05) than control (7.7±3.1 L/min). TPR doubled compared to control value (13±5.4 mmHg/L/min) at the end of phase II (p<0.05) and further increased by 50% at the end of phase III. Holding the breath while resting water immersed induced a rapid bradycardia, that corresponds to that described as diving reflex, but was not associated with changes in Ps II till the end of phase II. We conclude that: a) cardiac and vascular responses during immersed apnoea are distinct; b) bradycardia is not compensated for by an increase in SV; c) chemoreceptor stimulation may induce the vascular responses observed in phase III.

PROLONGED ENDURANCE EXERCISE IS ASSOCIATED WITH A REDUCTION IN FEMORAL, BUT NOT BRACHIAL, FLOW-MEDIATED VASODILATION

Dawson, E., Black, M., Jones, H., Hopkins, N., Shave, R., George, K., Wilson, M., Whyte, G., Green, D. 
Liverpool John Moores University, United Kingdom

Repetitive increases in shear stress on the vessel wall (endothelium) are associated with exercise training as an established stimulus for significant and positive adaptations in endothelial function and vascular health. Despite this, surprisingly little is known about the acute effects of exercise and associated shear stress elevation on endothelial function. Specifically there are no data describing endothelial function in different arterial beds after prolonged intensive exercise.

PURPOSE: To measure superficial femoral and brachial artery flow mediated dilatation (FMD) in healthy male runners before and after the completion of the 2007 London marathon.

METHODS: After ethical approval and provision of written informed consent, 11 male subjects (29±4 years, mean±SD) were studied before and within 1 hour of completion of the London marathon. High resolution B-mode ultrasound assessment of the diameter of the common femoral and brachial arteries was assessed simultaneously with pulsed-wave Doppler velocity measurement of blood flow. Post-hoc analysis from rest to the maximal dilation recorded in the three minutes immediately after cuff occlusion.

RESULTS: From rest to the maximal dilation recorded in the three minutes immediately after cuff occlusion. FMD of the brachial artery did not change following exercise (5.2±2.1 to 5.2±2.0%, p>0.05), whereas femoral FMD was significantly reduced (6.9±3.5 to 4.4±3.8%, p<0.05). Resting femoral artery diameters were similar pre and post race (72.6±11.1 to 76.7±4.3 mm, p>0.05) whilst femoral FMD was significantly reduced (6.9±3.5 to 4.4±3.8%, p<0.05).

CONCLUSIONS: A single bout of prolonged intense exercise resulted in a reduction in femoral, but not brachial, vascular endothelial function, as assessed by FMD. The short and long-term consequences of these acute changes have yet to be established. The data suggest that prolonged intensive exercise can impair endothelial function, which may theoretically lead to transient increases in cardiovascular risk. The mechanisms responsible for the regionally specific impairment in function require further investigation.

ANAEROBIC PERFORMANCE IN TAEKWONDO ATHLETES DURING ENTIRE SEASON

Chung, Y.C., Lai, C.C., Chiu, Y.C., Chou, KM. 
National Taiwan College of Physical Education, Taiwan

A few studies showed that fitness level, mostly related to anaerobic power, might influence Taekwondo performance. The purpose of this study was to explore the Taekwondo athletes’ anaerobic power of lower limbs through the entire training programs. Training program consists of three periods, the preparation period, the competition period, and the transition period. Twenty two male college Taekwondo athletes with an average age of 20.6±1.6 years old, and an average Taekwondo history of 10.6±1.5 years participated in this study. A 30 second of the Wingate anaerobic test (0.1 kp/kg) and intermittent anaerobic test (0.1 kp/kg, one cycle · active for 15 seconds and then rest for 15 seconds) were performed on a cycle ergometer at each stage of training program. Intermittent anaerobic test cycle was simulated the characteristics of intermittent attacks of Taekwondo competition. Peak power, mean power and power index of the Wingate test showed no significant differences during three periods. The peak power fatigue index and average power fatigue index during the intermittent anaerobic test of the transition period was significantly lower than those of the competition period and the preparation period (p<0.05). It is suggested that the intermittent anaerobic power peaked at preparation period and competition period during entire season.

EMG RESPONSES TO MULTIPLE-SPRINT EXERCISE: A SEX DIFFERENCE?

Billaut, F. 
University of Lethbridge, Canada

It has been demonstrated that men and women display different performance and fatigability during multiple-sprint exercise [1,2]. While part of this sex difference may be attributed to muscle metabolism [2], a difference in the neural drive to the muscle may also contribute [3], but has not yet been explored during MS. The aim of the present study was therefore to analyse the impact of sex on electromyographic EMG responses to MS. Fourteen men and fourteen women performed a MS consisting of twenty, 5-s cycle sprints, separated by 25-s rest. Surface EMG of the vastus lateralis muscle was recorded during each sprint and processed to obtain one value of integrated EMG (iEMG) and median frequency (MF) for each sprint. In addition, arterial oxygen saturation was estimated (SpO2) via pulse oximetry and the rate of perceived exertion (RPE) recorded throughout the MS. Statistical analysis revealed that both relative work (96±9
The relationship between wrist angle and MGF presented like a parabola. The peak was in medium position at extension 13.1 ± 8.1 vs. women: -11.9 ± 5.2%, p=NS). No sex difference was observed for SpO2 and RPE. This is the first study to explore muscle activation pattern in sexes during MSE. While the results agree with previous data on mechanical output, they highlight that the sex-related muscle fatigue induced by MSE may also be explained by the net motor unit activity.

THE POINT OF MAXIMUM CURVATURE AS A MARKER FOR HEART RATE AND OXYGEN UPTAKE TIME SERIES

Stirling, J., Zakynthinaki, M., Sillero, M., Sampedro, J., Refoyo, I.
Technical University of Madrid, Spain

We present a method [1] for determining the time and heart rate (or oxygen uptake) after which a plateau or a slow component in the heart rate or oxygen uptake kinetics is achieved. This method is used to find the point after which the heart rate no longer continues to rapidly rise and instead follows either a steady state or slow rise (i.e. the slow component). This point corresponds mathematically to the point of maximum curvature and is found via an analysis of the curvature of a heart rate or oxygen uptake time series in response to a step like increment in the exercise intensity.

Our method is applied to the mono exponential model which is commonly used in the literature to model the response to short duration moderate exercise intensity. We then use the method to find numerical solutions for higher exercise intensities inclusive of those containing a slow component, for the model presented in [1-6].

We explain how our method will be of much use and will provide new information regarding understanding the heart rate kinetics (and oxygen uptake) in response to constant intensity short duration exercise. Finally we show how to use the point of maximum curvature to understand speeded heart rate and oxygen uptake kinetics following training.

THE EFFECTS OF GRIPPING FORCE GAIN AND EMG RESPONSES IN THE ISOMETRIC WRIST EXTENSION TRAINING

Shimose, R., Tadano, C., Tajima, T., Yono, M., Naito, Y., Sakamoto, M., Seki, H., Matsunaga, A., Muro, M.
Toho University school of medicine, Japan

[PURPOSE] Gripping force is not only dependent on the activation of forearm flexors but also role of extensors becomes important due to optimal-length of the flexors. Gripping force is also affected by coupling of the forearm and wrist position because of changing suboptimal-length of finger flexors. The activation of extensors as a synergist is important in maintaining optimum balance of tension in extrinsic finger flexors[1], and it has been reported that the excitability of extensor motor units was higher than that of flexors during gripping[2]. We hypothesized that a gain in forearm extensor force would lead to an increase maximal gripping force (MGF), because training produces higher excitability of extensors and simultaneously leads to the excitability of flexors. The purpose of this study was to investigate whether a gain in forearm extensor force induced by training affects MGF. [METHODS] Thirteen healthy adults (30±12yrs) participated in this study. We measured MGF after isometric wrist extension training for 8 weeks. Training consisted of exercise 30 times equal to 70% maximal voluntary contraction with subjects' fingers relaxed. To evaluate the effect of this training, we measured MGF and electromyographic (EMG) activity simultaneously during maximal effort with each wrist angle before and after 4 and 8weeks training. Subjects sat in an adjustable chair and put their forearm on the device with forearm neutral. They gripped the force-transducer in the right hand. Wrist angles were set every 10 degrees in flexion and extension plane. EMG activity was recorded from six forearm muscles (FCR, FCU, FDS, ECRL, ECUL, and EDC). EMG signals were calculated by root mean square EMG (rms-EMG) and mean power frequency (MPF) using a computer. [RESULTS] The relationship between wrist angle and MGF presented like a parabola. The peak was in medium position at extension and after 4 and 8weeks training. Maximum force of wrist extension increased from 123N to 236N by 110% (p<0.01), and MGF also increased from 0.46mV to 0.56mV (p<0.01). The wrist angle at the peak MGF shifted the flexed direction by approximately 6 degrees but not significantly. The rms-EMG of extensors increased from 0.46mV to 0.56mV (p<0.01), however, that of flexors tended to decrease from 0.29mV to 0.26mV (p<0.01). In contrary, MPF of flexors increased from 64 4Hz to 66 4Hz after 8 weeks, but that of extensors did not change. [DISCUSSIONS] The rms-EMG of extensors and MPF of flexors increased markedly after training of wrist extension. Consequently, MGF increased significantly by means of neural adaptation. These results suggest that gripping efficiency increased because a smaller number of flexor motor units were needed to increase gripping force. We suggest this training method as a new approach to increase gripping force.

FITNESS PROFILE BEFORE AND AFTER 15 DAYS CYCLING TOUR IN COLLEGE STUDENTS

Yang, TJ., Chiu, YC., Hung, W., Ku, SH., Chang, CK., Wu, CL.
Taiwan Sport University, Taiwan

Long haul cycling tours have been gaining significant popularity in recent years. The aim of the present study was to examine the fitness profile before and after 15 days 1000km cycling tour in college students. Nineteen college students (13 males, 6 female) were recruited from a cycling tour group. Subjects voluntarily participated in fitness tests included body composition, grip strength, back strength, and maximal oxygen uptake (VO2max) test within one week before and after the cycling tour. VO2max was tested using a graded cycle ergometer starting at 75W for male and 50 W for female and increased 25W every 3 min until volitional fatigue. Results showed that VO2max (41.3±4.9ml/kg/min, post: 46.8±3.9ml/kg/min for male; pre: 33.5±1.9ml/kg/min, post: 38.0±1.8 ml/kg/min for female), time to exhaustion (increased male: 17.8±9.9 min, female: 31.7±13.9 min), maximal output (increased male: 11.8±4.9 min, female: 24.6±12.1 %).
and fat free mass (increased male: 1.2±1.97%, female: 3.1±2.85%) were significantly increased in both genders (p<0.05). Female subjects showed decreased body weight and male showed decreased in body fat percentage (p<0.05). There were no differences in grip strength, back strength, maximal heart rate. The current study suggested that 15 day cycling tour resulted in a better aerobic related fitness in both genders.

**EFFECTS OF FREQUENCY AND DURATION OF THE VOLUNTARY WHEEL RUNNING EXERCISE ON CELLULARITY OF ADIPOCYTE AND SECRETION OF ADIPOCYTOKINES IN HYPERPHAGIC AND OBESO OLETF RATS**

Kimura, M., Machida, M., Shinozaki, T., Hosoyamada, M., Shibasaki, T.

Kyoritsu University of Pharmacy, Japan

The purpose of this study was to investigate the optimal weight reduction program for the dietary and exercise therapy. We tested about the rate of weight reduction arranged by the voluntary wheel running exercise protocol that will effect on the cellularity of adipocyte and secretion of adipocytokines.

Otsuka Long-Evans Tokushima Fatty (OLETF) rats, an animal model of hyperphagia and obesity, was used in this study (n=12, 19-week-old at the end of experiment). The rats were randomly assigned to either the 2 (17 to 19-week-old, everyday, n=4) or 4 (13 to 19-week-old, about every two day, n=4) weeks voluntary wheel running exercise or sedentary control group (n=4). The cages of both exercise groups attached freely accessible running wheels with digital revolution counters, but access to the wheel was prohibited during the sedentary period. The exercise frequency and duration were arranged and all rats weighed about 85% of control rats at the end of experimental period. The rats were provided with water and standard chow food ad libitum.

At the end of experimental period, the rats were anesthetized with pentobarbital sodium. Blood samples were collected from carotid artery. Plasma concentrations of adipocytokines and other hormonal factors were determined using ELISA kits. Adipocal fibrin samples were collected and weighed immediately after death. For the quantification of number and size of adipocyte, adipose tissue were fixed with 10% formalin phosphate buffer, and embedded in paraffin. The sectional cell diameter of adipocyte were analyzed in the hematoxylin and eosin stained tissue preparations.

Compared to control group, both exercise groups exhibited the remarkable reduction in body weight, abdominal fat pad weight, and blood leptin concentration. Compared to 2 weeks exercise, 4 weeks exercise promoted the downsizing of adipocyte in abdominal fat pads and provided the weak reduction in the value of the blood adipocytokine concentration. These results suggested that the low frequency and long duration exercise therapy is more effective for the cellularity of adipocyte and maintenance of blood adiponectin concentration compared to the high frequency and short duration exercise therapy.

**LOCAL MUSCLE ACTIVATION AND OXYGEN CONSUMPTION DURING WHOLE-BODY VIBRATION EXERCISE**

Ogasawara, R., Kobayashi, Y., Fujita, S., Ishii, N.

The University of Tokyo, Japan

Introduction : Whole-body vibration (WBV) has been suggested to activate muscle spindles and elicit a reflex contraction[1]. WBV has been shown to increase local muscle activation as measured by surface EMG[2] and whole body oxygen uptake[3] as compared with control condition, suggesting an increased muscle oxygen uptake. However, no previous study has examined the local muscle oxygen consumption during WBV. The rate of hemoglobin and myoglobin deoxygenation by near-infrared spectroscopy(NIRS) immediately after a cuff induced ischemia to reflect muscle O2 consumption[VO2mus] has been used as a quantitative measure of muscle oxidative metabolism[4]. Therefore, the aim of this study was to investigate the effects of WBV on VO2mus and EMG of vastus lateralis (VL) muscles during static squatting exercise to examine the extent of muscle activation and muscle oxygen consumption.

METHODS : Seven volunteers (age: 25 ± 3.4 years, body mass: 67.7±10.6kg, height: 172.4±5.6 cm) participated in this study. Each subject performed static squatting exercise (knee angle at 130°) on vibration platform for 210 sec with WBV and without(CON) vibration. The vibration frequency was set to 31Hz, and amplitude of vibration was 2.5mm. Last 30 sec, blood flow to a leg was occluded by inflating a cuff on the thigh to a pressure of 300 mmHg for 30 sec. VO2mus was determined by the slope of a regression line of oxygenated hemoglobin(O2Hb) immediately after the initiation of ischemia[10sec]. Muscle oxygenation status by NIRS and surface EMG[1][2][4][8] was attached freely accessible running wheels with digital revolution counters, but access to the wheel was prohibited during the sedentary period. The exercise frequency and duration were arranged and all rats weighed about 85% of control rats at the end of experimental period. The rats were provided with water and standard chow food ad libitum.

At the end of experimental period, the rats were anesthetized with pentobarbital sodium. Blood samples were collected from carotid artery. Plasma concentrations of adipocytokines and other hormonal factors were determined using ELISA kits. Adipocal fibrin samples were collected and weighed immediately after death. For the quantification of number and size of adipocyte, adipose tissue were fixed with 10% formalin phosphate buffer, and embedded in paraffin. The sectional cell diameter of adipocyte were analyzed in the hematoxylin and eosin stained tissue preparations.

Compared to control group, both exercise groups exhibited the remarkable reduction in body weight, abdominal fat pad weight, and blood leptin concentration. Compared to 2 weeks exercise, 4 weeks exercise promoted the downsizing of adipocyte in abdominal fat pads and provided the weak reduction in the value of the blood adipocytokine concentration. These results suggested that the low frequency and long duration exercise therapy is more effective for the cellularity of adipocyte and maintenance of blood adiponectin concentration compared to the high frequency and short duration exercise therapy.

**INFLUENCE OF DIFFERENT RAMP TEST PROTOCOLS ON PEAK BLOOD LACTATE PARAMETERS IN RUNNERS**

Rakovac, M., Vucelic, V., Sentija, D.

Faculty of Kinesiology, University of Zagreb, Croatia

INTRODUCTION: Peak blood lactate concentration (peak) after exhausting exercise is often considered as a measure of the anaerobic glycolytic capacity. The aim of this study was to compare peak and recovery blood lactate parameters, measured in runners of diverse running disciplines, after performing two all-out treadmill ramp tests of different duration.

METHODS: The sample consisted of 48 male runners: 10 sprinters (S, 20.5±3.0 yrs, 184.9±4.8 cm, 76.6±4.4 kg), 15 400m runners (400R, 20.0±3.5 yrs, 180.9±4.2 cm, 73.0±6.3 kg), 10 middle distance runners (MD, 18.7±2.3 yrs, 180.4±5.7 cm, 68.6±6.2 kg), and 13 long distance runners (LD, 19.5±2.7 yrs, 184.7±5.6 cm, 79.1±9.4 kg). Two-way ANOVA was used to determine differences in the measured variables between the two tests in each subject group.

RESULTS: The average test duration was 2.6±1.0 min (F05) and 13.0±2.1 min (F10). The following peak blood lactate concentrations (mmol/L) were measured after the F05-test: 15.1±1.4 (S), 14.3±1.4 (400R), 15.3±3.3 (MD), and 10.4±2.0 (LD). After the F1-test peak values were: 15.1±2.7 (S), 14.0±1.4 (400R), 13.7±2.9 (MD), and 10.9±2.4 (LD). No significant differences between the Lpeak measured after the two tests within each subject group were found. The measured time to reach peak lactate concentration (tpeak(min)) was as follows: F05-test
(2.4±1.4 [S] 3.1±1.4 [400R]; 2.0±1.1 [WD]; and 2.4±1.3 [LD]), and F1-test (1.2±0.6 [S], 1.9±1.5 [400R]; 1.8±1.4 [WD]; and 1.5±0.9 [LD]). A significant difference in \( t_{\text{peak}} \) measured after the two tests was found only in the 400R group. The \( t_{\text{peak}} \) was significantly longer after the FOS test (\( p=0.039 \)).

CONCLUSIONS: Similar peak blood lactate values were achieved in the recovery period of both test protocols used in this study, regardless of the running discipline. On the other hand, the time to reach peak blood lactate concentration was longer after the short (FOS) test in all the subject groups, reaching the statistically significant level only in 400R runners. For practical implications, the duration of an all-out incremental treadmill test does not significantly influence the \( t_{\text{peak}} \) value, if volitional exhaustion is reached within 5 to 15 minutes, approximately. Nonetheless, the timing of recovery blood sampling should be chosen with caution, and taking two or more samples may assure the acquisition of true peak lactate values.

HYPERTHERMIA INDUCES PERIPHERAL MODULATION OF NEURAL DRIVE

Racinais, S., Gaoua, N., Grantham, J.

ASPETAR, Qatar Orthopaedic and Sports Medicine Hospital, Qatar

Purpose: To investigate if the deficit in voluntary activation that occurs with hyperthermia could be partly attributed to a spinal modulation of the motor output.

Methods: 16 subjects randomly performed neuromuscular testing in an hyperthermic state (HOT, room temperature: 50°C, core temperature: 38.9°C) and in control condition (CONT, room temperature: 20°C, core temperature: 37.0°C). Neuromuscular testing was based on maximal voluntary contractions (MVC) of the plantar flexors with recording of the EMG activity of the soleus (5000 Hz, bandwidth 20 - 450 Hz, gain = 1000). The tibial nerve was electrically stimulated (square waves, 0.2 ms, 400 V) to induce muscle action potentials (M-waves) and reflex waves (H-reflex) both at rest and during the contractions.

Results and discussion: Our data showed that a passively induced hyperthermia decreased the voluntary force production [82 Nm in CONT vs 73 Nm in HOT, -11%, P < 0.05]. This decrease was associated to a decrement in muscle electrical activity (RMS, 89 microV in CONT vs 71 microV in HOT, -16%, P < 0.05) while the force/RMS ratio remained unaltered (1.1 in CONT vs 1.2 in HOT, NS). This suggests that the alterations in the ability to generate maximal force with hyperthermia are linked to motor command disturbances. This assumption was confirmed by a significant drop in voluntary activation level (VA, twitch interpolated method, 77% in CONT vs 65% in HOT, -12%, P < 0.05).

In addition, this study aimed to localise the failure in the muscle drive string. A decrement in muscle activation is not necessarily evident for failure in the cortical areas but can also be a consequence of a peripherally altered transmission of the motor drive to the muscle fibre. For the first time, our results showed that the amplitude of electrically evoked reflex action potentials are reduced with hyperthermia at rest (-44% for H-max and -48% for Hmax/Hmax ratio, P < 0.05), during low contraction (-46% for H-reflex during a contraction at 10% of MVC, P < 0.05) and during MVC (-34% for Hsup, -21% for Vsup, -9% for Vsup/Msup, P < 0.05). These data demonstrate that hyperthermia is responsible for an alteration in neural drive transmission at spinal level and possibly below.

Our results also displayed a drop in the amplitude of an electrically evoked muscle action potential (M-wave) both during contraction (Wsup, -11%, P < 0.05) and at rest (Mmax, -7%, P < 0.05). This suggests an alteration in the transmission of the motor command from the axonal branches of the motoneuron to the sarcomlemma.

Conclusion: Our results showed that a passive hyperthermia (without any exercise induced fatigue) reduced the ability to voluntary activate a muscle. For the first time, our data demonstrate that this decrement is partly linked to alterations in the transmission of the motor output at both the spinal and sarcomembranous levels.

INTERMITTENT HYPOXIA DOES NOT EFFECT ENDURANCE PERFORMANCE AT MODERATE ALTITUDE IN WELL TRAINED ATHLETES

Faulhaber, M., Gatterer, H., Haider, T., Bartscher, M.

University Innsbruck, Austria

Endurance contests at moderate or high altitude such as ski mountaineering or cycling become more and more popular; but little is known on possible pre-acclimatization schedules for these events (1,2). Therefore the aim of this study was to determine the effects of a pre-acclimatization program using intermittent hypoxic exposures on endurance performance at moderate altitude in well trained athletes.

9 male cyclists (age: 37±7 years, height 183±6, body weight 73±7 kg, peak oxygen uptake: 61±6 ml/min/kg) performed two ergometer tests at low altitude (LA) (Innsbruck, Austria, 600 m) within 4 days. The tests comprised two submaximal stages (150 W and 200 W, each for 5 minutes) for warm-up and determination of submaximal ventilatory responses followed by a 30-min time trail. The results of the better test were included into the analyses. After the pre-tests participants were randomly assigned into the hypoxia group (H) or the control group (C) in a double-blind fashion. The pre-acclimatization program comprised seven 1-hour breathing sessions (face mask, group H: FiO2=12.6 %, group C: FiO2=20.9 %, Hypoxyclean HypO2, HypoMed, Moscow, Russia). The identical test procedure was repeated (a) within 1-3 hours after arriving (MA1) and (b) after 2 nights (MA3) at moderate altitude (Obergurgl, Austria, 1970 m).

Mean power output decreased from LA (H: 3.8±0.3 W/kg, C: 3.8±0.4 W/kg) to MA1 (H: 3.5±0.3 W/kg, C: 3.6±0.4 W/kg) and increased slightly at MA3 (H: 3.6±0.3 W/kg, C: 3.8±0.4 W/kg). The diminution of power output from LA to MA1 seems to be more pronounced in H but did only reach statistical significance when LA compared to MA3 (p=0.004). We detected no differences between groups neither in submaximal ventilation nor arterial oxygen saturation during the time trials.

We can conclude that a pre-acclimatization for endurance contests at moderate altitude seems not to be advantageous when using the described protocol. One important factor could be that an increased hypoxic ventilatory response initiated by short-term exposures to high altitude (FiO2=12.6 %, 4500 m) does not increase ventilation at moderate altitude (e.g. 2000 m) (3). Further studies have to be done to get more scientific based data on possible effects and optimal pre-acclimatization protocols in this field of research.

ACUTE EFFECTS OF EXERCISE MODE (TREADMILL VS. CYCLOERGOMETER) AND INTENSITY ON THE PHYSIOLOGICAL AND PERCEPTUAL RESPONSES

Abrantes, C., Reis, V., Sampaio, J., Duarte, J.

1University of Trás-os-Montes e Alto Douro, 2University of Porto, Portugal

This study aimed to (i) identify the effect of exercise mode on the acute physiologic (cardio-respiratory and metabolic) and perceptual responses between the treadmill and the cycloergometer and (ii) identify the exercise mode effect interacting with exercise intensity. The sample comprised 20 voluntary male subjects: age=22.5±1.8years, height=177.7±7.0cm, weight=72.6±7.9kg and fat mass =7.8±1.1%.

that performed five submaximal 8 min exercise bouts, interspersed with a 10 min period of passive recovery. Exercise intensity in the
treadmill was 10, 12, 14, 15 e 16 km/h (0% gradient), and 80, 120, 160, 180 e 200 W in the cycloergometer (65-70 rpm). Data analysis was performed through a general linear model with two dependent factors (Mode and Intensity) with polynomial contrast. There was statistical significant mode effect and interaction Mode x Intensity in VO2, HR, RPP, O2 pulse. Also, we have identified variables only affected by exercise mode (VE, Systolic and Diastolic BP, RPE). The VCO2/VO2 ratio and blood lactate concentrations were not affected by the studied factors. Globally, results allowed identifying a larger exercise mode effect on the cardio-respiratory variables with higher response patterns on the treadmill, changing according to exercise intensity.

ACUTE EFFECTS OF EXERCISE MODE AND INTENSITY ON THE PHYSIOLOGICAL RESPONSES DURING SHORT RECOVERY PERIODS

Abrantes, C., Reis, V., Sampaio, J., Duarte, J.  
1University of Trás-os-Montes e Alto Douro, 2University of Porto, Portugal

This study aimed to (i) identify the effect of exercise mode on the acute physiologic (cardio-respiratory and metabolic) and perceptual responses between the treadmill and the cycloergometer and (ii) identify the exercise mode effect interacting with exercise intensity in short recovery periods. The sample comprised 20 voluntary male subjects age=22.1±8.1years; height=177.7±17.0cm; weight=72.6±7.9kg and fat mass =7.8±1.3%, that performed five submaximal 8 min exercise bouts, interspersed with a 10 min period of passive recovery. Exercise intensity in the treadmill was 10, 12, 14, 15 e 16 km/h (0% gradient), and 80, 120, 160, 180 e 200 W in the cycloergometer (65-70 rpm). Data analysis was performed through a general linear model with two dependent factors (Mode and Intensity) with polynomial contrast. There was a statistical significant exercise mode effect and interaction Mode x Intensity on EPOC, body temperature, HR, VCO2/VO2 ratio and O2 pulse. The VE, RPP and blood glucose concentrations were only affected by exercise mode. Blood lactate concentrations, Systolic and Diastolic BP values were not affected by the studied factors.

PERFORMANCE ANALYSIS OF ELITE WOMEN’S FIELD HOCKEY WITH SPECIFIC REFERENCE TO HIGH INTENSITY ACTIVITY

Macutkiewicz, D., Sunderland, C., Bussell, C.  
Nottingham Trent University, United Kingdom

Background: Field hockey is a highly competitive amateur sport with worldwide appeal, defined as a fast moving intermittent sport involving bouts of high intensity efforts, separated by periods of low intensity activity (Boyle et al., 1994). Previous studies in hockey based on single match motion analysis have demonstrated that the volume of sprinting, high intensity running and distance covered are lower in the second half than in the first half of a game (Lothian & Farrally, 1994; Boddington et al., 2002). This may be an indication that performance is inhibited in the second half due to various mechanisms of fatigue. The aim of the present study is to develop the understanding of elite hockey through the measurement of player speed and distances during 13 international games using global satellite technology. Method. Twenty six female international hockey players (mean ± SD; age = 24.9 ± 3.1 years; height = 167.4 ± 4.6 cm, body mass = 62.4 ± 6.4 kg) volunteered for the study. Player distance and speed was recorded for a total of 13 games using a Global Satellite System (GPS) (GPSport, Fyshwick, Australia) and all players involved had regular international experience and played in out-field positions. A single GPS unit per player, positioned between the scapular plains and secured in place through the use of a harness, was used to assess match heart rate, and the distances run at particular speeds (stand: 0-0.7; walk: 0.8-5.9; jog: 6.0-10.9; run:11.0-14.9; cruise: 15.0-18.9; sprint: >19 km/h) and intensities (low:0-5.9; moderate: 6-14.9, high: >15 km/h). Data were analysed using paired t-tests. Statistical significance was accepted as P<0.05.

Results: There was no difference in mean playing time between the first and second half performances. The percentage of time at low intensity for first half performances were lower than second half performances (54.5 ± 7.4% and 56.6 ± 6.8% respectively P<0.001). Conversely the percentage of time performing moderate and high intensity activity in the first half (38.9 ± 6.0% and 6.6 ± 2.6%) were higher than the second half (37.3 ± 5.7% and 6.1 ± 2.2%; P=0.001 and P=0.003). Mean total sprint distance and the mean number of sprints declining in the second half. Differences were evident for mean sprint distance. The volume of high intensity activity during the second half has been shown to reduce, with mean total sprint distance and the mean number of sprints declining in the second half.

IMMUNE RESPONSES DURING AND AFTER CONSTANT AND ALTERNATING INTENSITY EXERCISE AROUND THE LACTATE THRESHOLD

Spanoudaki, S., Bogdanis, G., Baltopoulos, P., Baltopoulos, G., Maridaki, M.  
1Department of Sports Medicine & Biology of Physical Activity, Faculty of Physical Education and Sports Science, 2 School of Nursing ICU at KAT General Hospital, Greece

Although exercise intensity is an important determinant of the immune response during prolonged exercise (1) there is a sparsity of information regarding the effects of intensity fluctuations on the metabolic and immune responses. The purpose of the study was to investigate the changes in IL-6 and TNF-a concentration during and after prolonged continuous and alternating intensity exercise of the same mean power and duration. Ten male recreationally trained subjects (age=24.7±1.5, VO2max = 46.5±1.9% VO2max, condition I) so that the mean exercise intensity was maintained the same as in condition C. Blood samples were taken at rest, on the 30th and 60th min of exercise and 1 hour post exercise. Levels of TNF-a and IL-6 in whole blood supernatants were measured after in vitro LPS stimulation (Escherichia Coli). Differences between the two conditions were analyzed using two-way ANOVA with repeated measures. No significant differences were observed in TNF-a concentration between the two exercise protocols (p>0.75), but there was a significant time effect (P<0.01). TNF-a was increased from a resting value of 436.1±102.5 to 649.5±187.7
MOTION ANALYSIS AND PHYSIOLOGICAL DEMANDS IN INTERNATIONAL WOMEN’S TEAM HANDBALL

Manchado, C., Navarro, F., Pers, J., Platen, P.
University of Alicante, Spain

Introduction: Handball is a sport characterized by repeated accelerations, sprints, jumps, rapid changes in movement directions and a high number of direct contacts towards opponents. Due to changes in rules and new tactical strategies, international female handball has increased enormously in dynamics, velocity and intensity in the last years. Probably, the physiological demands of the players increased accordingly. The main aim of the present investigation was to analyze movement patterns during the match and their corresponding physiological reactions in top-level female handball players.

Methods: 25 elite handball players from Germany (n=11) and Norway (n=14) of different positions (3 goalkeepers (GK), 12 back, 10 wing and pivot (field players, FP)) agreed to participate (age: 25.2±2.8 years; height: 175.2±6.3 cm; weight: 67.8±4.9 kg.; VO2max: 53.1±4.8 ml/min/kg; HRmax: 194.8±5.2 l/min, V4: 3.6±0.25 m/s). The analysis of run distances and velocities was done with the software "Sagit", using virtually modified videos. Heart rates (HR) during the matches were recorded with the POLAR TEAM SYSTEM. Run velocity corresponding to 4 mmol/l blood lactate (lactate threshold) was determined during an incremental field test according to the method of Mader. Maximal oxygen uptake (VO2max) was determined by means of an incremental treadmill test.

Results. Mean HR during the match was about 86% of HRmax. For more than 90% of playing time it was higher than 85% of HRmax. With the exception of GK, who had lower values, no position-specific differences could be detected. During the 1st half of the matches, players stayed in higher intensities with mean heart rates higher than 95% of HRmax for a longer time period as compared to the 2nd half of the match. Mean run distance during the match was 4614 m and varied widely between 2066 m (GK) and 5251 m (FP). Accordingly, also mean run distance per minute varied in a remarkable manner between 31.3 m/min (GK) and 69.7 m/min (FP). No significant differences could be detected between FP of different positions. Run distance per min was lower during the 2nd half of the match (65.1±18.0 m/min vs. 71.5±17.2 m/min). Differences in acceleration categories among some field players might indicate some position-specific patterns.

Conclusions: The individual physiological demands of female handball player seem to be determined by their motorial capacities and their movement patterns rather than by position-specific loads.

EFFECTS OF TIME OF DAY ON POWER OUTPUT AND THERMOREGULATORY RESPONSES DURING CYCLING OVER A SIMULATED HILLY COURSE IN THE HEAT (35°C)

Bardis, K.
Liverpool John Moores University, Liverpool, UK, Greece

The aim of the present investigation was to compare responses to sustained exercise in the morning and evening in the heat (35°C) over a hilly prolonged simulated course. Thermoregulatory responses were examined: core temperature, skin temperature, mean body temperature and mean skin temperature. In addition, power output, heart rate (H-R), rate perceived exertion (RPE), thermal comfort (T.C.) and time were examined. Eight active males (25-40 years) were instructed to work as hard as possible over the entire exercise period, with variation of pedal frequency permitted at any time. The second and third prolonged sessions were performed at 08:00 and 17:00h, and counterbalanced with at least 5 days recovery between tests. The examined variables showed no significant main effect for time of day. Mean power in the evening was greater by 9 Watts (W) in comparison to the morning exercise, furthermore, time increased by 2.8% in the evening compared to the morning. Future studies should include the examination of circadian rhythms and performance during undulating courses using each gradient period.

CARDIORESPIRATORY ANALYSIS OF BALLET DANCE EXERCISES

Rodrigues, J., Cunha, G., Follmer, B., Ribeiro, J., Oliveira, A.
Federal University of Rio Grande do Sul, Brazil

The classical ballet is a dance modality that involves many components of the physical aptitude, such as aerobic and anaerobic capacity. However it has been observed that the performance in dance brings limited stimuli for physiological adaptations related to physical fitness. Studies directed to the assessment of dancers’ VO2max have been done, which VO2max perceptual differences have been checked between dance classes (36%VO2max) and rehearsals (80%VO2max). Nevertheless, more sensitive parameters to fitness changes due to training as the ventilatory thresholds (VTs) have received little attention in dance. Therefore, the objectives of this study were: 1) to quantify the female dancers’ VO2max and their respective first and second ventilatory threshold (VT1 and VT2); 2) to describe the cardiorespiratory variables responses VO2 (ml/kg-min-1), HR (bpm) and RER (respiratory exchange rate) during the execution of nine ballet exercises sets; 3) to relate the VO2 responses in ballet exercises to ballet dancers’ VO2max and VTs. Twelve trained female ballet dancers were volunteers. VO2max, VT1 and VT2 were determined by a treadmill running progress test. Ballet session included the execution of nine exercises sets (pliés, tendus, jetés, rond de jambes, fondu, adagio, grand battlements, petit allegro, sautés). The data were evaluated in a gas analyzer MGC/CPX. The movements’ rhythm was monitored by a metronome and there was five minutes of break.
between the exercises. The VO2max values (40.2 ± 2.2) suggest a low aerobic power in ballet dancers. VO2VT1 and VO2VT2 were respectively 17.3 ± 1.8 and 30.6 ± 2.4. The VO2 in ballet exercises showed the following crescent order: tendus (17.5 ± 1.8); plies (17.6 ± 1.6); adagio (20.3 ± 2.9); ronde de jamb (21.8 ± 3.1); fondus (22.1 ± 1.8); jetés (22.9 ± 2.0); sautés (24.5 ± 2.4); petit allegro and grand battement (23.8 ± 2.9). There were differences in HR values from sautés (168.9 ± 7.5); fondus (166.6 ± 13.4) and grand battements (172.2 ± 12.0) to tendus (148.8 ± 16.1). RER’s value of sauté (1.1 ± 0.06) was higher than other exercises. Tendus and plies were near to VT1; adagio, ronde de jamb, fondus and jetés between VT1 and VT2, sauté, petit allegro and grand battement were close to VT2. The relations of VO2 in ballet exercises with ballet dancers’ VO2max and VTs allows a direction to elaborate parallel trainings with classes’ routines, using those with intensities related to expected goals.

WEEKLY MONITORING OF SALIVARY IGA RESPONSE DURING A WINTER SWIMMING TRAINING SEASON: IMPLICATIONS FOR UPPER RESPIRATORY TRACT INFECTIONS SUSCEPTIBILITY

Rama, L., Alves, F., Rosado, F., Teixeira, A.
Faculty of Sport Sciences and Physical Education, Coimbra University, Portugal

Objectives
In spite of a number of studies focusing the potential relationship between the fatigue imposed by systematic training in endurance sports and immunodepression and higher risks of contracting upper respiratory tract infections (URTIs) remains unclear. The aim of this study was to evaluate the influence of the training loads on the immune status, expressed by changes in salivary IgA concentration and secretion rates, and the predispositions for URTI occurrence, on a group of well-trained swimmers during a competitive swimming winter season.

Methods
19 well-trained national level swimmers (13 men and 6 women, age: 16.46 ± 1.29 years old) were recruited for this project. The training volume and intensity, as well as participation on competition, were monitored during 29 weeks of a winter season. Before the beginning of the research as well as on a weekly routine, saliva samples were collected to access salivary IgA concentration (sIgA), determined by ELISA. IgA secretion rate (srIgA) was computed from saliva flow rate. All the upper respiratory tract infection (URTIt) episodes that occurred during the study period were documented using daily logs.

Results
No significant differences were found for sIgA and srIgA values between genders. The association between training load and sIgA showed a negative trend, more pronounced with the increment of the volume. Although the high variability of sIgA values, a small but significant correlation was found between mean weekly volume and mean sIgA concentration (r=-0.150, p=0.001) and mean srIgA (r=-0.183; p<0.001). The pre-season values of sIgA correlated well with the mean weekly sIgA during the study (r=0.488, p=0.034). sIgA values tend to be significantly depressed in association with high training loads and after intense participation in competition. Reduction of training load was related to the elevation or return of sIgA values to typical pre-season ones. During the study period 21,1% of individuals did not register any URTI episodes and 31,6% recorded more than 3 URTI episodes. The pre-season sIgA concentration and secretion rate values were unable to predict the predisposition for URTI occurrence, but most of the URTI episodes (51,3%) occurred at a sIgA- lower-ed condition, and a statistically significant correlation was found between sIgA concentration and the URTI episodes number (p=0.501, p=0.006).

Conclusion
More than the intensity, the volume of swimming training load seems to affect the sIgA response. Lower values of sIgA and srIgA seem to be related to predisposition to URTI. The high interindividual variability of sIgA and srIgA values, in connection to the verified occurrence of immunodepression as a chronic effect of exercise training, seems to justify an individual surveillance using these markers.

IMPACT OF DRINK FLAVOUR AND COMPOSITION ON VOLUNTARY FLUID INTAKE AND THE PHYSIOLOGICAL AND BEHAVIOURAL RESPONSE TO RECREATIONAL EXERCISE

Peacock, O., Stokes, K., Thompson, D.
University of Bath, United Kingdom

Many physically active adults take part in exercise moderately dehydrated and typically fail to consume sufficient fluids during exercise to replace losses. This has been associated with more negative changes in psychological affect, and could influence adherence to an exercise programme. This purpose of this study was to investigate the impact of drink flavour and composition on voluntary fluid intake and selected physiological and behavioural responses to a typical recreational exercise session.

Twelve recreationally active men aged 26 ± 1 years (mean ± SEM) completed three trials in a randomised, counterbalanced design. Each trial was performed in temperate conditions and consisted of three 20-min bouts of exercise at 75% of HRmax on a treadmill, cycle ergometer and cross-trainer, respectively. Participants then completed 4 sets of 10 repetitions at 75% of 1RM, for chest and leg press resistance exercises, followed by 20 min of seated recovery. In each trial, participants either had ad libitum access to water (W), a lightly flavoured hypotonic 2% carbohydrate-electrolyte solution (CES), or had no access to fluids (NF). Urine samples were collected on arrival for analysis of osmolality and to ensure eurhodoxy at baseline. Core temperature, oxygen uptake, fluid intake and nude body mass were recorded at regular intervals. Taste preferences were recorded using a 9-point category scale, whilst ratings of pleasure were determined using an 11-point scale with anchors ranging from very bad (=1) to very good (=5). Venous blood samples were drawn pre- and post-exercise and post recovery.

Fluid intake was greater with CES than W (1706 ± 157 vs. 1711 ± 152 ml; P < 0.01). The change in body mass during exercise was greater with NF than the other two trials (NF vs. W vs. CES: -1668 ± 73 vs. -700 ± 99 vs. -273 ± 78 g; P < 0.01). This was equivalent to a greater percentage change from pre-exercise body mass with NF than either fluid trial (NF vs. W vs. CES: -2.13 ± 0.09 vs. -0.91 ± 0.14 vs. -0.34 ± 0.10%; P < 0.01). Plasma volume was better maintained throughout trials with CES relative to NF, but was not different to W (CES vs. NF: -4.41 ± 0.73 vs. -6.96 ± 0.95%; P < 0.05; vs. W: -4.99 ± 1.26%). Plasma glucose concentration was greater throughout trials with CES.
relative to NF or W (CES vs. NF vs. W: 4.26 ± 0.12 vs. 4.06 ± 0.08 vs. 3.97 ± 0.10 mmol·L⁻¹, P < 0.05). Ratings of pleasure were more positive with CES than during the other two trials (CES vs. NF vs. W: 2.72 ± 0.23 vs. 1.09 ± 0.20 vs. 1.74 ± 0.33, P < 0.01), whilst ratings of drink flavour were greater with the CES than W (CES vs. W: 7.0 ± 0.3 vs. 4.9 ± 0.5, P < 0.01).

The lightly flavoured hypotonic carbohydrate-electrolyte drink promoted greater voluntary fluid intake and was more effective than water in maintaining fluid balance and enhancing feelings of pleasure during a simulated recreational exercise session. Supported by a research grant from GlaxoSmithKline, Consumer Healthcare (UK).

EXHAUSTIVE EXERCISE: INDUCED OXIDATIVE STRESS CAUSES INTESTINAL MITOCHONDRIA DISORGANIZATION

Nouailhetas, V., Rosa, E.F., Freymüller, E., Aboulafia, J.
Universidade Federal de São Paulo, Brazil

Introduction. Exhaustive exercise (EE) is associated with oxidative stress, which can induce adverse effects on health. It was recently demonstrated that intestine is quite susceptible to EE, but these effects were poorly understood. We thus investigated the effects of EE on ultra structure of ileum myocytes and the possible relationship with oxidative stress. Methods. C57BL/6 mice were divided in control (CT), exercised for 4 (E4), and 10 days (E10), and supplemented control (CT-V), and supplemented and exercised for 4 (E4-V) and 10 days (E10-V). EE program consisted of a daily treadmill running session at 85% of the maximum velocity until exhaustion. Animals were supplemented with intraperitoneal injections of vitamins C and E, 2h before the running session. Morphologic alterations were analyzed by transmission electron microscopy. Ileum oxidative stress was assessed by protein carbonyl content and total antioxidant capacity. Results. Ten days of EE causes mitochondrial disorganization of intestinal myocytes, which was accompanied an increase about 115% in the intestinal protein oxidation, and a reduction of 36% in the intestinal total antioxidant capacity compared with the control group. These effects were totally prevented by vitamins C and E supplementation. The E4 group did not differ from the control animal group. Conclusion. Altogether these results suggest that the mitochondrial damage caused by 10 days of EE, but not after 4-days, is tightly related to the exercise-induced tissue oxidative stress.

CHANGES IN LEUCOCYTE AND LYMPHOCYTE SUBPOPULATIONS AND UPPER RESPIRATORY TRACT INFECTION SUSCEPTIBILITY IN ELITE SWIMMERS DURING A TRAINING SEASON

Rama, L., Teixeira, A., Azevedo, S., Paiva, A., Alves, F.
Faculty of Sport Sciences and Physical Education, Coimbra University, Portugal

Objectives
Seasonal variations in training loads influence on the immune status of athletes undergoing systematic and heavy training programs is not well established yet. The aim of this study is to verify the variation basal values of leukocytes, B, T and NK lymphocytes in well trained swimmers during a competitive season.

Methods
19 well-trained swimmers (13 men and 6 women, mean age 16,46 ± 1,29 years old) were recruited for this study and gave their written informed consent. The training load, volume, intensities and participation on competition events were monitored during 29 weeks of a winter swimming season. Quantification of leukocytes, B, T and NK lymphocytes was done by flow cytometry. Blood samples were taken before the beginning of training season (M1), after the first 7 weeks of incremental training load (M2), after 6 weeks of an intermediate intense training mesocycle (M3) and immediately after a major competition (M4). All the upper respiratory tract infection (URTI) episodes that occurred during the study duration were documented using daily logs.

Results
Leukocyte counts were lower in M1 than in M2 (p=0,011) and those found after the major competition, in M4 (p=0,033). The % of total lymphocytes, on the contrary, was lower in M2 then in M1 (p=0,003), in M3 (p<0,001) and in M4 (p=0,053). The T lymphocytes also decreased from M1 to M2 (p=0,011), M3 (p=0,001) and M4 (p=0,033). The % of B lymphocytes was higher at the beginning of the study and decreased M3 (p=0,025) remaining depressed in M4 (p=0,009). % of NK showed a decrease in M2 and M3 but recovered to the initial values in M4, following the decrease in training volume. The CD4+/CD8+ ratio showed higher values M2 when compared to M3 (p=0,006) and M4 (p=0,002). A higher frequency of URTI episodes occurred on the two intense training phases (M2 and M3) with four more episodes in the incremental load period when compared with the intense training cycle.

Conclusion
Production of antibodies that protects against bacterial infection may be compromised after intense periods of training and after major competition. T helper cells are recognized as activators of B cells and monocytes, and T cytotoxic cells are able to kill tumour and virus-infected cells, so lower values could also impair the immune response. The NK cells showed a decrease after major training cycles which could explain the depression in immunity as a result of heavy loads training phases. The higher incidence of URTI episodes in these phases justifies the need for immune surveillance.

DYNAMIC EXERCISE DOES NOT DECREASE AN INCREASED HAND AND WRIST VOLUME DURING VENOUS-STASIS

Yamauchi, J.
University of California, San Diego (UCSD), United States

Exercise is often recommended to use for reducing edema and further protecting against symptom of deep vein thromboemboli (DVT). However, there is no evidence to show that exercises promote to decrease an increased local limb volume while venous blood flow is obstructed. Rather, I have recently demonstrated that repetitive exercise induces an elevation of the hand and wrist volume [HWV] (Yamauchi et al. 2007, 2008). Therefore, the purpose of the study was to investigate how exercise affected to local volume of hand and wrist during venous-stasis of arm. I hypothesized that exercise would not decrease HWV, but maintain or increase accumulation of blood volume and interstitial fluid volume. Six healthy men (age, 35 ± 7 yr; height, 173 ± 6 cm; body mass, 68 ± 10 kg; mean ± S.D.) volunteered for this study. HWV was measured with a hand volumeter during rest, after the 5-minute of venous-stasis, after the following dynamic exercise with venous-stasis, followed by a 5-minute of recovery. Initially during rest, HWV was measured after the hand was passively hung for 5 minutes. Venous-stasis was created by a 14.5-cm-wide pneumatic arm tourniquet, which was inflated to 60 mmHg. Dynamic exercise was performed by repetitive squeezing and relaxation of the hand around an elastic ball at frequency of 1 squeeze/second, consisted of 6 sets of 30 seconds contractions with 10 seconds of rest between exercise bouts. A diameter of hand-sized ball was 7 cm and commercially available as a therapeutic hand ball. Also, maximum voluntary contraction (MVC) was measured with a handgrip

13TH ANNUAL CONGRESS OF THE EUROPEAN COLLEGE OF SPORT SCIENCE
EFFECTS OF A 7-DAY SUPPLEMENTATION OF ANTRODIA CAMPHORATA FOLLOWING INTENSELY FATIGUED RUNNING ON SALIVARY IGA RESPONSES

Li, TL., Lin, CH., Hsieh, CC., Kan, NB., Chen, P., Kuo, MT.

National Dong Hwa University, Taiwan

Salivary immunoglobulin A (sIgA) is secreted by the local plasma cells of salivary glands and protects against oral and nasal epithelial infections. The lower levels of sIgA have been associated with recurrent upper respiratory tract infection. The purpose of this study was to investigate the influence of Antrodia camphorata (AC) supplementation following a single bout of intensely fatigued exercise on sIgA responses.

With local ethics committee approval, twelve male volunteers (age 23.2 ± 1 years, height 1.75 ± 0.01 m, body mass 69.6 ± 2.3 kg, VO2max 50.4 ± 2.2 mLkg-1min-1, means ± SEM) participated in this study. After a preliminary trial of VO2max measurement, participants completed four main trials, which were exercise (running on treadmill at 80% VO2max until fatigue) with placebo (EP) or AC supplementation (EA) and rest with placebo (RP) or AC supplementation (RA) in a double blind crossover design after an overnight fast. The amount of AC supplementation was 200 mg kg-1 body mass per day for 7 days after exercise. Water ingestion was allowed ad libitum during the trials except for the 10 minutes preceding each saliva sample collection. Timed, unstimulated saliva samples were collected at pre-exercise (preEX), post-exercise (postEX), and 0.5 h (0.5h-postEX), 1h (1h-postEX), 2h (2h-postEX), 24h (24h-postEX), and 72h (72h-postEX) after exercise. Salivary IGA concentrations were determined by ELISA. Results were analysed using a two-factor (trial x time) repeated measures ANOVA with post hoc Tukey tests.

The main findings of this study were: (1) the saliva flow rate was significantly decreased at postEX (P<0.05) compared with preEX in both exercise trials, however, no significant differences among trials were found. (2) there were no significant changes in sIgA concentration and secretion rate among trials and timepoints. In conclusion, the findings of this study suggest that a 7-day supplementation of Antrodia Camphorata following an intensely fatigued running does not appear to affect salivary IGA responses.

CHANGE IN BLOOD PROPERTIES BEFORE AND AFTER CLIMBING OF HIGH MOUNTAINS

Kohno, T., Hujiiya, H., Yatabe, K., Terawaki, F.

St. Marianna University School of Medicine, Japan

High mountain climbing places a great deal of stress on climbers. Body composition and blood tests before and after climbing were examined in climbers who scaled 8,000m or more than two times over a two year period.

Methods

Examinations were conducted on four climbers. A (26 years old), B (27), C (28) and D (29). Body weight and body fat were measured.

Particular items involved in the blood test included measuring red blood cell count (RBC) and haemoglobin (Hb), hematocrit (Ht), serum iron, ferritin, total cholesterol, triglyceride, and total protein levels.

Results

The mean RBC (106/mm3) levels before and after climbing were 4.87±0.14 and 5.73±0.49 (p<0.05), respectively. The mean Hb (g/dl) levels before and after climbing were 15.4±0.60 and 17.6±1.3 (p<0.05), respectively. The mean Ht (%) levels before and after climbing were 45.6±0.8 and 53.0±4.4 (p<0.05), respectively. In looking at each subject on an individual basis, we found that although in three of the subjects the figures for Hb, Ht, and serum iron had all increased after high mountain climbing; in one of the subjects we were unable to find any significant changes in these indices between before- and after-ascent levels.

Discussion

In a hypoxic atmosphere, oxygen-carrying capacity decreases. Because of this, hematopoietic function becomes hyperactive to improve oxygen-carrying capacity and as a result RBC increases. In all of these two times of climbing, 4 climbers stayed at more than 2,500m for more than 60 days, and generally gained altitude during the period and finally reached more than summit of 8,000m. We did a blood test for three to four weeks after descending to less than 2,500m, and three out of four climbers had an increase of RBC compared to what they had before climbing and also had an increase in Hb, Ht and serum iron. Three to four weeks after descending the mountain, the effects of high altitudes were still apparent. Their reticulocyte count decreased after going down the mountain, which means there was no hyperactivity of the hematopoietic function at this time.

On the other hand, the fourth climber didn’t see any changes in RBC, Hb, Ht and serum iron after descending the mountain, compared to before climbing. He also didn’t have experience any changes in reticulocyte count before and after climbing. This means he didn’t have any changes of hematopoietic function in a hypoxic atmosphere. However, there was no decreased ability to exercise and he succeeded in climbing to more than 8,000m two times. This means there was no decreased ability to exercise in a hypoxic atmosphere.

Conclusions

Under low oxygen and low pressure conditions the effects of climbing activity showed themselves in the increase after climbing rates of RBC, Hb, and Ht. We did, however, see individual differences among the subjects regarding these increases.
DIFFERENCE IN PHYSIOLOGICAL RESPONSES TO INCREMENTAL EXERCISE BETWEEN HYPERCAPNIC AND HYPOXIC CONDITIONS

Kato, T., Matsumoto, T., Tsukanaka, A., Nakano, M., Ito, R., Amano, M., Matsui, N.
Toyota National College of Technology, Japan

<Introduction> The purpose of this study was to determine the difference in physiological responses to incremental exercise between hypercapnic and hypoxic conditions.

<Materials and methods> Eight healthy males volunteered to participate in the present study. Each subject performed incremental exercise until exhaustion on three occasions; 1) breathing ambient air (Air); 2) breathing hypercapnic (21% O2, 6% CO2, N2=balance) gas (HCl); 3) breathing hypoxic (12% O2, N2=balance) gas (HP). Subjects breathed ambient air, hypercapnic or hypoxic gas from 10 min before the start of exercise until the end of exercise. Exercise was conducted with an electrically-braked cycle ergometer. The initial workload was 30 Watt (W), and thereafter the workload was increased by 30 W every 2 min until exhaustion. Arterialized blood was drawn from a superficial vein.

<Results> Exercise performance time in HC and HP were significantly shorter than that in Air (P<0.05). VO2 was significantly lower in HP than those in Air and HC (P<0.05), but those did not differ between HC and HP. RER was significantly lower in HC than those in Air and HP (P<0.05). VE and ETCO2 were significantly higher in HC than those in Air and HP (P<0.05). HR was significantly lower in HC and HP than that in Air at the end of exercise (P<0.05). HR did not differ between HC and HP. Blood pH was significantly lower in HC than those in Air and HP (P<0.05). Blood PCO2 was significantly higher in HC than those in Air and HP (P<0.05). Plasma lactate concentration (La) was significantly lower in HC than those in Air and HP just after exercise (P<0.05). La was significantly lower in HP than that in Air at the end of exercise, but those did not differ between HP and Air just after exercise. Plasma ammonia concentration (NH3) was significantly lower in HC than that in Air just after exercise, but those did not differ between HC and HP. NH3 was significantly lower in HP than that in Air at the end of exercise, but those did not differ between HP and Air just after exercise.

<Conclusion> On cardiorespiratory responses, under hypercapnia, accumulation of CO2 in pulmonary alveoli and blood led the larger increase in pulmonary ventilation and a decrease in RER during exercise. On the other hand, hypoxia led a decrease in oxygen uptake during exercise. Maximum heart rate was reduced in both conditions. On acid-base status, exercise induced blood acidosis was promoted by respiratory acidosis under hypercapnia, but was attenuated by respiratory alkalosis under hypoxia. On metabolic status, accumulation of anaerobic metabolites was limited during exercise under hypercapnia, but did not differ under hypoxia in comparison with normoxia.

<Acknowledgements> This research was supported in part by a Grant-in-Aid for Young Scientists (B) from the Japanese Ministry of Education, Culture, Sports, Science and Technology (Grant No. 18700518).

INFLUENCE OF AGING ON VERTICAL JUMP PERFORMANCE IN RELATION TO DYNAMIC PROPERTIES OF LOWER LIMB MULTI-JOINT MOVEMENT

Yamauchi, J. I., Ishii, N.
University of California, San Diego (UCSD), United States

The declines of muscular power capability in lower limb are associated with impaired functional mobility in elderly individuals. There are numerous studies on aging and muscle functions, however, only few studies have demonstrated some mechanisms underling aging-related decline in vertical jump performance. No studies have ever examined aging-related changes in vertical jump performance in relation to the dynamic characteristics of lower limb multi-joint movement. It has been demonstrated that the muscle function of lower limb multi-joint movement measured with the servo-controlled dynamometer (Yamauchi et al. 2007) is profoundly correlated with the vertical jump performance (Yamauchi & Ishii 2007). Therefore, the present study was to investigate how aging influenced the vertical jump performance in women in relation to the dynamic properties of leg multi-joint movement. Two groups of women, twelve per group Y; age, 22.3±3.7yrs and E; age, 69.2±6.3yrs, means±S.D, performed three different types of vertical jump: i) a countermovement jump combined with arm swings (CMJA), ii) a countermovement jump without arm swing (CMJ), and iii) a squat jump starting from a semi-squatting position (SJ). The vertical jump heights were evaluated with force-velocity-power properties of lower limb multi-joint movement measured with the servo-controlled dynamometer. All three types of vertical jump height were significantly lower in E than in Y. CMJA was higher than CMJ and SJ, and CMJ was higher than SJ in Y, whereas in E, CMJA was higher than CMJ and SJ, but CMJ was not statistically different from SJ, suggesting that the performance difference between CMJ and SJ was diminished so as to impair full utilization of elastic component in elderly women. Analyzing the force-velocity-power properties of lower limb multi-joint movement, body weight (BW) as a resistive load for vertical jump performance was almost close to optimum load for the maximum power output in Y; however, in E, BW was heavier than optimum load. As a result of this, the velocity of the lower limb multi-joint movement at BW was lower in E than in Y. These are due mainly to the lower level of relative maximum force capacity (Force/body weight). These results indicate that decrease in vertical jump performance in elderly women was related to the development of power at less optimum force level so as to decrease velocity of the leg extension movement. Such impairment of muscle functions causes less a capability of accelerating and decelerating the mass. Therefore, to maintain maximum power ability of vertical jump performance in elderly women, it is necessary to improve the relative maximum force capacity i.e., reduce body weight and/or increase maximum force generating capacity and the ability to utilize elastic components of muscles to some extent.

TIME COURSE OF THB AND CYCLE ERGOMETER PERFORMANCE DURING 21 DAYS OF SIMULATED ALTITUDE

Clark, S., Saunders, P., Quod, M., Martin, D., Clark, M., Gore, C.
Australian Institute of Sport, Australia

Living at simulated moderate altitude but training near sea level (LHTL) is a common practice among athletes seeking to enhance sea-level performance (1), with an increase in red cell mass considered to be important (2). A dose of hypoxia equivalent to ~2500 m for >12 h/d for ~3-4 weeks is proposed as optimal for increasing red cell mass (3), but the weekly rate of accelerated erythropoiesis is unclear. Consequently the aim of the current study was to determine the time course of changes in total haemoglobin mass (THb) and cycling...
performance during 3 weeks of LHTL. 11 well-trained male endurance cyclists spent 14 h/d for 21 consecutive days, in simulated moderate altitude (3000 m) and trained at normoxia (600 m). Thb and cycling performance were measured twice before, weekly during and 1wk-post LHTL. Thb was measured using CO re-breathing (4) and cycling performance was measured using a 'power profile' test, which involved successive maximal efforts on a cycle ergometer of progressively longer duration (6s, 15s, 30s, 1 min, 4min and 10min) interspaced with progressively longer recovery periods (2 10min). Mean power (watts) was measured during each time interval using SRM chronos. Statistical analyses were performed with the log-transformed data to report the change in the mean. Precision of estimation was established using 90% confidence intervals (CI).

The mean ±SD Thbmass increased weekly (0.6±1.4%, 1.9±1.2%, 3.3±1.3%, 3.5±1.7% at wk1, wk2, wk3 and 1wk-post, respectively). Nine of the 11 cyclists exhibited an increase in Thb above their own pre-altitude value 1 wk after LHTL. Mean power increased for all time intervals except 6s, by the 3rd wk and at 1wk-post. The magnitude of these increases at the 3rd wk were 2.1±4.1% for 15s, 5.8±4.7% for 30s, 6.4±3.8% for 60s, 4.9±1.4% for 4min and 3.8±2.6% for 10min, and the corresponding increases at 1wk-post were 4.4±4.4, 6.6±6.5, 10±3.1, 9.8±2.6 and 8.9±3.0%.

For the first time, serial measurements reveal that Thb increases progressively by ~1% per wk for an optimal dose of simulated hypoxia. This result is similar to that previously observed at natural altitude (5) and supports the idea of an 'optimal dose' of hypoxia to induce physiological changes. Interestingly, improvements in performance were observed across the spectrum of time intervals including those with a high anaerobic contribution suggesting factors other than increased red cell mass may be contributing to performance improvements. However, the practical ability of athletes to combine training while accumulating 14 h/d using simulated altitude to obtain this optimal dose may be difficult and therefore limit the benefits achievable using simulated LHTL.

**EFFECT OF AGONIST AND ANTAGONIST EMG ACTIVITY DURING SIMULTANEOUS MOVEMENTS OF ELBOW AND WRIST**

Seki, H., Yona, M., Tadano, C., Tajima, T., Shimose, R., Naito, Y., Muro, M.
Niigata University of Management, Japan

Introduction: Recently, many studies in the control of arm-movements have shifted from single to multi-joint movements in human. Interactions of multi-joint movements are influenced change of kinematics, changing the timing of joint movement onsets and EMG activity. Changes in muscle activity and EMG onset during multi-joint movements in comparison with single-joint movements are less clear. The present study was to clarify the kinematics of multi-joint movements of elbow and wrist at fast- and slow-speeds.

Methods: Right-handed five normal subjects [25-60 years] with no known history of motor system disorders participated in this study. We did informed consent about the experimental aim and risk to all subjects. Experimental posture was seated in a chair and shoulder was supported on the trunk with the forearm supine position. All subjects performed simultaneously elbow flexion movements accompanied by wrist flexion or wrist extension in a tracking paradigm using visual feedback of oscilloscope (CRT) including two bar-beams of forearm- angle and target position. Fast and slow movements are to move fast and accurately and two seconds attainment between the target bars, respectively. Target amplitude of elbow flexion was 45° and 90°, and range of wrist movement was full flexion and extension. In addition, other task was each movement at weight holding of dominant-hand (500g). Each movement was performed 10 practices and interval of rest was after rest for five minutes. During some movements, angle of joint (wrist, elbow) and EMG (BB, TB, FCU, ECR, deltoid) were measured in all experimental conditions.

Results and Discussion: When subject perform forearm movement, elbow-flexion preceded more than onset of wrist in unidirectional fast movement of 90° amplitude. Conversely, wrist-flexion preceded more than onset of elbow-flexion in unidirectional slow movement of 90° and 45° amplitude. EMG activity was significant correlation between agonist (biceps) and antagonist muscles (triceps) of upper-arm in unidirectional and bidirectional fast movements. However, there was no significant correlation in slow movement. During handhold of weight EMG activity was significant correlation between both muscles in unidirectional and bidirectional slow movements of 90° and 45° amplitude. Similarly, EMG activity was significant correlation between agonist (biceps) and synergist muscles (deltoid) in unidirectional fast movement of 90° and 45° amplitude. In contrast, EMG activity was significant correlation in unidirectional and bidirectional slow movement. These results suggest that EMG activity of agonist and antagonist muscles in elbow movement related to direction of wrist movement and to speed of elbow movement.

**CONTRALATERAL STRENGTH FACILITATION DURING ATTEMPTED HIGH VELOCITY MOVEMENTS**

Groeller, H., Sampson, J., Taylor, N.
University of Wollongong, Australia

Neural mechanisms are thought to be responsible for contralateral strength gains following unilateral resistance training. We hypothesised the elevated motor drive associated with explosive exercise may produce increased contralateral facilitation, but in the absence of repetition failure. Therefore, we investigated neuromuscular adaptation of contralateral biceps brachii in untrained males (N=29) using three elbow-flexion (60°-160°) treatments: C controlled 2-s eccentric and concentric to repetition failure, in contrast EC attempted explosive concentric and eccentric without repetition failure, performing 31% less work than C. Each group exercised 3 days per wk for 12 wks at 85% of one repetition maximum (IRM). Strength was assessed isometrically (90°) and dynamically via a IRM elbow flexion task. Filtered electromyographic (EMG) data were sampled at 2 kHz (Digitimer, Neurolog). Peak and average root mean square (RMS) and mean frequency (MF, Spike 2 Ver5.13) were calculated over scrolling 250 ms windows with a 50% overlap. Data means ±SE with alpha set at 0.05. Dominant limb mean IRM and MVC strength gain for all groups was 30.7% and 13.3% respectively, with no significant between-group differences. Contralateral limb IRM strength increased significantly SSC 17.6% (3.0 ±0.8 kg), EC 13.4% (2.75 ±0.5 kg), C 12.2% (2.13 ±0.4 kg), again with no differences between groups. Relative to IRM dominant limb strength gain, contralateral limb strength gain, increased by 57.2% (SSC), 45.3% (EC) and 37.2% (C), differences were not significant. The explosive exercise groups recorded significantly greater IRM contralateral peak RMS (SSC 13.43 ±10.4%, EC. 8.34 ±5.1%) and mean biceps RMS (SSC 28.6 ±9.4%, EC. 7.66 ±5.1%) compared to C-18.0 ±7.1% and 11.5 ±3.3%. Isometric strength increased in SSC (20.12%, 15.73 ±6.2 Nm) and C (14.10%, 9.93 ±3.5 Nm), but not EC (-0.36%, -0.63 ±3.8 Nm). The cross-over effect observed within this investigation has been proposed to be due to cortical mechanisms, postural stabilisation or familiarity with the test procedures (Munn et al. 2005). Despite the absence of repetition failure and a significant reduction in total work, the attempted explosive exercise groups were equally effective in facilitating contralateral strength gains compared to C. This suggests cortical mechanisms, via increased motor drive, may be responsible for the adaptations observed.
Cyclosporine (CsA) is an effective immunosuppressive agent widely used to prevent allograft rejection and chronic inflammation in clinical practice. CsA exerts its immunosuppressive action by interfering the activation and proliferation of T cells. There is growing evidence that regular exercise can increase immune function. Patients taking CsA may be benefit from regular exercise in improving cardiovascular and musculoskeletal functions. However, the effect of exercise on immune functions in patients who are taking CsA is unclear. The aim of this study was to measure the interactive effect of CsA administration and regular exercise on the functions of immune cells in mice. Fourty-eight adult female BALB/c mice were randomly assigned to one of the 6 groups: 0-Ex (no CSA, no exercise), 0+Ex (no CSA, exercise), 10-Ex (10 mg/kg/d CSA, no exercise), 10+Ex (10 mg/kg/d CSA, exercise), 20-Ex (20 mg/kg/d CSA, no exercise), 20+Ex (20 mg/kg/d CSA, exercise). The 3 exercise groups were trained 3 times a day at approximately 75% VO2max for 6 weeks. Nitric oxide and interferon-gamma production abilities by mitogen-activated macrophages and spleen cells respectively were higher in 20+Ex group comparing to 20-Ex group. The proliferation of mitogen-stimulated spleen cells was not significantly different between the exercise and non-exercise groups receiving the same dose of CSA. The results of this study indicated that in lower dose of CsA, regular exercise had no effect on immune function in mice. However, regular exercise may enhance immune function in mice receiving higher dose of CsA.

**MODERATE FITNESS DOES NOT AFFECT SHORT-TERM HEART RATE VARIABILITY AND BAROREFLEX SENSITIVITY IN HEALTHY MALES**

Davis, G., Groeller, H.

The University of Sydney, Australia

Considerable scientific research has pointed to the clinically beneficial effects of increased beat-to-beat heart rate variability (HRV) and vagal tone for reducing the risk of cardiac morbidity. Alterations in HRV and modified cardiac parasympathetic modulation in individuals with disease, obesity, and during acute exercise have been observed by previous investigators. Evidence obtained from cross-sectional research designs have demonstrated that increased physical fitness elevates HRV, while lowering the resting heart rate in healthy individuals. This investigation had two primary aims: i) to investigate the effect of physical fitness on time- and frequency-domain indices of HRV, and, ii) to determine the effect of graded orthostatic stress on autonomic control in healthy young men of differing physical activity and fitness levels.

Nineteen male subjects, 8 of lower activity (LA) and fitness (VO2peak: 44.0 ± 1.1 ml/kg/min) and 11 higher activity (HA) and fitness (VO2peak: 60.5 ± 2.7 ml/kg/min), aged 23.8 ± 1.8 y and 24.0 ± 1.5 y, respectively, volunteered to participate in this study. Each individual was required to rest supine for 20 minutes prior to collection of RR-intervals and beat-to-beat blood pressures (from fingertip photoplethysmography) for 520 cardiac cycles during entrained breathing. Graded incremental lower-body negative pressure was applied at 0, -15, -30 and -45 mmHg for 520 cardiac cycles. Time- and frequency-domain indices of HRV and spontaneous baroreflex sensitivity were determined at rest and during each level of lower-body negative pressure. Resting HR was significantly lower in HA (58.6 ±2.5 b/min) than LA (66.9 ±2.4 b/min). However, no significant differences were observed between the groups in time- and frequency-domain indices of HRV and baroreflex sensitivity at rest or during lower-body negative pres-
To examine the pacing of an 800 m running race, six collegiate male middle distance runners performed maximal bicycle exercises for 2 min, and the relationships of total work to energy of the exercise and muscle fiber composition were determined. They carried out the maximal exercise four times, and the total work was calculated from the number of wheel revolutions, while oxygen uptake and oxygen debt were obtained by collecting expired gas in a Douglas bag at rest, during exercise and during recovery. At first, the subjects performed the maximal exercise imagining their pace in an 800 m race (Control). Then, they performed the exercise at work during the first 1 min of 95% (SF), 100% (Steady) and 105% (FS) of one half of the total work for 2 min in the control. During the second 1 min, the subjects performed the exercise with maximal effort. The order of the trials was counter-balanced. In another experiment, they performed 50 maximal knee extensions at the load of 180 degree/sec, from which their percentages of fast twitch fibers (%FT) were estimated. There was a significant negative correlation between personal 800 m record times and the total work of the 2-min maximal bicycle exercise (r = 0.931, p < 0.01). The total work was the greatest in the FS trial, but was not significantly different from the other trials. However, the total work in the five of the six subjects was the greatest in the FS trial. The total work was significantly correlated with oxygen requirement (r = 0.502, p < 0.05) and oxygen debt (r = 0.467, p < 0.05), which were the highest in the Steady trial. There were significant correlations between %FT and percentage of work during the first (r = 0.838, p < 0.05) and the second (r = -0.838, p < 0.05) 1 min, when maximal total work was achieved. Performance in maximal bicycle exercise for 2 min by middle distance runners is an indicator of their 800 m run records. Performance is influenced by %FT fibers and can be improved when work during the first 1 min is increased by 5% of one half of the total work.

EFFECTS OF WALKING VELOCITY ON THE CARDIAC AUTONOMIC NERVOUS SYSTEM ACTIVITY DURING TREADMILL WALKING

Komiyama, M., Nismura, K., Onodera, S.
Kawasaki University of Medical Welfare, Japan

Introduction: The purpose of this study was to investigate a relationship between the walking velocity and the cardiac parasympathetic nervous system activity during treadmill walking on land and in water.

Methods: Experiment1Eight healthy Japanese males voluntarily participated in this study. Their mean age, height, body weight and % body fat were 22.1±1.8 years, 169.9±6.9 cm, 64.7±6.4 kg and 15.0±3.2%, respectively. After resting for 5 minutes in a standing position, subjects walked on the treadmill for 45 minutes with the progressively increasing and decreasing its velocity by 2, 3, 4, 5, 4, 3, 2 and 1km/h; each stage continued for 5 minutes. After the exercise, they rested for 10 minutes in a standing position. The room temperature and room humidity were 25.4±1.2 degrees Celsius and 36.8±8.0%, respectively. Heart rate, cardiac autonomic nervous system activity and oxygen uptake were measured. Experiment2Subjects who participated in the experiment 1 also voluntarily participated in this study. The room temperature and room humidity were 25.6±0.5 degrees Celsius and 73.6±3.3%, respectively. After resting for 5 minutes in a standing position, subjects walked on the treadmill for 45 minutes with the progressively increasing and decreasing its velocity by 2, 3, 4, 5, 4, 3, 2 and 1km/h; each stage continued for 5 minutes. After the exercise, they rested for 10 minutes in a standing position. The room temperature and room humidity were 30.6±0.2 degrees Celsius and 36.0±3.3%, respectively. Water temperature was 30.6±0.2 degrees Celsius. Subjects had a rest for 5 minutes in a standing position on a land and had a rest for 5 minutes in a standing position in water. Then, they walked on the treadmill for 45 minutes. After the exercise, they rested for 10 minutes in a standing position in water. The measurement items were the same as experiment 1. All subjects were not allowed to drink caffeine components on the experiment day. Also, they ate nothing for three hours before the experiment. All subjects signed the informed consent forms before the experiment.

Results:Experiment1Heart rate and oxygen uptake increased with the gradual increase in the walking velocity and decreased with its gradual decrease (ANOVA: P<0.05). LogHF decreased with the gradual increase in the walking velocity and increased with its gradual decrease (ANOVA: P<0.05). Exercise intensity was equivalent to 3.7 METS during the treadmill walking on land of 5 km/h. Experiment2Heart rate and oxygen uptake increased with the gradual increase in the walking velocity and decreased with its gradual decrease (ANOVA: P<0.05). Exercise intensity decreased to 5.5 METS during treadmill walking in water of 5 km/h.

Discussion: Heart rate was increased by the inhibition of cardiac parasympathetic nervous system activity during the gradual increase in the walking velocity. Heart rate was decreased by the hyperactivity of cardiac parasympathetic nervous system activity during the gradual decrease in the walking velocity. These data suggest that changes of cardiac parasympathetic nervous system activity depend upon the walking velocity during treadmill walking on land and in water.

HUMAN CORE TEMPERATURE RESPONSES DURING EXERCISE AND SUBSEQUENT RECOVERY: THE INTERACTION BETWEEN MEASUREMENT SITE AND TIME OF DAY

Gregson, W., Morris, C., Drust, B., Marrin, K., Atkinson, G.
Research Institute for Sport and Exercise Sciences, United Kingdom

Background: Oesophageal temperature [Tes] is considered the gold standard site for measurement of core body temperature in exercising humans due to its high sensitivity to changes in central blood temperature. Both rectal (Trec) and intestinal temperature (Tit) measured with an ingestible temperature sensor, provide valid measures of core temperature during extended periods of exercise and recovery. The validity of these measures is, however, questionable under conditions were rapid changes in core temperature occur. Moreover, the
rate of increase and decrease in core temperature may be subject to diurnal variation, depending on measurement site (Waterhouse et al., 2005). Therefore, we present the first comparison of Tes, Trec and Tit during exercise and recovery at different times of day.

Methods: Seven healthy male subjects (age, 27 ± 5 years) completed 30 min of cycling at 70% of maximal oxygen uptake followed by 30 min of rest at two times of day (08:00 h and 17:00 h). Tes and Tit were continuously assessed during exercise and recovery. Tit was measured using an ingestible telemetric pill ingested eight hours before arriving at the laboratory. Heart rate, skin temperature, ratings of perceived exertion and total sweat loss were also measured. Data were analysed using a three-factor (condition x time x site) within-subjects general linear model (GLM).

Results: Tes (37.16°C, s=0.45) was significantly lower than Trec (37.35°C, s=0.48) and Tit (37.45°C, s=0.51) across the entire protocol (P<0.01). This difference was, however, dependant on exercise/recovery time due to the greater rate of change in Tes relative to Tit and Trec (P<0.001). The relationship between measurement sites, particularly Tes and Tit, was also influenced by time of day with greater differences noted in the afternoon (37.27, ±0.44, 37.52, ±0.44, 37.67, ±0.48) compared to morning (37.06, ±0.45, 37.19, ±0.47, 37.22, ±0.42). Differences between Trec and Tit sites were not significantly different (P=0.083). The rate of change in core temperature during the afternoon (0.01°C.min⁻¹, s=0.0037) and afternoon (0.0074°C.min⁻¹, s=0.0054) was similar regardless of measurement site (P=0.67). Core temperature was significantly lower throughout the morning trials (37.15°C, ±0.45) compared to the afternoon (37.48, ±0.48; P=0.0032). This difference (exercise and recovery) was greater for Tit (0.45°C, ±0.32) compared with Trec (0.33°C, ±0.24) and particularly Tes (0.2°C, ±0.21) (P=0.019).

Conclusions: The present findings suggest the rate of change in core temperature during exercise and recovery is not influenced by time of day, however, the absolute value of core temperature is over estimated by Tin compared to Tes and Trec in the afternoon. This greater time of day difference may be related to the circadian rhythm in gastrointestinal motility (Goo et al., 1987).

CHANGES IN FORCE OUTPUT OF HUMAN MUSCLE FIBERS DURING REPETITIVE ACTIVATION AT PHYSIOLOGICAL RATES

Kamo, M., Morimoro, S.
Japan Women’s College of Physical Education, Japan

Introduction: The spike interval of MU gradually elongated from several seconds to minutes during even constant force contraction in a wide range of developed force levels. To account for the maintenance of constant force during spike interval elongation, some researchers have implicated the potentiation of muscle fibers developed force. However, the electrical stimulus rates used in human experiments are higher than the discharge rate during voluntary submaximal constant force contraction.

Methods: Six healthy adult subjects participated in the study. They sat with hip and knee joints fixed at 90 deg. and with an ankle fixed to record force. The vastus medialis muscle was stimulated with constant intensity at its motor point. The stimulus duration was 1ms. To determine the stimulation intensity, we obtained the relationship between the time to the peak of twitch (CT) and stimulus intensity. Furthermore, we used the minimum level of stimulus intensity at which the CT became constant despite the intensity increased. This intensity was within the pain tolerance of subjects during tetanic stimulation at low frequencies [10 Hz]. Two patterns of stimulation were delivered at constant intensity. One was constant frequency stimulation for 3 min: 5 Hz, 6.7 Hz, 10 Hz, and 20 Hz. Another was brief stimulation for 1 s and 30 s at 10 Hz. We investigated the twitch response before and immediately after the brief stimulations.

Results: We observed potentiation of the force during electrical stimulation at all frequencies. The evoked force showed respectively two peaks and one peak during 10 Hz and 20 Hz. These patterns of change correspond to our previous results. The rate and duration of the potentiation at 10 Hz was larger and longer than that at 20 Hz. The peak force (PF) of twitch tended to increase and CT shortened significantly after stimulation at 10 Hz for 1 s. However, PF significantly increased and CT shortened no change after 10 Hz for 30 s.

Conclusion: Potentiation is expected to contribute to the elongation of the MU spike interval during voluntary contraction. Furthermore, this effect in MU at low activity level might be larger than that at the high activity level. Moreover the two peaks of the force in MU at low activity level might result from different mechanisms. This work was partially supported by the Academic Frontier Project of JWCPE.

EFFECTS OF EXERCISE TRAINING ON PLATELET FUNCTION AND PLASMA TOTAL ANTIOXIDANT STATUS

Zergeroglu, A., Ficicilar, H., Erdogan, A., Tekin, D., Ozdemir, S., Ersoz, G.
Ankara University Medical School, Turkey

It is clear that platelets implicated in the pathophysiology of variety of conditions including coronary heart disease. Therefore prevention of enhanced platelet activation is one of the major targets of therapeutic strategies. Although no valid conclusion can be drawn on the effects of physical training on platelet functions, results of some recent studies have clearly shown that long term physical training of moderate intensity reduces platelet activations both at rest and in response to intense exercise. On the other hand, causing oxidative stress, exercise changes redox status of the plasma which may also interfere platelets, and antioxidant defenses of the body appear to be modulated by the state of physical training.

Preliminary Data: Male Sprague-Dawley were randomly assigned to two experimental groups: 1) control, 2) exercise. The protocol for the acute exercise bout was 30 min, 0% grade, for 60 min, which elicits a workload of approximately 65% maximal oxygen consumption.

Exercise decreased plasma TAS (p<0.05). This finding indicates that the host was unable to deal effectively with the increased free radical load due to the exercise.

PURPOSE: The present study was undertaken to seek whether a short-term training protocol is capable of increasing plasma total antioxidant status (TAS) and desensitising platelets and elucidate a possible relationship between plasma TAS and platelet responsiveness.

METHODS: Adult male Sprague-Dawley rats were randomly divided into short-term training and control groups. Rats in the short-term training group were subjected to an exercise protocol consisted of three bouts of treadmill running on three consecutive days for 30 min at 25 m/min. Blood samples were taken twenty four hour after the end of last bout of exercise. ADP and collagen-induced maximal platelet aggregation rates and platelet ATP release were measured in the whole blood using an aggregometer. Plasma TAS were measured in plasma according to Miller’s method. RESULTS: Composed with control group, trained rats had higher plasma TAS and lower ADP-induced platelet ATP release (p<0.05). A negative correlation was seen between plasma TAS and ADP-induced ATP release from platelets. Exercise protocol did not elicit any statistically significant changes in aggregation response and collagen-induced ATP release. CONCLUSION: Findings of the study suggest that even short-term training may enhance antioxidant defenses in plasma and this improvement, not enough to inhibit aggregation may play a role in incomplete desensitising of platelets.
EFFECT OF LOW INTENSITY ECCENTRIC EXERCISE ON OXIDATIVE STRESS AND ANTIOXIDANTS IN RAT SKELETAL MUSCLE
Chigaya, T., Tajima, T., Shimose, R., Yona, M., Seki, H., Nito, Y., Muro, M.
Toho University, Japan

[Introduction] Eccentric exercise frequently induces development of muscle damage. The exercise is maintained by recruitment of a small number of motor units, that causes an enhancement of muscle fiber stress. Even if the exercise is performed at low intensity, it is easy to develop muscle damage for a long period. Exercise induces the generation of a reactive oxygen species (ROS) that facilitates muscular damage via peroxidation. The mitochondrion is a major site of ROS generation that depends on metabolic rate and an increase in nuclear (nDNA) and mitochondrial DNA (mtDNA) damage during exercise. But, whether mtDNA has been damaged similarly to nDNA is still unclear because a high metabolic rate is not necessary to maintain eccentric exercise. The aim of this study was to examine the effect of contraction type and intensity on muscular oxidative damage during exercise. [Methods] Male wistar rats (10-11 wk, 360-380 g BW) were used in this experiment. Animals in exercise groups performed running on a treadmill at different inclines and speeds, i.e. uphill (UH: 16 degree, 16 m/min for 90 min), downhill (DH: -16 degree, 16 m/min for 90 min) or downhill at low speed (DL: -16 degree, 10 m/min for 3 h). Immediately after the exercise, quadriceps muscle was removed from both legs and was stored at -80 °C until analysis. nDNA and mtDNA were extracted from the muscle specimen and were treated with nuclease P1 and alkaline phosphatase to isolate nucleoside. 8-hydroxy-2'-deoxyguanosine (8-OHdG) was determined by enzyme-linked immunosorbent assay (ELISA) as an index of the muscular oxidative DNA damage. Activities of superoxide dismutase (SOD), glutathione peroxidase (GPH), glutathione reductase (GR) and lipid hydroperoxide content (LH) in aliquot of the muscle specimen were determined. Blood was also collected with muscle. Contents of glucose (Glu), free fatty acid (NEFA), lactate (La) and creatine kinase (CK) activity in plasma were determined. [Results] Plasma CK activity showed 2-3 fold increase in DL similar in DH and UH. LA level showed a 2 fold increase in DH and UH, but did not change in DL. Glu and NEFA were also elevated in DL and UH, but NEFA did not change in DH. Muscular LH levels increased in all exercise groups depending on their work intensity (DL < DH < UH). Oxidative mtDNA damage (8-OHdG) also increased in DH and UH, this might depend on running speed (DL < DH = UH). In nDNA, damage increased in DL and no changes were observed in DH and UH. No changes were observed in antioxidant enzyme activities depending on their muscular oxidative damage. [Discussion & Conclusion] Eccentric exercise, even if at low intensity (DL), enhances oxidative stress in the muscle. However, there is no similar change in DNA damage in the nucleus and mitochondrion suggesting that muscle DNA damage is not necessary to involve a common factor in exercise.

HIGHER MUSCLE DESATURATION HETEROGENEITY DURING BICYCLE EXERCISE AT HEAVY WORK RATES
Kim, R., Niwayama, M., Shiroishi, K., Fujikawa, M., Osawa, T., Shimomura, K., Osada, T., Murase, N., Katsumura, T.
Tokyo Medical University, Japan

Background: Muscle tissue oxygen saturation (StO2) is derived from the oxygen balance (O2 balance) between muscle oxygen consumption and oxygen supply. We hypothesized that the StO2 in the activating muscle will be more heterogeneous at heavy work rates as nonuniform O2 balance distribution is greater. The purpose of this study was to examine the muscle desaturation heterogeneity in a single muscle during arterial occlusion and bicycle exercise using multi-channel near infrared spatial resolved spectroscopy (NIRSRS).

Methods: Fourteen healthy male subjects participated in this study (Age: 19-34 yrs, Height: 171.1 +/- 5.2 cm, Weight: 66.6 +/- 6.9 kg, VO2peak: 54.3 +/- 10.8 ml/kg/min). The eight measurement probes were arranged vertically and the measurement probes were attached on the left vastus lateralis muscle along the direction of the long axis. The sampling rate of the signal was 0.5 sec. To determine the minimum value of the StO2, a cuff was attached on the thigh to occlude the femoral artery for 6 min. After the experiment, the subjects performed a 30W ramp incremental bicycle exercise until exhaustion. The pulmonary O2 uptake was monitored continuously during the experiment. As Komiyama et al (2001) reported, fat layer thickness affects StO2 as determined by NIRSRS, thus the fat layer thickness of each measurement site was measured using ultrasound device for correction of the effect of fat layer thickness on reduced scattering coefficient. Results: The StO2 was significantly lower at the distal site than the proximal site (Distal: 76.0 +/- 5.8 % vs. Proximal: 80.2 +/- 4.6 %, p<0.05) and the StO2 differences were higher at 6 min of arterial occlusion (Distal: 15.1 +/- 9.8 % vs. Proximal: 42.5 +/- 10.2 %, p<0.01). In addition, the StO2 at the end of exercise was significantly lower at the distal site than the proximal site (Distal: 40.4 +/- 5.8 % vs. Proximal: 52.7 +/- 5.8 %, p<0.01). Moreover, the heterogeneity of the StO2 during exercise was significantly higher at heavy work rates (p<0.05). Conclusions: This study revealed that O2 balance was significantly different in a single muscle not only at rest but also during arterial occlusion and bicycle exercise. These results suggest that O2 extraction is greater at the distal than the proximal site and nonuniform O2 balance distribution in a single muscle is greater in heavy work rates.

CHANGES IN THE CROSS SECTIONAL AREA OF THE FEMORAL VEIN AND HEART RATE DURING STANDING, SITTING, LONG-SITTING, SUPINE AND PRONE POSITIONS AT REST
Hirao, M., Yoshioka, A., Seki, K., Takahara, T., Takahashi, K., Tim, C., Onodera, S.
Kawasaki University of Medical Welfare, Japan

INTRODUCTION It is thought that gravitational force affects the amount of venous return. It has been postulated that posture may affect amount of gravitational force exerted on the body. Therefore, the purpose of this study was to determine the effects of the standing, sitting, long-sitting, supine and prone position on the cross sectional area of the femoral vein and heart rate whilst at rest. METHODS: Six healthy males volunteered for this study. Their mean age, height, body mass and % body fat were 23.2±1.3 years, 173.7±5.4 cm, 69±17.0 kg and 16±2.6%, respectively. All subjects were instructed about the protocol and they gave their informed consent before the experiments. The cross sectional area of the femoral vein and heart rate were measured. The cross sectional area of the femoral vein was measured in the right-side inguinal section by using B-mode ultrasonography. Heart rate was continuously measured by electrocardiography. The experiments were conducted under five positions: the standing, sitting, long-sitting, supine and prone positions. Subjects performed the five positions in each experiment at random and rested in each position before the experiments. RESULTS: The cross sectional area of the femoral vein was 1.73±0.16cm² in the standing position, 1.73±0.18cm² in the sitting position, 1.64±0.37cm² in the long-sitting position, 0.41±0.17cm² in the supine position and 1.78±0.51cm² in the prone position. The cross sectional area of the femoral vein in the standing, sitting, long-sitting and prone positions were significantly higher in the supine position (P<0.05). Results of the standing, sitting, long-sitting and prone positions suggested that storage of blood could have occurred in the
EFFECT OF THE DURATION OF INTERMITTENT HYPOXIA ON VENTILATORY CHEMOSENSITIVITY IN HUMANS

Katayama, K., Ishida, K., Iwasaki, K., Miyamura, M.
Nagoya University, Japan

Intermittent exposure to hypoxia associated with rapid ascents and descents from high altitudes have been utilized as methods of pre-acclimatization before climbing to high altitude (Richalet et al. 1992, Savourey et al. 1994). Previous studies showed an increase in ventilatory response to hypoxia after intermittent hypoxia in humans (Garcia et al. 2000, Katayama et al. 2001, 2005, 2007). However, there are no published studies that have maintained the levels of altitude or the inspiratory fraction of O2 (FI O2) and the period of the exposure constant while only varying the daily exposure duration. The purpose of the present study, therefore, was to clarify the influence of duration of intermittent hypoxia per day on ventilatory chemosensitivity in humans. For this purpose, we determined ventilatory responses to hypoxia and hypercapnia before and after 1 and 3 hours of exposure each day for 7 days of intermittent hypoxia. We hypothesized that the magnitude of the increase in ventilatory chemosensitivity would be larger as the duration of intermittent hypoxia is prolonged. Nineteen subjects were assigned to one of three groups, i.e., the first hypoxic group (H-1 group, n=6), the second hypoxic group (H-2 group, n=6), or a control group (n=7). The hypoxic tent system was utilized for intermittent hypoxia, and the oxygen levels in the tent were maintained at 21.3±0.2% (simulated altitude of 4,300m). The H-1 group spent 1 hour per day and H-2 group spent 3 hours per day in the hypoxic tent for 7 days. Resting hypoxic ventilatory response (HVR) and hypercapnic ventilatory response (HCR) were determined in each subject before, after 7 days of intermittent hypoxia, and again after the cessation of hypoxic exposure for 7 days. HVR was increased significantly (P<0.05) after 1 and 3 hours per day of intermittent hypoxia for 7 days, but the magnitude of the increased HVR after 3 hours per day did not differ from that after 1 hour per day of intermittent hypoxia. After 7 days of the cessation of intermittent hypoxia, HVR in the H-1 and H-2 groups were still higher (P<0.05) than those before intermittent hypoxia. There were no significant changes in HCR in either group throughout the experimental period. The results suggest that the duration of hypoxic exposure each day from 1 hour to 3 hours could not affect the magnitude of the increase in hypoxic ventilatory chemosensitivity.

THE EFFECT OF CARBOHYDRATE INGESTION ON THE INTERLEUKIN-6 RESPONSE TO A 90-MINUTE RUN TIME-TRIAL

Ansley, L., Barwood, M., Eglin, C., Robson-Ansley, P.
Northumbria University, United Kingdom

Cytokines released during exercise have been implicated in suppressing the immune system [1,2] and mediating fatigue [3]. Carbohydrate (CHO) ingestion during constant load exercise is associated with an attenuated interleukin-6 (IL-6) response immediately post-exercise [1,2], although, during intermittent high intensity exercise [4] and self-paced running [5,6] the effect of CHO ingestion on immediate post-exercise IL-6 is equivocal. However, the self-paced studies comprise field studies and such factors known to affect IL-6 release are not accounted. Therefore the aim of this study was to evaluate the effect of CHO ingestion during a laboratory-controlled self-paced time-trial on post exercise IL-6 concentration. Seven recreationally trained runners completed two 90-minute time trials ingesting either CHO or a placebo, in a randomized order. The study was of a double-blinded, placebo-controlled, cross-over study design. Immediate post-exercise IL-6 levels were significantly lower in the CHO trial compared with the placebo trial (5.3±1.9 pg/ml vs. 6.6±3.0 pg/ml, respectively, p=0.029). Furthermore, distance covered in 90 minutes was significantly greater with CHO compared to placebo ingestion (19.1(1.7) km vs. 18.3(1.9) km, respectively, p=0.002). Blood glucose was maintained during both conditions. The results from this study support the model in which IL-6 release during exercise is attenuated by CHO ingestion. Furthermore, the full extent of the mediating effect of CHO is probably masked by the increased intensity at which the CHO trial was performed. However, improvement in time trial performance is unlikely to be explained by the physiologically insignificant difference in post-exercise IL-6 between trials. The confounding effect of intensity in self-paced exercise trials examining IL-6 illustrates the need to use a different model to assess the role of IL-6 in mediating fatigue. In conclusion, CHO intake attenuates the immediate post-exercise IL-6 response in a 90-minute running time-trial.

items from Italian version of PSDQ need to be revised in order to improve their measurement precision.

Additional questions were raised which require further investigations. It would be relevant to relate Italian PSDQ scales to alternative external measures. These results emphasize the importance to design effective interventions to improve overweight disorders.

CONCLUSIONS: Additional items were raised which require further investigations. It would be relevant to relate Italian PSDQ scales to alternative external measures. These results emphasize the importance to design effective interventions to improve overweight disorders.

METHODS: A questionnaire about physical self-description (PSDQ) and a test battery to assess physical performance (EUROFIT) were administered to 103 Italian high school students (age 12-15) coming from a wide range of family backgrounds.

RESULTS: A comparison between our results of the PSDQ and those of a previous Italian research showed lower scores for each scale with the exception of Health, Physical and Esteem representing higher scores in our participants. In the present work there were not so many differences between boys and girls about physical self perception. In the PSDQ and EUROFIT tests boys scored significantly higher with the exception of Health, Physical and Esteem presenting higher scores in our participants. In the present work there were not so many differences between boys and girls about physical self perception. In the PSDQ and EUROFIT tests boys scored significantly higher than girls in the PSDQ Strength (W=815, p=0.00) and Endurance (W=815.5, p=0.00) scales, in Standing broad jump test (W=898.5, p=0.00), in Endurance shuttle run test (W=939, p=0.00), while girls scored significantly higher then boys in Sit and reach test (W=2167, p=0.00). Results also supported the construct validity of PSDQ responses in relation to some external validity criteria. The largest correlations between internal and correspondent external criteria were found between endurance perception and endurance performance (p=0.05), and between body fat perception and BMI (p<0.05). Overweight adolescents perceived themselves as really they were. They also showed a low level of self esteem, a poor physical attractiveness perception and a negative conception of their physical performance. These results emphasize the importance to design effective interventions to improve overweight disorders.

THE UTILISATION OF REFLECTIVE PRACTICE BY SOCCER COACHES IN THE UK

Cropley, B., Hanton, S., Mellalieu, S., Jenkins, R.

Movements in UK coach education programmes to a focus on what a coach should be able to do rather than on what they should know has increased support for the notion that experience plays a central role in influencing practice (Cushion, Armour, & Jones, 2003, Miles, 2001). However, while the practicum experience lies at the heart of coach education, National Governing Bodies (NGB's) have, to date, done little to introduce structures that support learning from experience. Nevertheless, one particular framework that has consistently
been demonstrated as beneficial for both personal and professional development is that of reflective practice. Therefore, in an attempt to enhance understanding of the current reflective practices of coaches and inform future developments in coach education, this investigation examined the how? what? why?, where?, and when? of reflective practice within soccer coaches. Six highly qualified (UEFA A Licence), experienced (number of years coaching M = 11, SD = 2) soccer coaches completed a two-stage interview. Part one examined participant knowledge and general use of reflective practices, while part two explored a chosen critical incident experienced by the participant in order to understand the processes involved in generating learning from practice. Inductive and deductive content analysis procedures were adopted and the results were displayed in the form of causal networks. Findings highlighted a greater use of unstructured, reflection-on-practice away from competitive and practice environments. Participants also emphasised the importance of personally-defined critical incidents for the instigation of and focus for reflection, rather than reflecting on experiences as a whole. In addition, the use of either structured or unstructured reflection enabled participants to manage their own development and learning by gaining greater awareness of their coaching practice and coaching behaviours. Consequently, informed decisions could be made about how to approach issues concerning the effectiveness of their coaching. These findings highlight the value of reflective practice as a tool for improving future coaching performance and its defining role within the coaching process. NGB’s need to recognise the necessary role of reflection in excavating learning from experience and become familiar with the basic elements of a reflective practice. This will allow practitioners to begin to act on the notion that knowledge is embedded in the experience of their work, and to realise the importance of this knowledge in furthering their practice.

THE ACUTE EFFECT OF SELF-PACED FATIGUING EXERCISE ON PERCEPTION OF MENTAL FATIGUE AND MENTAL TASK PERFORMANCE

Thomas, K., Longstaff, F., Ansley, L., Neary, P., Stone, M., Wilkinson, M., Hunter, A., & St Clair Gibson, A. Northumbria University, United Kingdom

There is considerable evidence supporting the positive impact of exercise on mood states, affect and psychological well-being. Less robust is the notion that exercise positively influences cognition (Tomporowski and Ellis, 1986, Etnier et al., 1997). A recent review however concluded that submaximal aerobic exercise (< 60 mins) facilitates specific aspects of information processing, but relatively little systematic laboratory-based research has been conducted (Tomporowski, 2003). In addition, self-paced exercise has received very little attention. The purpose of this study was to investigate the effect of a bout of self-paced exercise on mental fatigue and performance on a rapid visual information processing (RVIP).

Nine physically active participants volunteered (mean (SD) age = 27 (5) years, stature = 178.8 (6.0) cm, mass = 78.3 (9.7) kg). All participants completed two trials on consecutive days. On day 1 participants completed multiple 5 minute sets of a RVIP task for 30 minutes or to volitional mental exhaustion (Mental fatigue trial [MF]). The RVIP task provides performance scores for reaction time and correct, incorrect and missed responses. After each 5 minute block participants were asked to rate their mental fatigue using visual analogue scales (‘How mentally fatigued are you?’), their associative score (‘How much of your focus is on sensations of mental fatigue?’) and their affect score (‘How much are you enjoying the task?’). On day 2 the participants completed the same mental fatigue trial after a time-matched self-paced bicycle time trial with instructions to ‘cover as much distance as possible’ (Exercise and mental fatigue trial [E+MF]).

Two participants failed to complete the mental fatigue task during the E+MF trial due to excessive symptoms of fatigue. Mental task performance decreased, and mental fatigue increased, from set 1 to 6 in both trials (P < 0.05). No main effects were detected between trials for any of the performance or fatigue measures. (P > 0.05). Post-hoc analysis however did reveal exercise had a positive effect on mental task performance and mental fatigue, with the effects limited mainly to the first 3 sets of RVIP testing for all outcome measures (P < 0.05).

Self-paced exercise had an acute positive effect on mental fatigue and mental task performance. This positive effect dissipated with time. The RVIP has elements relating to response speed, response inhibition, attention and short-term working memory. The finding that exercise positively influenced these components is consistent with previous literature that have employed similar tasks.

REFLECTIVE PRACTICE: THE INFLUENCE ON COMPETITIVE EXPERIENCE AND INTERPRETATION OF ANXIETY RELATED SYMPTOMS

Cropley, B., Hanton, S., Lee, Z.

Cropley, B. - Swansea University, Hanton, S. - University of Wales Institute, Cardiff, Lee, S. - Hartpury, United Kingdom

Recent research has demonstrated that competitive experience influences the way in which athletes interpret symptoms associated with anxiety (e.g., Hanton et al., 2007, Mellalieu, Hanton, & O’Brien, 2004). Further, Hanton et al. (2007) found that athletes engage in forms of reflective practice in order to generate knowledge from their competitive experiences. Specifically, athletes improved their understanding of symptoms associated with anxiety, allowing them to learn how to interpret these symptoms as facilitative to performance. The purpose of this study therefore was to provide an in-depth examination of these reflective processes that athletes undertake in order to better cope with their anxiety related symptoms. Six experienced, elite athletes were interviewed regarding their reflective practices adopted following both positive and negative critical sporting incidents with a view to generating knowledge concerning their interpretation of competitive anxiety symptoms. Composite sequence analysis procedures were employed to allow data to be considered as meaningful sequences for both the positive and negative incidents. Findings showed distinctions between the effects of positive and negative incidents on the reflective and learning processes and how this influenced further appraisal of competitive anxiety symptoms. Positive incidents resulted in greater occurrence of reflection with significant others leading to improved understanding of the situation and how to recreate positive aspects of performance in future experiences. Conversely, negative incidents generated more deliberate, critical processes of reflection, resulting in the active process of learning how to restructure negative symptoms so that they could be interpreted...
more positively. The findings suggest sport psychologists and coaches need to be aware of the importance of reflective practice as a method to help athletes generate the knowledge required to better cope with anxiety related symptoms. They also provide support for reflective practice as a framework for experiential learning within sport and highlight the need for the skills required for effective reflection-on-action to be nurtured and developed within athletes.

**PERSONALITY AND EMOTIONAL RESPONSES TO SPORTS INJURY IN U-14 SOCCER PLAYERS**

Yatabe, K., Aoki, H., Kohno, T., Fujiya, H.
F-MARC KAWASAKI/ST. Marianna University School of Medicine, Japan

It is important to consider and understand not only physical fitness, appropriate training and competition conditions, but also each player's individual character and emotional responses, when nurturing adolescent soccer players and to take necessary preventive measures against sports injury that can occur. We investigated both personality and emotional responses using the Yatabe-Guilford(YG) personality questionnaire and POMS in U-14 (30 male) soccer players during short elite-programme camp. The purpose of the present study is to identify (1)physical changes, (2)personality traits, (3)psychological changes, (4)personality traits that influence situations with respect to the emotional states and injuries.

Most players, were evaluated as Directoral type by YG personality questionnaire. It was said that the personality profile was not Sports-Injury(acute injury/chronic injury) group specific. However, differences were revealed in the factors of personality traits between injured group and uninjured group. The 'Anger' scale of POMS showed a high score in acute-injured group before they were injured. The difference in personality traits was considered a risk of injury as follows:
1) Each factor of personality traits was directly related to an emotional response(mood states), and influenced the incidence of sports injury.
2) During the short-period camp under similar conditions, it was suggested that sports players, who were not able to change mood states in a positive-direction early without psychological care and preparation for such condition, were considered to be at high risk of injury occurrence.
In a training programme under special environment, the influence of psychological factors should be considered important to reduce the risk of sports injuries.

**INDIVIDUAL X TEAM: COMPARATIVE ANALYSIS OF THE SPORT COMPETITIVE ORIENTATION BEHAVIOR AMONG MEN ATHLETES FROM JUDO AND FOOTBALL**

Oliveira, S., Serassuelo Junior, H., Simões, A.
Sao Paulo University – Physical Education and Sport School (EEFEUSP), Londrina Stadt University (UEL), North Paraná University (UNOPAR), Brazil

INTRODUCTION: The sports are social phenomena of great importance in Modern Society, a game of fighting between micro-society in which the actions are established in function of a specific objective to be achieved. The practice competitive sports can still be classified as highly individual or team, a fact that influences, particularly the way in which the individual builds his competitive behaviour. Knowing this behavior can help the athletes and coaches to seek improvement and sportive conquer. OBJECTIVE: The objective of this study was to identify male athletes of Judo and Football Field the competitive trends analyzing them comparatively between the terms and correlate them according to age and time of practice of the athletes. METHODS: the instrument The Sport Orientation Questionnaire - SOQ (Gill & Deeter, 1988) was adopted and validate by Simões (2000) it was used to identify the Sport Orientation (SO) in athletes of Judo JU (n = 18), members of the Junior Men’s Selection of the State of Sao Paulo and Football FO (n = 27), Junior Men’s Team belonging to a traditional club football in Brazil. For a comparative analysis between groups in the qualitative variable (SO) the Chi-square was used. In the analyses of the quantitative variable, age (AGI) and time of practice (TP) the test t applied. For the correlation between qualitative and quantitative variables it was used the procedure of correlation of Spearman. The level of significance adopted for all the analyses was p<0,05. CONCLUSION: The results descriptive of the variables (SOI and AGI) of the analyzed athletes were: SO JU = 40,22±9,86 and SO FO = 36,22±5,99; AG JU = 17,50±1,33 and AG FO = 18,55±1,05; these results showed significantly statistic different. The Football athletes have a better level of competitiveness and greater age than the Judo, while both groups have similar in time of experience sports. The high rate of default deviation observed and the largest scale of the minimum and maximum values of SO found for the athletes of Judo (min 25 - max 56) compared to football (min 28 - max 49), show a lower homogeneity of the group, a fact that may indicate a greater orientation for victory of Football athletes than Judo athletes and therefore they are better able to seek achieve personal goals. The highest average age found in football athletes serves as guidance to greater maturity as competitive the establishment of goals. Despite the climate pre-established by the groups where we find young athletes of Judo and Football field, the reality of professional Brazilian experience in football seems to influence a higher potential of the competitiveness of these athletes.

HARDINESS AND COMPETITIVE ANXIETY SYMPTOM INTERPRETATION: A QUALITATIVE EXAMINATION
Neil, R., Evans, L., Hanton, S., & Lane, A. University of Wales Institute, Cardiff, United Kingdom

The resilient nature of the hardy individual has not only been attributed to the components of commitment, control, and challenge, but also to the effective coping style associated with the dynamic combination of these attitudes (Kobasa et al., 1982). Indeed, it is through the use of such strategies as positive appraisals, active coping, planning, and increased effort that individuals high in hardness excel in the face of adversity (Maddi & Khoshaba, 2005). This notion has been supported within the sporting literature by Hanton et al. (2003) who found that elite high hardy individuals interpreted their anxiety symptoms as more beneficial (i.e., facilitative) to upcoming performance compared to those elite, low in hardness and nonelite, high and low in hardness. The purpose of this study was to examine how and why elite high hardy athletes interpret their anxiety symptoms as facilitative in the face of adversity. Qualitative interviews were conducted with five elite high hardy athletes in an attempt to identify the underlying mechanisms of their facilitative interpretations. Findings suggested that elite performers initially appraised a stressful situation as threatening and, consequently, experienced anxiety symptoms. These symptoms were then interpreted as facilitative towards upcoming performance through the initiation of strategies that included rationalising the situation and subsequent thoughts, positive self-talk, reflecting on previous successful performances, and focusing on increase effort to accomplish these tasks. The current findings have implications for sport psychologists and coaches, along with athletes who interpret their anxiety symptoms as detrimental to their performance.

PHYSICAL SELF-PERCEPTION AND MOTOR ABILITIES IN MALE ADOLESCENTS: EFFECTS OF BMI AND PHYSICAL ACTIVITY PRACTICE
Colella, D., Morano, M., Capranica, L. University of Foggia 1, University of Foggia, IUSM of Rome 2, IUSM of Rome 3, Italy

Introduction
Physical self-perception is associated with certain health behaviours such as exercise, which plays an important role in the prevention and treatment of obesity. Data suggest that obese adolescents (Bar-Or & Baranowski, 1994) and youth with low perceived sport competence (Marsh, 1996) are less physically active than their respective counterparts. Consequently, obese adolescents showed lack confidence in their physical ability (Bar-Or, 1993) and poorer performances on weight-bearing tasks (Delorme et al, 2003) compared to their non-obese peers. The purpose of the study was to examine the differences by BMI and physical activity practice in physical self-perception and motor abilities of high school male students.

Methods
An Italian reduced version of the Physical Self-Description Questionnaire (Meleddu et al, 2002) was used to measure perceived Coordinations (CO), Body Fat (BF) and Sports Competence (SP) in 80 boys (15.6±0.9 yrs), who were (n=38) or were not (n=42) involved in organized extra school physical activity. The Perceived Physical Ability Scale (Bortoli & Robazza, 1997) and fitness tests of standing long jump (SLJ), 2 Kg medicine-ball throw, 30m sprint and 10x5m shuttle run were also administered to the students. Participants were categorized into non-obese (n=48) or overweight and obese (n=32) groups according to age- and sex-specific BMI cut-off points (Cole et al, 2000).

Results
ANOVA 2 (group) x 2 (practice) showed differences (p<0.01) between groups, with overweight and obese boys reporting higher scores in the BF scale (18.2±7.9 vs. 8.2±4.0) and poorer performances on weight-bearing tasks (SLJ: 1.7±0.3 vs. 1.9±0.3 m; 30m: 5.1±0.5 vs. 4.7±0.4 sec; 10x5m: 21.8±1.7 vs. 20.3±1.3 sec) than their leaner peers. Differences (p<0.01) also emerged for practice, with students involved in organized physical activity showing lower scores in the BF scale (10.3±5.6 vs. 13.9±8.8) and higher scores in the CO (27.4±6.9 vs. 24.8±6.1), SP (28.5±5.4 vs. 23.3±7.8) and Perceived Physical Ability (19.5±3.0 vs. 17.7±3.6) scales compared to their counterparts.
Conclusions

Results provide evidence on the important role physical activity can play to the improvement of self-perception in adolescence. Enhancing the individual's ability levels can result in improved physical self-efficacy and motivation to participate in exercises programs (Bar-Or, 1993). In particular, to raise their self-perception of obese adolescents not only a reduction of body weight, but also with an improvement of motor abilities is recommended.

PHYSICAL SELF-EFFICACY, BODY DISCREPANCY AND MOTOR ABILITIES IN YOUNG GIRLS: EFFECTS OF BMI AND DIFFERENT SPORT PRACTICES

Morano, M., Colella, D., Capranica, L.

University of Foggia, IUSM of Rome 1, University of Foggia 2, IUSM of Rome 3, Italy

Introduction

Participation in sport has positive impacts on self-perceptions such as physical self-efficacy and body image (Sabo et al., 2004). Self-efficacy perceptions vary across different activities and different levels of the same activity, and are related to some aspect of body image. Chan et al. (1989) found that subjects characterizing themselves as fat reported lower perceived physical ability than did subjects characterizing themselves as slim. However, the link between self-efficacy beliefs and body image related to body mass and sport involvement has not been investigated in girls. Thus, this study aimed at examining the effects of BMI and different sport practices on the self-efficacy, body satisfaction and motor abilities in young girls.

Methods

Participants were 135 girls (9.2±0.8 yrs) involved in non-agonistic sport activities (rhythmic gymnastics, volleyball, and basketball) 3 times week-1, were equally divided (n=45) into non-overweight (NOW), overweight (OW) and obese (OB) groups according to BMI cut-off points (Cole et al., 2000). Perception of personal strength, speed, and coordinative abilities was assessed by the Perceived Physical Ability Scale for Children (Colella et al., while difference between perceived and ideal body image (body discrepancy, BD) was measured through Collins’ Child Figure Drawings (1991). Fitness tests of standing long jump (SLJ), basketball throw, 10m and 20m sprint were also administered. A 3 (group) x 3 (sport) ANOVA (p<.05) and post-hoc Scheffé test were applied.

Results

Differences (p<.001) between groups emerged, with NOW presenting a smaller BD and OW showing poorer SLJ performances than their counterparts. Differences (p<.01) between sports were found, with girls practicing basketball reporting higher perceived physical ability and better results in 10m sprint than girls practicing rhythmic gymnastics. Participants involved in volleyball showed lower (p<.01) SLJ and 20m sprint performances than the other groups. Significant correlations (p<.001) was shown between BMI and BD (r=-.38), and between BD and self-efficacy (r=-.40).

Conclusions

Findings confirm that obese girls were more dissatisfied with their body image than normal-weight peers (Vander Wal & Thelen, 2000). Moreover, an increase in BMI is related with a desire to have a thinner body size (Tiggemann & Pennington, 1990). Further research is needed to examine the causal link between feelings of satisfaction/dissatisfaction with own body and perceived physical ability, as well as children’s sources of self-efficacy in the sport domain in relation to age.

WHEN EAST MEET WEST: MODEL INVARIANCE OF 2 X 2 ACHIEVEMENT GOALS IN TWO COUNTRIES

Nien, CL

Taiwan National Sport University, Taiwan

The importance of how individuals judged their competence in an achievement setting has been long-term interests when discuss about achievement-related processes and outcome (Roberts, 2001). Different achievement goal theories (Deweck, 1989; Elliot, 1999; Nicholls, 1984) have been conducted in educational and sport setting in order to investigate motivation. The aim of the present study is going to test the model invariance of newly created 2 x 2 achievement goals on athletes from two different countries: A large sample of athletes from a far east Asia country is going to be included in this study and is going to compare with a western country sample via SEM to examine the factorial invariance of 2 x 2 achievement goals proposed by Elliot (1999). Several instruments are going to employ to measure concepts such as perceived competence, fear of failure as well as motivation regulations. The factorial invariance of four goals as well as the structural invariance of antecedent-goals-consequences model is going to be analyzed. The results should give implications beyond gender invariance based on Nien and Duda (2008) and suggestions will be made according to possible cultural differences.

ACHIEVEMENT GOALS, SELF-DETERMINATION AND BELIEFS ABOUT THE NATURE AND DETERMINANTS OF SPORT COMPETENCE - A COMPARISON BETWEEN YOUNG FOOTBALL PLAYERS COMPETING AT DIFFERENT LEVELS

Sarmento, H., Catita, L., Fonseca, A. Faculdade de Desporto da Universidade do Porto, Portugal

Competitive environments are likely to promote a focus on winning, promote ego involvement and subsequently a decrease in intrinsic motivation through its adverse effect on self-determination (Vallerand et al., 1987). There has been little research that investigated the differences in motivation as function of competitive level (Mallet & Hanrahan, 2004) and the research to date has yielded equivocal findings. Hence, the purpose of this study was to compare the achievement goal, self-determination and beliefs about the nature and determinants of sport competence in function of competitive level in young football players.

The participants were 140 male football players that competed in National League (n=78) and in Regional Leagues (n=62). Ages ranged from 15 to 16 years (M=15.73, SD=.62). Participants completed the following tools: Task and Ego Orientation in Sports Questionnaire (TEOSQ), Self-Regulation Questionnaire (SRQ), and Questionnaire relative to Beliefs about the Nature and Determinants of Sports Competency (QCNHS). Student’s t test for independent samples was used to analyse the differences between the two groups (National vs. Regional League). Statistical significance was set at P = .05.

Football players competing in the National League had significantly higher scores for ego orientation (2.85±.97 and 2.47±.87; respectively, p=.02), introjected regulation (3.28±.96 and 2.96±.86, p=.04), identified regulation (4.44±.51 and 4.12±.65, p=.00), intrinsic regulation (4.18±.63 and 3.90±.70, p=.02), beliefs that the sport competence result to learning (4.50±.46 and 4.26±.64, p=.01), is subject to improvement (4.3±.48 and 4.10±.64, p=.02) and if’s a gift (3.28±.79 and 2.96±.87, p=.03), than did players who competed in Regional Leagues.

As suggested by the literature (White & Duda, 1994), athletes who were involved in the highest competitive level were significantly more ego-oriented than the football players involved in a less competitive atmosphere. In contrast, as previously found by Mallet & Hanrahan, (2004) our study does not fully support the prediction of social-cognitive theories of motivation in that the structure of competitive sport environments will promote a decrease in intrinsic motivation and self-determined forms of extrinsic motivation. National league football players were characterized by higher levels of intrinsic motivation and self-determined forms of extrinsic motivation. These athletes also believe, more than regional league athletes do, that their sport competence is due to learning and is subject to improvement. The results suggest that high-level football players were more intrinsically motivated, were more likely to choose to commit to the demands of competitive sport and had a higher perception of control on the development of their competence.

ACHIEVEMENT GOALS, SELF-DETERMINATION AND BELIEFS ABOUT THE NATURE AND DETERMINANTS OF SPORT COMPETENCE - AN AGE-GROUP COMPARISON BETWEEN MALE FOOTBALL PLAYERS

Sarmento, H., Catita, L., Fonseca, A. Faculdade de Desporto da Universidade do Porto, Portugal

Motivation is a particularly important outcome that coaches require because it can affect the quality of athletes’ experience in sport as well as the likelihood of maintaining sports practice in the future (Conroy et al., 2006). The purpose of this study was to compare the achievement goals, self-determination and beliefs about the nature and determinants of sport competence in function of age in age-group football players.

The participants were 339 senior players (S) (19 years), 98 juniors A (JA) (17-18 years), and 140 juniors B (JB) (15-16 years). Participants completed the following tools: Task and Ego Orientation in Sports Questionnaire (TEOSQ), Self-Regulation Questionnaire (SRQ), Questionnaire related to Beliefs about the Nature and Determinants of Sports Competency (QCNHS). Analysis of variance (ANOVA, One-Way) was used to analyse for differences between the three groups. Statistical significance was set at P ≤.05. The analysis of data suggests that the three groups were preferentially task oriented although no significant differences were found between them. The seniors, when compared with the juniors B, tended to report significantly higher levels of introjected regulation (S, 3.44±.83, JB, 3.14±.93, p=.00) for the beliefs that the sports competence is specific to football (S, 3.90±.70, JB, 3.69±.62, p=.01) and is a gift (S, 3.36±.85, JB, 3.14±.84, p=.04), and report significantly lower levels for the belief that the competence to play football is stable (S, 2.51±.69, JB, 2.69±.69, p=.03). The senior players also showed significantly higher levels than the juniors A relatively to the belief that sport competence is a gift (S, 3.36±.85, JA, 3.14±.84, p=.01). As for the belief that sport competence is general more significant differences were found between the three groups (S, 2.09±.83, JA, 2.36±.87, JB, 2.78±.86, p=.00).

In accordance with other studies with sport Portuguese footballers (Fonseca & Maia, 2000), our results suggest that during growth football players do not modify their motivational orientations or, the more or less self-determinate form as they were being involved in the activity. The only exception is with senior football players who reported higher levels of introjected regulation when compared with juniors B. All groups strongly believe that their sport competence is specific, due to learning and is subject to improvement. This is a positive and desirable tendency, because these players showed a higher perception of control during the development of their competence (Sarrazin et al., 1995). However, the observed differences suggest that these football players modified their beliefs as they got older.

BODY MASS INDEX AND INTRINSIC MOTIVATION IN FITNESS EXERCISERS

Moutão, J., Silva, C., Chicau, C., Cid, L.
Sports Science Schools of Rio Maior, Portugal

Drop-out from exercise programmes could be a function of the motivation underlying exercise behaviour. Accordingly with the Self Determination Theory (Deci & Ryan, 1985), some individuals exercise due to the enjoyment they get during the workout, but others may exercise to attain extrinsic or intrinsic rewards, such as to look more attractive, lose weight, or obtain recognition (Markland & Ingledew, 1997).

The purpose of the present study was to examine the relation between Body Mass Index (BMI) and different motivational regulations. It was hypothesized that less determinate types of exercise motivation (i.e. external and introjected regulation) would be superior in exercisers with high BMI.

117 fitness exercisers, 31 male and 86 female, aged 15-66 years (mean = 32.9 ± 3.9), from three fitness health clubs in the littoral centre of Portugal, took part of the study. It was considered the participants IMC (mean = 23.2 ± 2.9) and also the exercise motivation through the Portuguese version of the Behavioural Regulation in Exercise Questionnaire 2 (Palmeira, Teixeira, Silva & Markland).

Person correlation shows a negative correlation between the relative autonomy index and the IMC, which mean that the exercisers with a higher IMC were more external regulated.

It was conclude that in order to reduce the drop-out from exercises, especially in those with a high BMI, interventions should also considered the way exercisers think, feel and behave. A multidisciplinary approach was recommended with the inclusion of strategies to promote intrinsic motivation and eradicate pressure.

COLLECTIVE DECISION MAKING : NEW CHALLENGES TO MATCH ANALYSIS

Lusófona University of Humanities and Technologies, Portugal

Analyses of team sport performance are supported by a range of statistical data of discrete actions that typically inform what happens, and not how and why it happens. One way to examine these questions is to observe the behavioural dynamics in sports teams to understand how players’ interactions in game sub-phases give rise to successful intra-team coordination patterns. To achieve our aim we followed insights of Couzin and colleagues on coordination in biological systems when they argued that researchers should account the ability of grouping individuals to modify their motion on the basis of those local interactions (Couzin et al, 2005, pp. 513). In every match situation rugby players attempt to maintain relative positioning with and interpersonal distance between teammates to successfully receive the ball or support the ball carrier. We sought to understand whether, similar to collective behaviour observed in biological systems (e.g. schools of fish, colonies of ants and locusts), such decision making in team games demanded sharing and propagation of information available in the performance context. In this research we attempted to identify the existence of pattern forming dynamics in rugby union where the ball carrier has preferred information that propagates through a behavioural interaction with support players.

In our analysis of (4×2+2) sub-phases of rugby near the try line, videogrammetry captured players’ motion and TACTO 7.0 software digitized player positions (Passos et al., 2006). Collective actions in team sports can be described by a single point defined as the geometric centroid of the area composed by a group of players. Centroids were calculated based on the values for interpersonal distance between players within a micro unit and their changes over time. Vector linked centroids were used to define a collective variable that described attacker-defender group interactions.

Our findings showed that when a defender disturbed the stability of a micro-unit formed with an attacker in a game, this sub-system self-organized to maintain its goal directed behaviour. Results suggested that different curve shapes of the collective variable described when the attacker’s collective decisions broke the defensive balance in a micro unit instigating a phase transition in the system’s pattern dynamics. Data confirmed that the centroid trajectory that emerged due to systemic couplings between players allowed collective decisions and actions to be described as a whole rather than as stand-alone entities in analyzing the tendency of a micro unit to self-organize when perturbed.

RELATIONSHIPS BETWEEN MOOD AND COHESION IN FITNESS

Silva, C., Borrego, C., Moutão, J., Cid, L., Matias, R.
ESDRM- Sport Sciences School of Rio Maior, Portugal

The main goal of this study was to investigate Perceptions of group cohesion and mood in a fitness group. Participants were all female (n=43), from a community program Community Physical Activity, developed in a small municipality (Alenquer) and completed the Group Environment Questionnaire (GQG) and the Profile of Mood States (POMS).

Main conclusions of this study were, -individuals higher perception of cohesion in the ages between 35 and 63 years old showed High individual attraction towards the group relating to the social aspects (AIG-S) and integration in the group relating to the task (IG-T). The dimensions -individual attraction towards the group relating to the task and Integration in the group relating to the social aspects, show no significant differences between the two age stadims. Participants with less than 50% of assiduity to the classes show a higher perception of cohesion and integration in the group relating to the task and relating to the social aspects.

In General, participants exhibit an iceberg profile with the Vigour dimension relatively higher than all the others. Participants with over 75% assiduity to classes reveal, higher values, in the dimensions Depression and Hostility. This probably means that those participants who tend to be more depressed attend more often to classes in pursuit of a good time. Results are discussed in relation to the R. F. Bau- mester and M. R. Leary (1995) proposition that the need to belong is a fundamental human motive.

Concerning to mood states in all its dimensions (Tension, Depression, Hostility, Vigour, Fatigue and Confusion) relating to age, we found no significant statistical differences.

In this study we found no statistical significant relation between group cohesion and mood states.
EXPLORING HIGHER ORDER CATASTROPHE MODELS IN ELITE JUDO ATHLETES

Beattie, S., Jones, B.
Bangor University, United Kingdom

This study re-examines Hardy, Woodman, and Carrington's (2004) findings that self-confidence may act as a bias factor in Hardy's (1990, 1996) higher order catastrophe model. Hardy's (1990) catastrophe model proposes that under conditions of high physiological arousal increasing levels of cognitive anxiety should have a detrimental effect upon levels of performance. It is proposed that self-confidence can moderate this effect. In other words, high levels of self-confidence can allow performers to tolerate higher levels of physiological arousal when they have high levels of cognitive anxiety before suffering a decrement in performance (Hardy et al., 2004). However, athletes with low levels of self-confidence should suffer performance decrements at a much lower level of physiological arousal when cognitive anxiety is high. Hardy et al. (2004) found support for their hypothesis in that the maximum interaction effect size between cognitive anxiety and somatic anxiety was at a higher level of somatic anxiety for the high self-confidence condition than for the low self-confidence condition. However, the sample that Hardy et al. analysed (i.e., golfers) requires low levels of physiological arousal to perform well (i.e., a physically relaxed state). Hence, the generality of the findings and their application to sport is limited. The present study further extends these findings in a sport where high levels of physiological arousal are required (i.e., Judo). Presently 13 senior judo athletes (10 male; 3 female) report their cognitive and somatic anxiety and self-confidence immediately before an international judo bout. Performance is assessed via coach assessment, athlete assessment and subjective judging points.

It is expected that maximum interactive effect sizes between cognitive anxiety and somatic anxiety will be at a higher level of somatic anxiety for the high self-confidence condition than for the low self-confidence condition. However, due to the nature of the sport, the exact nature of the interaction may be somewhat different to that predicted by the catastrophe model in that, under conditions of high cognitive anxiety, increasing physiological arousal may not be detrimental to performance.

MOTIVATIONAL ORIENTATIONS AND INTENSITY OF NEGATIVITY AND SELF-CONFIDENCE IN ELITE PORTUGUESE ATHLETES OF INDIVIDUAL SPORTS

Coelho, E., Vasconcelos-Raposo, J.
University of Trás-os-Montes and Alto Douro, Portugal

The aim of this study was to compare elite athletes of different individual sports at the level of ego and task motivational orientations, pre-competitive intensity of negativity and self-confidence.

The sample consisted of 323 athletes (207 male and 116 female, age 20.5±4.0 yrs) from six individual sports (track and field n= 115, swimming n=60, gymnastics n=29, judo n=49, wrestling n= 34, badminton n=36). The athletic experience was 10.1 ±5.0 years. The sample was organized into four groups namely: National (n=221), European (n=49), World (n=38) and Olympic (n=15). The instruments used were Task and Ego Orientation in Sport Questionnaire (TEQOSQ) and an adaptation of Competitive State Anxiety Inventory-2 (CSAI-2). The independent variable was individual sports and dependents were ego and task motivational orientations and intensity of negativity and self-confidence. The nonparametric tests Kruskal-Wallis (H) and Mann-Whitney (U) were used to compare groups.

Main results demonstrated differences among six sports in task motivational orientation (H= 20.99, p=0.00). Higher values were obtained by gymnasts than track and field athletes, swimmers and judo players. The differences among the groups might be explained by the sport characteristics, since swimming and athletics are objective scored sports (measured by time), while the excellence in gymnastics depends on perfection of the movement, as perceived by judges, thus a result of a subjective interpretation. The concentration of gymnast tends to be focused on the task at hand, because their’s is an isolated performance. Both explain why gymnastics obtained higher task oriented scores.

Results also showed differences between the six sports at the levels of negativity (H=11.30, p=0.04), and self-confidence (H=16.08, p=0.00). Among the comparison made between sports, only evidenced differences at the intensity of self-confidence: track and field vs. judo (26.4±5.1 vs. 23.1±4.8). The results are in agreement with the literature that suggests that lower scores on self-confidence should be found among athletes in contact sports, in part due to the increased threat that emerges from personal confrontation situations.

In conclusion, there are differences between the sports and the results can be explained by the characteristics of the sport itself. The results of the present study are in agreement with the literature.

AN INTERVENTION TO INCREASE SOCIAL SUPPORT AND IMPROVE PERFORMANCE

Freeman, P., Rees, T., Hardy, L.
University of Exeter, Bangor University, United Kingdom

Sarason, Sarason, and Pierce (1990) proposed that social support might affect various aspects of sports performance, and recent studies have demonstrated links with performance-related factors in tennis (e.g., Rees & Hardy, 2004) and performance outcome in golf (Rees, Hardy, & Freeman, 2007). In sport psychology, however, no study has investigated the effects of an intervention designed to increase social support and improve performance. The present study addressed this issue and investigated the effects of a professionally-led intervention designed to increase social support and improve performance using a single-subject multiple baseline design. Participants were 3 high-level male golfers. Participant A was a 27 year old professional golfer. Participant B was a 22 year old amateur golfer with a +1 handicap. Participant C was a 26 year old amateur golfer with a +2 handicap. The baseline phase consisted of participants playing 14, 12, and 10 competitive rounds, prior to the introduction of the intervention. The intervention consisted of all participants playing 10 competitive rounds with social support provided by the principal researcher over the duration of this period. The intervention was individually-tailored, and each participant was provided with emotional, esteem, informational, and tangible support (cf. Rees & Hardy, 2000). All participants reported significantly higher levels of emotional, esteem, informational, and tangible support in the intervention phase compared to the baseline phase. The performance of all participants improved during the intervention phase compared to the
baseline phase. Participant A improved by an average of 90 shots per round, Participant B by 1.33 shots per round, and Participant C by 3.10 shots per round. The effectiveness of the intervention upon performance outcome was supported by a chi-square analysis (p < .05).

Further, social validation data demonstrated that all of the participants rated their improvement in the intervention phase as important, and the provision of social support as both acceptable and useful. The results suggest that a professionally-led intervention may be a useful strategy to increase social support and improve performance. The findings indicate that sport psychologists should be aware of the potential influence of social support interventions upon performance.

**STRENGTH TRAINING IMPROVES SHORT-TERM MEMORY PERFORMANCE**

Goekint, M., De Pauw, K., Njemini, R., Bautmans, I., Mets, T., Meeusen, R.
Vrije Universiteit Brussel, Belgium

Introduction: Many is known about the effect of strength training on cognition in elderly. A period of strength training could improve cognition in elderly [1]. However, in the current society sedentism is becoming widely present. This group could also gain from physical activity, both in a physical and psychological way. We wanted to investigate if strength training in young sedentary subjects could lead to an improvement in cognition, more specifically memory performance.

Methods: Fifteen untrained subjects (age 20.1 ± 1.5 yr; BMI 23.9 ± 1.1) followed a 10-week strength training program. Strength training was performed 3 times per week and consisted of 6 different exercises at 80% of 1 repetition maximum (1RM). Before and after the training period short-term memory (digit span forward and backward) [4] and mid-term memory (memorisation-recall of images) [2;3] were tested.

Results: Muscle strength improved significantly for all six exercises (p<.01), with an improvement of 39.78% of total weight lifted after 10 weeks of training. Mid-term memory was unaffected by exercise (p<.05). However, total score on the short-term memory exercise, measured by the digit span, was improved after the training period (p< .01). The difference between pre- and post-training was situated in the backward part of the digit span. No correlations were found between the increase in strength for the different exercises and the improvement of performance on the digit span.

Conclusion: Not only in elderly, but also in young sedentary subjects strength training can promote cognitive performance. A prolonged period of strength training seems to improve short-term memory, measured by the digit span. Future studies could relate cognitive performance to metabolic changes as a result of strength training.

**SPORT NUTRITION CONSULTANTS' PHYSICAL CHARACTERISTICS INFLUENCE POTENTIAL CLIENTS' PREFERENCE TO WORK WITH THEM AND PERCEPTIONS OF THEIR EFFECTIVENESS**

Parker, J., Lovell, G.
University Of Gloucestershire, United Kingdom

There are many factors that contribute to the effectiveness of a sport nutrition consultant (SNC). Although each context presents different challenges to the SNC, the first barrier is often gaining entry. As Lubker and his colleagues point out, the world of performance sport is a fraternal system where entry is not automatically open to all (Lubker et al., 2005). Despite research in other sports science disciplines demonstrating that practitioner’s physical characteristics do influence clients’ perceptions of their effectiveness which potentially mediate the efficacy of subsequent interventions, e.g., psychology (Lubker et al., 2005), little attention has been directed towards SNC’s. Therefore, the purpose of this investigation was to identify if physical characteristics of SNC’s, specifically body mass index (BMI) and type of dress, influences potential clients’ preference to work with them and perceptions of their potential effectiveness. Furthermore, if these perceptions are effected by the potential clients’ sex or standard of competition.

Participants (age mean=18.68, SD=0.82 years) all participating in regular competitive sport, classified by sex (male, n=55, or female, n=45) and competitive standard (elite / sub-elite, n=68, or club / recreational, n=32) viewed slides representing four concurrently presented computer generated images of the same female SNC. These slides represented the SNC dressed in sports attire manipulated to represent a range of BMI’s (23, 28, 33, and 38 kg/m2) typifying four World Health Organisation classifications of obesity (normal, pre-obese, obese class I, and obese class II), and in formal attire again representing the same four BMI’s. Participants were asked to rank the SNCs in order of their preference to work with them, and secondly, to rate their perceived effectiveness of each of the SNCs on a 7 point Likert scale. Results of the sex by competitive standard by BMI by dress MANOVA demonstrated a significant BMI main effect F6,91=287.28, p<0.001 (effect size 0.95) with participants’ ranking of preference and rating of perceived effectiveness of SNC decreasing with increasing BMI. Other significant MANOVA results, although with weak effect sizes, were BMI by dress and BMI by competitive standard interactions. No sex main effects or interactions were evident. In conclusion, SNCs physical characteristics do influence potential clients’ preference to work with them and perceptions of their effectiveness. Implications of these findings include that SNCs should consider their physical appearance when meeting with sports performers. This relationship is likely to be complex, including factors such as expected social etiquette and physique associated with the client’s sport, justifying further research.

EFFECTS OF PSYCHOLOGICAL TRAITS ON PERCEPTUALLY BASED VALUES

Coquart, J., Dufour, Y., Garcin, M.

Faculty of Sports Sciences and Physical Education, Lille 2 University, France

The Ratings of Perceived Exertion scale (RPE) of Borg (1970) is frequently used to measure the perceived exertion. Garcin et al. (1999) proposed to associate it with the Estimated Time Limit scale (ETL) to have further information on the exercise psychological load. These scales are valid and reliable. However, psychological states can mediate RPE and ETL. Hall et al. (2005) suggested that the effect of psychological states on RPE change with the exercise intensity. No study tested the influence of psychological states on ETL in different intensities. The purpose was to test the influence of psychological states on RPE and ETL, in different intensities.

Subjects
Twenty-three cyclists (22.8±5 yr, 70.1±5.6kg, 178±6cm) were recruited.

Material
Perceived effort was expressed with the RPE (Borg, 1970) and ETL (Garcin et al., 1999) scales.

Procedure
Cyclists performed an incremental test on a cycle ergometer. The initial power output was set at 150W/4min then increased by 50W/4min, until 300W. Then, an increment of 25W/2min was set until exhaustion. RPE and ETL were collected during the 4 first stages.

Statistical Analysis
RPE and ETL at 25, 50, 75 and 100% maximal aerobic power (MAP) were computed. The correlations between these values and the scores for the different psychological states were examined with the Bravais-Pearson test and coefficients.

Results
Significant effect of familial self-esteem at 100% MAP for RPE was noticed (r= 43). Significant correlation was found between leadership and RPE at 25 and 50% MAP (r = - .48). RPE was significantly correlated to the psychological resistance (<= - .51 at 25, 50 and 75% MAP) and psychological endurance (<= - .51 at 25 and 50% MAP). Social desirability was significantly correlated to ETL at 25% MAP (r = .45). The psychological endurance was correlated to ETL but only from 75% MAP (r = - .46).

Discussion
Some psychological states influence the effort hardness and the time limit predicted by teleoanticipation. However, these effects vary according to the exercise intensity. The lack of significant correlation between the RPE and/or ETL and some psychological states may be linked with the cyclists' high athletic experience.

MOTIVATION, TEAM LOYALITY AND VIOLENCE TENDENCIES OF HANDBALL SUPPORTERS: A CASE STUDY IN TURKEY

Celiksoy, M., Celiksoy, S.

Anadolu University, Turkey

Handball is a sport that has a large number of spectators in the world. It is seen that the number of handball spectators and supporters has decreased but the number of rows has increased on courts and grandstands, and recently, these events have been figured in mass media. A lot of projects have been prepared in order to ensure handball spectators and supporters' interest in handball. On the other hand, it can be said that there have been no prosperous results. Furthermore, there are not enough studies on handball spectators, supporters, marketing of handball and sponsors. In addition, the existing studies are not satisfactory for handball.

In this research, the answer was sought for the following questions: Is there a correlation between the tendencies and the supporters' demographic characteristics? In order to answer these questions, a survey has been prepared by the specialist researchers in Istanbul, Ankara, Bursa and Eskisehir and the survey was conducted with 386 handball supporters.

In analyzing data, a statistical program was used. Frequency, percentage, mean average and standard deviation were revealed in analyzing of data. Cronbach Alpha was used for the reliability of the variants. T-test and ANOVA were used to reveal the differences between the tendencies (the motivational factors, team loyalty, and violence) and demographic characteristics (age, gender, education and marital status).

% 47.4 of the supporters are male, % 77.2 of them are single, % 67.4 of them are students, % 45.3 of them are university graduate, % 51.8 of them are under the age of 21, % 45.6 of the supporters' earn 400 or fewer than 400 dollars in a month. It can be said that majority of the handball supporters are singles and students, for this reason they have low income. The most common answer in terms of motivational factor is that: "I feel excited when I watch my favorite team." Most of them like going to handball matches because they get excited.

In terms of team loyalty 'I support my team even if there is no famous handballer in the team' was the most common opinion. It means that when they watch their team, they have emotional relations with their team and they try to support it in any case. "I believe that hard game makes the game exciting" was the most common answer which reflects the supporters' opinions on violence tendency. As the large number of spectators is under 21, they like watching hard games.

The findings of the research revealed that there are significant discrepancies between the tendencies (motivation, team loyalty, violence and gender). Female supporters' mean value is higher than male supporters' in motivational factors and team loyalty. It can be said that female supporters' tendencies such as supporting the team, emotional relations with the team, watching the match with friends are higher than male supporters.
INQUIRY EXAMINING TEACHING MOTIVATION AND CONTENTS OF A TWO-YEAR COURSE SSIS

Frattini, G., Vago, P., Cilento, F., Mondoni, M., Marchetta, S., Melica, S., Casolo, F.

Catholic University of Sacred Hearth, Milan, Italy

In Italy SSIS (Specialization School of Secondary education) consists of a two-year course meant to prepare future teachers in Physical Education. One can be admitted via an open competition, after getting a University degree. The only examination centre in Lombardia is at Università Cattolica del Sacro Cuore in Milan. To know the motivation of those students who choose to attend SSIS, a school that teaches people how to teach, is the aim of this survey.

Secondly we tried to inquire into the contents and the organization of SSIS.

SSIS is divided into three modules:

1) common area which is shared by students who usually attend different faculties; themes are studied in depth from a sociological, psychological, pedagogical point of view (with an evaluation of the courses at the end);
2) specialist area, restricted to the students of SSIS with a Physical Education degree, [epistemology, planning-evaluation in PE], themes and methodologies are examined closely (with regard to the pupils' age, from 11 to 14 and from 14 to 19);
3) teaching practice, which is compulsory for both "Secondary education school from 11-14 year and 14-19 year".

Potentially future teachers must assist an experienced teacher (a 'tutor') who has been working for seven years at least in public schools, in order to get the know how of their profession. We gathered data about student's motivation through questionnaires, subjects were asked to rate the questions using a Likert scale (1-7), from "1" being of little importance to "7" being of very important. The sample consists in 67 interviewed students, attending the second year of the SSIS course, 37 were male and 30 were female.

The age of these students is between 20 and 29 (43 people); between 30 and 40 of age (23 people) and just one is over 40 years of age.

As to the Common Area activities, most students think that it was uninteresting and rather boring. Teaching Motivation: almost all students love teaching. 75% thinks it's well to be employed by the state. Analyzing the results of our search, the feedback should be used to modify the common area contents.

Teaching practice has been considered very interesting by all the participants to the course.

ATTITUDE TOWARD PHYSICAL ACTIVITY - DIFFERENCES BETWEEN PARTICIPANTS AND NON PARTICIPANTS

Cid, L., Chicau, C., Silva, C., Mouțoță, O.

Sport Sciences School of Rio Maior, Portugal

According several authors (e.g. Doganis & Theodorakis, 1995, Dosil, 2002, Biddle & Mutrie, 2001) the structure of attitudes can be defined by a three component model: cognitive (e.g. beliefs about exercise), affective (e.g feelings about exercise) and behavioral (e.g. approach or avoidance of exercise). In last years studies linking attitudes with physical activity participation have increased considerably on scientific literature (Dosil, 2005). This fact reveal the influence of this psychological construct into human behavior. However, most of the studies are conducted with people who are already involved into physical activity. This fact maybe supposes a wrong idea that positive attitude towards physical activity depends exclusively on the degree of participation (Dosil, 2005). For this author it is logical for those who do exercise or sport to have a positive attitude towards it. However, it is likely possible for those who don't do it, have a similar attitude. So, the main propose of this paper is to present the study of differences between participants and non-participants into attitude toward physical activity and sport.

For such, we studied a sample of 325 individuals, of both genders, with 23 ±5.2 years old of mean age and different degree on participation in physical activity (i.e. 114 non-participants and 211 regular participants). The measurement instrument was the Attitudes towards Physical Activity and Sport Scale, developed by Dosil (2002).

The main results indicate that participants attitudes are significant higher (i.e. more positive) than the non-participants (t=3.621; p=0.000).

This result is consistent with the literature. However the calibrate result of attitudes scale show us a similar percentile between groups: non-participants 61.1±8.4 (percentile 40 medium attitude) and participants 64.9±9.3 (percentile 45 medium attitude). This fact suggests that a negative or positive attitude can be found independently of the degree of participation. According Caetano & Raposo (2005), this happens because apparently everybody recognizes the importance and the benefits of physical activity.

PHYSICAL EDUCATION PRACTICE LEVEL AND ATHLETIC AND PHYSICAL SELF-ESTEEM CONTROLLING FOR AGE, GENDER AND SCHOOL GRADE

Rosado, A., Januario, N., Reis, P., Sousa, P.

Faculty of Human Movement of Technical University of Lisbon, Portugal

For developmental and educational well known reasons the aim of numerous programs among adolescents is to improve their self-esteem. To achieve these objectives, Physical Education is often presented as an effective tool. As part of their attempt to understand how students feel about themselves in Physical Education, researchers have asked whether different levels of practice might be related to self-esteem, defined as how well a person prizes, values, approves, or likes him or herself, an important benefit of sport practice. With regard to the relationship between these variables, research has been mixed. In view of these somewhat conflicting findings, we re-examined
In last years studies linking attitudes with physical activity participation have increased considerably on scientific literature (Dosil, 2004). According Biddle & Mutrie (2001), the definition of attitudes can be delimited by three components (i.e. beliefs, feelings and behaviors), that leads individual intentions to action. This fact reveal the influence of this psychological construct into human behavior. According Dosil (2004), the exercise conduct could be determinate by a negative or positive attitude toward physical activity and sport. In general, attitude and subjective norm explain about 30% of the variance in intentions to exercise and the addition of perceived behavioral control increased the value up to 40% (Biddle & Mutrie, 2001); however, attitude is far more consistently associated with intentions and behavior. Some recent studies (e.g. Dosil, 2003, Caetano & Raposo, 2005, Araújo, Calmeiro & Palmeira, 2005) are not consistent in results about the differences between genders. So, the propose of this paper is to clarify the differences between female and male individuals into attitudes toward physical activity.

For such, we studied a sample of 325 individuals (i.e. 165 female and 160 male), between 16 and 40 years old (i.e. 23.8±5.2 mean of age) and different degree on participation in physical activity (i.e. non-participants and participants). The measurement instrument was the Attitudes towards Physical Activity and Sport Scale, developed by Dosil (2002).

The main results indicate that male attitudes (67.2±7.9) are significant higher more positive (t=7.610, p=0.000) than the female (60.1±9.0). This result was consistent when we divided the sample by groups of different degrees of physical activity participation. In both cases the results are significantly different between genders: Non-Participants Group (female 58.1±8.4; male 65.2±6.4) and Participants Group (female 61.4±9.1; male 68.1±8.3).

THE EFFECT OF SELF-TALK ON SELF-EFFICACY

Hardy, J., Kirkman, D., Wright, M.
Bangor University, United Kingdom

The mental skill of self-talk is heavily promoted within the sports psychology literature and one aspect of self-talk that is commonly referred to is its valence (i.e., positive vs. negative self-talk). To date, research focussed on self-talk has been relatively atheoretical in nature. In line with the predictions of self-efficacy theory, if a person is told to perform a task or engage in a specific activity, their self-efficacy towards that activity will increase (Bandura, 1986). Therefore, self-talk is often seen as a means of influencing performance expectancy. However, recent research suggests that the use of positive self-talk can have a detrimental effect on self-efficacy levels. Participants using positive self-talk were expected to have higher levels of self-efficacy compared to those utilising negative self-talk.

Forty five Sports Science undergraduate students were randomly assigned to one of three groups; positive self-talk (n = 17), negative self-talk (n = 14), and a control group (n = 14; given no self-talk instructions). All participants completed a novel throwing task which provided minimised options for performance feedback. This was done in order to limit the influence of previous mastery achievements which have been found to have a potent source of efficacy beliefs. To supplement this strategy, participants were also provided with standardised feedback regarding task performance (60% successful). Following this all participants completed the same task again, except that those in the self-talk treatment groups were assigned I can do this, strong wind (positive self-talk) or I’ll never do this, poor technique (negative self-talk) to repeat to themselves before each attempt. Self-efficacy was assessed twice, once follow the standardised feedback and once after having completed the throwing task for a second time.

A one-way ANOVA revealed that no significant differences between the three groups were evident prior to the self-talk intervention. However, results from a 3 x 2 (group x time) mixed model ANOVA revealed a significant interaction (p < .001). More specifically, self-efficacy levels significantly decreased for the negative self-talk group (p < .001) whereas, self-efficacy did not change for both the positive self-talk and control group.

From an applied perspective the results suggest that the potential detrimental effects of negative self-talk (on self-efficacy, at least) are of a greater magnitude than the potential benefits of positive self-talk. However, not only does the present study suggest that practitioners should aim to reduce athletes’ usage of negative self-talk but it is recommended that they also provide their clients with an active strategy (e.g., positive self-talk) to act as an alternative and thus, prevent the use of negative self-talk by their athletes.
RAPID WEIGHT LOSS AND RISKS FOR EATING DISORDERS IN JUDO, TAEKWONDO, AND KARATE ATHLETES

Furian, T., Schneiderhan, M., Blümel, M., Eckert, S., Eben, K., Striegel, H., Brückner, H., Niess, A.

Medical Clinic, University of Tuebingen, Germany

Rapid weight loss (RWL) in preparation for competitions is a common method in certain sports to achieve a desired weight which enables the athlete (AL) to compete in a lower weight category. The issue of whether AL who compete in sports in which weight plays a crucial role are at an elevated risk for developing eating disorders has been of concern during the past years. Several studies have pointed out that at least some of the methods used by AL for weight control resemble those observed in clinically bulimic patients. American wrestlers have been shown to have higher risks for bulimic disorders, at least during the season. To examine whether this observation also holds true for AL competing in other sports, a questionnaire was used to evaluate weight loss methods, nutrition knowledge, and possible eating disorders. AL from the national and state Taekwondo, Judo, and Karate teams (NA, SA, and from local clubs (CA) were surveyed using a standardized questionnaire including the Eating Disorder Inventory (EDI). 1199 questionnaires (response rate approx. 35%) were analyzed, 39.3% females (16.5 +/- 3.7 years, 56.7 +/- 11.4 kg body weight [BW], body-mass-index [BMI] 20.4 +/- 3.1 kg/m²) and 60.7% males (18.1 +/- 4.9 years old, 66.7 +/- 13.7 kg, BMI 21.6 +/- 2.9 kg/m²). According to the WHO classification, 66.2% of females (F) and 72.3% males (M) had normal BMI if 24.0% underweight (UWF), 6.1% overweight (OWF), M 13.7% overweight (UWM), 9.9% overweight (OWM).

40.1% F and 49.5% M reported using RWL to prepare for a competition. Among them 21.6% F and 26.2% M stated that they had to lose weight before every competition. On average, AL reported losing 3.1 +/- 1.8% (F) and 3.3 +/- 1.9% (M) of their BW, respectively, equivalent to 0.005 +/- 0.005% (F) and 0.006 +/- 0.003% of their BW per day.

The results of the EDI show significantly higher values for F compared to M in 6 of 8 subscales.

Compared with AL who did not have to lose weight, those who reduced at least 4% of their normal BW had significantly higher scores in the subscales Drive for Thinness (DFT) [F: 16.7 +/- 7.3 vs. 21.7 +/- 8.6; M: 13.3 +/- 5.6 vs. 15.5 +/- 6.0], Bulimia [B] [F: 11.7 +/- 5.1 vs. 14.1 +/- 5.1; M: 10.6 +/- 4.2 vs. 12.2 +/- 5.0], and Body Dissatisfaction (BD) [F: 26.9 +/- 11.1 vs. 31.3 +/- 9.8; M: 20.5 +/- 9.4 vs. 21.2 +/- 8.0]. However, the magnitude of the higher scores in the RWL group did not reach the published levels of bulimia patients.

AL with an over weight BW displayed significantly higher scores in the DFT, B, and BD subscales. In female over weight AL, BD subscale showed levels comparable with published data from bulimia patients (OWF 36.2 +/- 11.5, UWF 24.4 +/- 10.0).

There was no significant difference between NA, SA, and CA concerning EDI scores.

In conclusion, significant differences were observed between RWL and non-RWL-AL. The magnitudes of the scores in bulimia-typical subscales do not suggest a clinically relevant risk for eating disorders in these sports.

YOUNG NATIONAL TEAM FOOTBALL PLAYERS- COMMON CHARACTERISTICS OR NOT?

Segberg, U.

University of Agder, Norway

In order to develop football players’ skills, possessing more knowledge about elite players’ backgrounds, lifestyles, activities and motivation may be important. The aim of this study is to describe some characteristics regarding to family backgrounds and motivation. 45 male football players in three National teams of Norway, U17, U19 and U21 participated in the study. Among these players, two thirds reported they were part of big families. Two thirds were three or more siblings and more than 20% reported they were four or more siblings. More than two thirds reported that they have older siblings. Furthermore, they reported about athletically active families, all of their siblings, more than fifty percent of their mothers and seventy five percent of their fathers had been athletically active. 35% of their siblings, 20% of their fathers and about 10% of their mothers had played sport at a high level. All of the players reported about a very high activity level in their childhoods, at age six, 65% and at age eight, more than 90% had been members of an athletics club. Moreover, most of the players also reported about a diversified involvement in a number of sport activities. From the ages of six until fourteen, more than 70% participated in one or more athletic activities in addition to football. The players’ ambitions were high, more than 75% wanted to be National team players or players on the international level.

Poster presentations (PP)

PP-RE02 Rehabilitation 2

MUSCULAR TONE CHANGE DUE TO INDIVIDUAL HYDRO-REHABILITATION TREATMENT

Petrov, A., Charsukajia, B.

Veliki Luki State Academy of Physical Education and Sport, Russia

Research objective: to determine the influence of individual hydro-rehabilitation exercises on the lower extremities and back muscle tone with patients suffering from the lumbosacral osteochondrosis at the remission stage.

Twenty-two women aged 25-45 were tested. The group was divided into two sub-groups - a control, comprising 11 healthy females, and a test one of 11 females with a clinically proved diagnosis.

Muscle contraction value was analyzed, i.e. the difference between muscle tone at rest and the one at maximum muscle tension.

It was discovered that unaffected subjects did not show a significant difference of bilateral muscle tone both at rest and at supertension - Rectus Femoris M. (RFM), Tilialis Anterior M. (TAM), Erector Spinae M. (ESM), M. Gluteus max. (MGM), M. Biceps Femoris (MBF), M. Gastrocnemius med. (MGm) (P=0.05). The mean contraction value appeared to be as follows - RFM - 1.1 mm, TAM - 1.3 mm, ESM - 2 mm, MGM - 1.4 mm, MBF - 1.2 mm, MGm - 1.2 mm.

Osteochondrosis patients are observed to have a hypertonia of all the muscles under study. In comparison with the healthy subjects the mean difference made 14.1% for RFM, 15.6% for TAM, 12% for ESM, 12.4% for MGM, 8.9% for MBF, and 10% for MGm. However, the contraction mean value for all the muscles under study was 2.1 times lower in comparison with the healthy subjects. The latter might attest to a lower functional condition of the neuromuscular apparatus owing to the osteochondrosis.

Predominancy of afferent or efferent nerve fiber affection of the mixed peripheric nerve was taken into account to individualize rehabilitation methods, the former was stated with the help of a complex electromyography.
40% of exercises in the system for those with predominant efferent nerve fiber affection took those for movement coordination. Such motor exercises are accompanied by parallel work of the cerebral cortex, subcortical systems, the cerebellum, the vestibular apparatus, spinal alpha-motoneurons, which peripherically activate damaged motor nerve fibers. For patients with afferent nerve fiber affection 40 per cent of the entire exercise set were those containing movements, with visual control off, to develop minor motor activity of the lower extremities’ neuromuscular apparatus. The choice of exercises enabled an increased activation of the affected sensitive neurifibers.

After a course of hydro-rehabilitation exercises held for 3 months the test group showed a decrease in the muscle tone level for all the muscles tested. The results changed significantly in TAM, MGM, in the right side of the MBF, MGM (P<0.05) and came up close, though not reaching, to the values typical for the healthy. There was a 44 per cent improvement of the muscle contraction in this group. Individually selected hydro-rehabilitation exercises made it possible to reduce the muscle tone and improve the functional condition of the neuromuscular apparatus.

**EVALUATION PROCEDURE OF PREDISPOSITION TO NARCOTISM AND MOTOR-MENTAL CONTROL DURING REHABILITATION PROCESS**

Baryaev, A., Evseev, S., Shklov, O.
St Petersburg Research Institute of Physical Culture, Russia

Introduction. Numerous researches of domestic and foreign experts on the given problem do not answer to the basic question: why the rising generation starts to accept drugs? Results of many sociological researches show that the main motives of drugs consumption:

- thirst of pleasures;
- desire to test sharp sensations;
- euphoria.

Drugs among youth have extended in the sizes disturbing the public of Russia. The narcotism is a complex condition of a brain which has psychological, social and biological aspects.

Methods of research. Inclusion in rehabilitation process at narcotism various stages means, methods and methodical approaches from area of physical training and sports will allow to raise efficiency of this process, due to complex influence on psychological, motor and socially-biological structure of a human body. In control system of person occurrence over a prospective narcotism condition from stimulators, and also in rehabilitation process it is necessary to allocate three basic stages causing application of specific complexes, methods.

Results. The first control stage is directed on revealing of person’s genetic predisposition to narcotism at early life stages.

The second control stage is directed on definition of person type on the basis of research its specific features-psychological. We can find a lot of information on these methods in the special literature about predisposition of various psychological person types to the use of drugs.

The third stage of the control is the most complex and less developed. The primary goal of the given stage is diagnostics of a condition of the person on the various beginning periods of the use of drugs. Thus it is necessary to consider a narcotism level, drugs type, age, social and other features. In Saint-Petersburg research institute of physical culture the unified complex of a quality monitoring is developed at carrying out of mass inspections which in the further was a basis for formation of the automated complex of an person condition estimation, allowing operatively to evaluate parameters of motor maintenance of impellent activity on different parameters reflecting realized impellent and vegetative components of a mental condition. The automated unified complex includes 43 parameters received skilled and settled.

Conclusion. Basic researches which have been carried out on various contingents of people, various age groups, practically healthy both having in motor-mental sphere of life-support have shown the various congenital and got high informative deviations and reliability of the received results. It is a necessary condition of adequate scientifically-methodical recommendations according to and corrections of a motor-mental condition surveyed, including in rehabilitation process of drug addiction people in conformity with a narcotism stage, characteristics of used drugs, age features and social conditions.

**EFFECTS OF DIFFERENT COOLING CONDITIONS ON THE EXERCISED SKELETAL MUSCLE**

Yanagisawa, O., Fukushima, T., Miura, T., Iwasaki, T., Takahashi, H., Fukubayashi, T.
Waseda University, Japan

Background: Cooling at a very low temperature, such as by ice bag application (almost 0ºC), frequently causes cold-induced pain. Thus, cooling at a temperature that does not evoke excessive pain is desired. However, the effects of a relatively higher cooling temperature on the skeletal muscle have not been sufficiently elucidated (1).

Materials and Methods: Axial T2-weighted and diffusion-weighted MR images of the ankle dorsiflexors (7 subjects; mean age, 27.6 years) were obtained before and after ankle dorsiflexor exercise and at 60 min after postexercise treatment by using a 1.5-Tesla MR device with a knee coil. T2 relaxation time, indicative of the intramuscular water level, and apparent diffusion coefficient (ADC) were calculated from the T2-weighted and diffusion-weighted images, respectively. The ADC values were divided into ADC1 and ADC2, the former reflects the diffusion and perfusion within the muscles, while the latter provides the approximate true diffusion coefficient within the muscles. The temperature of the skin over the ankle dorsiflexors was measured during 60 min after postexercise treatment successively. Postexercise treatments were classified into noncooling (60 min), ice bag application (20 min cooling followed by 40 min noncooling), and 10ºC gel pack application and 17ºC gel pack application (60 min cooling). As a common treatment, 30 mmHg pressure was applied to the cooled portion. The subjects received all the treatments separately.

Results. The T2 values showed significant increases immediately after exercise in all the treatment groups but were restored to values at rest after postexercise treatment, regardless of the treatment administered, there was no significant difference among the treatments in the T2 values. The ADC1 and ADC2 values (×10-3 mm2/s) showed significant increases immediately after exercise in all the treatment groups. All the cooling treatments resulted in significantly lower ADC values (ice bag: ADC1/ADC2, 2.4/1.51 at rest, 1.95/1.4 posttreatment; 10ºC gel pack: 2.4/1.53 at rest, 1.89/1.36 posttreatment; 17ºC gel pack: 2.49/1.5 at rest, 1.84/1.34 posttreatment), however, there was no significant difference among the cooling treatments in the posttreatment ADC values. For skin temperature, the noncooling and all cooling groups showed significantly greater and lower posttreatment ADC values compared with the postexercise values, respectively.

Conclusion: Local cooling decreases perfusion and water diffusion within the exercised muscle. Moreover, even when the cooling temperature is mild, effective cooling is achieved without evoking cold-induced pain by prolonging the application time.
EXERCISE TRAINING IN BREAST CANCER PATIENTS RECEIVING ADJUVANT TREATMENT

Sagarra, L., Ensenyat, A., Rodriguez, R., Ruidia, M., Moros, T.
INEFC-Lleida (UdL) and Universidad de Zaragoza, Spain

Chemotherapy frequently results in fatigue that impairs the development of a normal life, and patients are unable to perform daily activities. However, recent studies show that regular physical activity will blunt the deconditioning process and may help to improve the quality of life and psychological status of these patients.

The aim of this study was twofold; (a) to assess the effects of physical exercise training on functional capacity in breast cancer patients during their chemotherapy treatment, and (b) to determine the level of functional impairment in the early recovery of chemotherapy cycle.

Eight women (49.6 years SD: 5.7) with breast cancer in stage I, IIA or IIB (Singletary, 2002) that have undergone surgery and were receiving adjuvant chemotherapy treatment participated in the study. After receiving oral information, they signed an informed consent document.

Chemotherapy regimen comprised 4 to 6 cycles. Forty hours before and after the infusion, functional capacity was evaluated by means of Six minute walk test.

The exercise program lasted 6 months with a frequency of 3 sessions per week that lasted approximately one hour. Activities were mainly aerobic and intensity was set at 50-75% of their maximum heart rate.

Results show that 48 hours after chemotherapy infusion (post-infusion test) the distance covered in the 6-minutes test declined significantly (p<0.05) from 566.2 (SD: 60.9) (pre-infusion test) to 556.5 (SD: 81.4) metres in the first cycle and from 598.0 (SD: 49.2) to 554.7 (SD: 57.7) metres three months later. In the last cycle, that took place at the end of the six months of the exercise programme, the distance covered was slightly inferior (12 meters) in the post-infusion test, but did not differ significantly from pre-infusion data. Maximal heart rate registered at the end of each post-infusion test did not differ significantly from the values observed in pre-infusion test for any of the 3 time points.

Data show that chemotherapy impairs the functional capacity in the early recovery period, but even with the cumulative effect of several cycles of chemotherapy, women who attended to the exercise program were able to perform the post-infusion 6 minutes walk test suffering a minor functional impairment than at the beginning of the treatment.

THE EFFECT OF PELVIC CORRECTION AND SWISS BALL EXERCISE ON PELVIC TILT AND PELVIC TORSION IN THE SPINE

Gi Duck, P., Chul-Ho, S., Han-Young, L.
Namseoul University, Korea, South

We analyzed female students of N univ. who had a deformation-disposition or displacement of pelvis and for 4 weeks they’ve been treated by correction of pelvis and Swiss-Ball exercise. After checking the its effect on pelvic slope and rotation, we suggest that manipulation and exercise be a good program for curing displacement of spine. For 4 weeks manipulation and Swiss-Ball exercise had been given to female univ. students with lower back pain and menstrual pain due to displacement of pelvis, and then we’ve got the following conclusion: 1) concerning with the degree of slope of pelvis, both two groups had significant effects compared with non-therapy group. 2) concerning with the change of length of pelvic slope, both of two groups had smaller numerical value than before, but the difference between them was not significant in the pelvic manipulation group, the numerical value reduced from pre- manipulation 0.05±1.19(°) to after-manipulation -0.14±1.25(°), but there were no significant difference in the Swiss-Ball exercise group, the numerical value increased from pre-exercise -0.04±1.19(°) to after-exercise -0.90±2.47(°).

As a result of the dual variant analysis on pelvic rotation, there was no significant difference between them. In conclusion, two ways of therapy (manipulation and Swiss-ball exercise) had effects on pelvic displacement, so we suggest that new programs using these ways be made.

VALIDITY AND RELIABILITY OF HIP ABDUCTOR MUSCLE STRENGTH ASSESSMENT IN THREE DIFFERENT BODY POSITIONS

Widler, K., Glathhorn, J., Bizzini, M., Impellizzeri, F., Leunig, M., Munzinger, U., Maffiuletti, N.
Schulthess Clinic Zürich, Switzerland

Hip abductor muscles are responsible for hip stabilisation in the frontal plane during single leg stance and gait. Hip abductor weakness has frequently been associated with sport-related knee injuries and also with hip osteoarthritis. Unilateral hip abductor muscle strength has been assessed using either the lateral, supine or upright position but to our knowledge the optimal posture remains to be determined.

The aim of this study was to test the validity and reliability of unilateral hip abductor muscle strength assessment in the lateral, supine and upright body positions. Sixteen healthy subjects (8 men, 8 women) participated in two identical testing sessions separated by 2-3 days. In both sessions unilateral isometric hip abductor muscle strength was measured in the three body positions (randomly presented) using a portable dynamometer fixed to a custom-designed frame. Construct validity was based on concomitant gluteus medius electromyographic (EMG) activity recordings from the tested and contralateral hips. The posture permitting greater muscle activation on the tested hip, while minimizing muscle activation on the contralateral hip, was considered as the more valid position. For this, the tested-to-contralateral EMG ratio was compared between the three body positions. Maximal isometric strength and EMG data were analysed with a 3-way ANOVA (position x session x side). Coefficients of variation (CV), systematic bias ± random error (Bland-Altman plots) and intraclass correlation coefficients (ICC) were also calculated to determine the test-retest reliability in the different positions.

Maximal isometric hip abductor muscle strength was significantly higher in the lateral posture (364 ± 74 N) than in the upright (310 ± 56 N) and supine (243 ± 61 N) positions. EMG recordings showed considerable activation of the contralateral gluteus medius muscle in all body positions indicating that isolated unilateral hip abductor muscle strength assessment was not feasible. However, only in the lateral position the tested-to-contralateral EMG ratio was lower than one, thereby achieving our construct validity criterion (lateral: 0.79, supine: 1.17, upright: 1.21). Test-retest reliability of the maximal strength measurements in terms of CV (lateral: 3.7, supine: 6.1, upright: 4.2), Bland-Altman (lateral: -1.2 ± 6.9, supine: -0.3 ± 8.4, upright: -0.6 ± 7.5) and ICC (lateral: 0.90, supine: 0.83, upright: 0.88) was better in the lateral posi-
tion. Valid and reliable assessments are needed for bilateral comparison of hip abductor muscle strength (e.g., dominant vs. non-dominant side for healthy subjects or affected vs. non-affected side for patients). In this study we observed the highest validity and reliability for unilateral hip abductor muscle strength assessment in the side-lying lateral posture and therefore we strongly recommend the use of this body position to clinicians and practitioners.

MUSCLE STRENGTH AND STABILITY IN ACL RECONSTRUCTED PATIENTS AND CONTROLS

Kellis, E.
Aristotle University of Thessaloniki, Greece

Anterior cruciate ligament (ACL) injury is associated with increased knee instability, alterations in neuromuscular function, muscle strength and movement pattern, defective proprioception and impaired postural control and functional performance. The aim of this study was to examine the isokinetic muscle strength and stability during one-leg stance in patients who had undergone unilateral ACL reconstruction. Twenty five males who had surgical reconstruction of the ACL (reconstructed group), 8-10 weeks after surgery and 15 participants without knee injury (control group) participated in this study. Eccentric and concentric strength testing was performed for knee flexion and knee extension at 60, 120 and 180°/s on a Biodex isokinetic dynamometer. The subjects also performed five single-leg stance trials on an EPS pressure platform (Loran Engineering S.r.l., Bologna - Italy). The duration of the test was 30 sec. The distance and velocity of the center of pressure (COP) and the sway area were examined. Independent t-tests were used to examine group differences in each dependent variable at p < 0.05. The results indicated that ACL reconstructed individuals demonstrated a significantly (P < 0.05) higher COP distance (499 (133) mm) compared with controls (387 (81) mm). Similarly, sway velocity was significantly higher in ACL reconstructed individuals (21 mm/s) compared with controls (16.5 mm/s). Furthermore, subjects with ACL reconstruction displayed significantly lower (p < 0.05) knee extension and flexion muscle strength compared with controls. It appears that ACL-reconstructed individuals demonstrate significantly lower knee extension and flexion moments and higher COP movement compared with healthy subjects. Reduced muscle strength and sensory deficits after ACL reconstruction lead to decreased stability and explain the increased movement problems at the early stages of ACL reconstruction.

STRENGTH TRAINING ACCOMPANYING CHEMOTHERAPY AFTER LUMPECTOMY

Knicker, A., Müller, S., Baumann, F., Krakowski-Roosen, H., Schneider, J., Strüder, H.
German Sport University Cologne, Germany

Purpose.
To examine 1. the feasibility of strength training during chemotherapy in breast cancer patients, 2. the effects of strength training on muscular performance of upper and lower extremity muscles under isometric and isokinetic conditions, 3. the effects of strength training on indicators of quality of life.

Methods.
Ten female patients aged 56.6 (SD=9.41) years participated in a 12 weeks strength training program after lumpectomy and during chemotherapy. The strength training program consisted of 3 sets of 7 exercises at strength training machines at a 12 repetition maximum level twice a week. The exercises involved shoulder rotation, knee extension - flexion, spine stabilisation, shoulder elevation, latissimus pull, active back extension - flexion and elbow extension - flexion. Neuromuscular performance was registered before and after the study on an isokinetic dynamometer (IsoMed2000) under isometric (3 positions within the tested range of motion) and isokinetic conditions for leg flexion extension and arm inward outward rotation respectively.

Quality of life was evaluated with the EORTC QLQ-C 30 questionnaire at the start, after six weeks and at the end of the study.

Results.
None of the patients retreated from the study or missed a training session. Strength parameters: independent from the surgery site we registered improvements of strength parameters under isometric (maximum torque, average torque) as well as under isokinetic conditions (maximum torque, average torque, total work and total as well as maximum power) for knee extensor muscles and shoulder rotator muscles respectively. The differences were independent from handlingness and the side of the extremity.

There was a slight tendency of a bigger improvement of the strength parameters on the side where the surgery had taken place which must not be attributed to improvements of muscular abilities only but are obviously due to an improved confidence in general movement abilities.

Quality of life: the patients subjective quality of life improved significantly throughout the test period. Symptoms of nausea particularly after medication were significantly moderated towards the end of the training period. The same came true for state of fatigue and loss of appetite. A significant improvement of the overall emotional state together with a better estimation of the social situation could be identified. The parameters of physical function, pain, shortage of breath and sleeplessness showed a decrease during the first half of the study but an improvement above the starting level at the end of the study.

Conclusions.
Strength training during chemotherapy of breast cancer patients leads to improvements of neuromuscular performance. It also helps to improve quality of life as it moderates side effects usually attributed to chemotherapeutical treatment. The study proofed its feasibility as all patients finished the study after regular participation.

ANALYSIS OF PERFORMANCE OF WHEELCHAIR HANDBALL TEAMS

Collegari, D., Gorla, J., Carminato, R., Silva, A., Araújo, P.
Universidade Paranaense, Brazil

Every day the Adapted Sport is gaining more space, which is justified by the importance of this activity as a factor of Reintegration, Social Inclusion, Rehabilitation and promotion of a better quality of life for people with disabilities. A good example is the Wheelchair Handball, created in the Toledo city from Brazil, in 2005, and which is being contested in two ways: the HCR7, who adopted the rules of the Handball Team, and is the object of this study, and HCR4, who adapted the rules of the Beach Handball, which will be discussed in another study. This study aimed to evaluate the performance of teams participating in the II WEST CUP. Were recorded and quantified the following factors: 1) index of Technical Errors (TE = were considered only the mistakes that resulted in loss of ball possession), 2) rate of Shots...
Errors (SE), 3) Attack Effectiveness = goal (AE/G) of each team in the competition. The sum of these three factors indicated the total of Ball Possession (BP), which is an index of the influence of different indexes (TE, SE, AE/G) in the performance of teams. METH-ODS - The form of assessment (scale) to register the shares of play. Data collection was performed by the team of arbitration, because in this mode the chip in evaluation (scale) is a summary of departures. Data analysis was performed using the percentages of errors (TE and SE) and goals (EA/G) in relation to the total of PB. Three teams participated in this competition. RESULTS & DISCUSSION. The competition presented a total of 336 possessions of balls, of which 160 (47.7%) were wasted with shots errors. Other 103 (30.7%) were wasted with technical errors and only 73 (21.6%) were converted into goal, the greater goal attack in the game of handball. There is a high number of shots errors with balls defended by goalkeeper (80/50%), indicating that the decision to keep the goalkeeper in the wheelchair allied to reduce the crash, maintained the importance of the role player in this adaptation of the sport. In Technical Errors there was a predominance of errors in the plea pass (74/71.8%), which we infer that the coordination between area of the chair to field the ball needs to be improved. In Attack Effectiveness there was a predominance of Goals of 6 meters (42/57, 5%), which indicates that the release of long distance are elements that still need to be developed and that can become differential result of the evolution of the sport. CONCLUSION: This study has identified the factors that influenced the performance of the participating teams of the 2nd. West Cup WCH, establishing parameters initial analysis and serving as reference for the implementation, planning and training of new teams this new adapted sport. It has been as expectation that the performance of a larger number of competitions and the production of new scientific studies provide the evolution of the WCH, which has been an effective tool for the inclusion of the poor, especially those who are unable to pursue other modalities collective, as the basketball and rugby, for example.

ADAPTATIONS IN HUMEROSCAPULAR RANGE OF MOTION AND SCAPULOTHORACIC ARTHROKINEMATICS IN FEMALE HANDBALL PLAYERS

Boeyens, J.P., Felix, P., Viroux, P., Cabri, J. Vrije Universiteit Brussel (BE), Universiteit Antwerpen (BE), Universidade Tecnica de Lisboa (PT), Physiotherapieschule Thim van der Laan (CH), Belgium

34 female handball players were studied for 3D scapulohumeral and humeroscapular arthrokinematics by means of electromagnetic tracking. The purpose of this study was to measure and compare 3D scapulohumeral orientation during scapular plane humeral elevation, as well as the humeroscapular range of motion during external/internal rotation at 90° abduction and internal rotation at 90° flexion. Methods: Dominant (throwing) and heterolateral shoulders of the subjects had 3 electromagnetic sensors secured to the humerus with a cuff, to the scapula with a specially designed adjustable spine scapulae fixator (1), and to the sternum. A fourth sensor was used as a stylus to digitize the anatomical landmarks used to embed the anatomical coordinate systems, according the recommendations from the international Shoulder Group of the International Society of Biomechanics. Orientation of the scapula was defined as internal/external rotation, upward/downward rotation, anterior/posterior tipping. Humeral orientation was expressed as rotation into plane of elevation, elevation, and longitudinal axis rotation. Orientation of the scapula was analyzed at the initiation of movement 0°, 30°, 60°, 90°, and 120° of humeral elevation. Not above 120° of elevation because of the lack of validity due to skin-bone motion (1). Results: Comparing the throwing with the contralateral shoulder in these female handball players, the results indicate a significantly (p<.05) enhanced upward rotation and internal rotation. No significant differences could be demonstrated with respect to anterior/posterior tipping. Related to the humeroscapular arthrokinematics, a significant (p<.05) gain in external rotation at 90° abduction, a decrease in internal rotation at 90° abduction and a decrease in internal rotation at 90° flexion was found. Conclusion: Female handball players develop adaptations that most likely result from the throwing motion. It remains difficult to determine if the adaptations result in improved throwing skill or injury prevention (increased scapulothoracic upward rotation) or contribute to joint injury (such as decreased humeroscapular internal rotation which has been demonstrated to correlate with subacromial and internal impingement). References.

EFFECTS OF REHABILITATION PROGRAM BASED ON THE INTERMITTENT WALK

Coquart, J., Lemaire, C., Garcin, M. Faculty of Sports Sciences and Physical Education, Lille 2 University, France

Physical activity (PA) has beneficial effects on obesity. However, obese patients weakly adhere to PA probably because of continuous exercises monotony often proposed (Wing et al., 1988). To increase the adhesion to PA, intermittent exercises may be more appropriated.

Subjects

Twenty obese women were recruited (Age: 52.4±7.6yr; Body mass: 108.2±14.9kg; Height: 162±8cm; Body mass index, BMI: 41.4±8.1kg/m²; Body fat: 47.4±4.9%). Ten women integrated a training group and 10 women were not trained (control group).

Material

Body mass and fat were assessed using a bioelectroencephalic impedance scale (TBF 543, Tanita®). Resting systolic (SBP) and diastolic (DBP) blood pressures were measured by an electronic device (BP 3AC1-T, Microlife®). Resting heart rate was recorded by a cardiotachometer (Accurex+, Polar®). Perceived effort was expressed with the Ratings of Perceived Exertion (RPE) (Borg, 1970).

Procedure

During a baseline visit, anthropometric and physiological data were collected (age, body mass and fat, height, resting SBP and DBP, and resting heart rate). Then, the women performed a 6-min walking test to determine a maximal distance (Dlim). To examine the less hard walk, the control training group performed CW and IW on a treadmill with a similar velocity and duration (32 min). During CW, women continually maintained 70% velocity during the 6-min walking test, whereas during IW, they alternated 60 and 80% velocity during the 6-min walking test. The less hard walk was determined by lower RPE. Then, the trained women performed IW during 10 weeks (3
(TA) and internal oblique abdominals (IO) activity while minimizing that of the mobilizers, including the rectus abdominus (RA) and external oblique abdominals (EO). However, no studies have investigated the motor control responses in the abdominal muscles to maintain the lumbar stability after applying therapeutic modalities to the abdominal muscles themselves.

**Material and Methods.**

Subjects: 8 healthy adult males free of low back pain. Measurements: Surface EMG activity was recorded from the right RA, EO, IO, erector spinae (ES), and multifidi (MT) during the 2 tasks (abdominal hollowing exercise and static full-forward bending position) before and after applying a hot pack to the anterior and lateral sides of the upper and middle abdomen for 20 minutes. Furthermore, surface EMG activity was recorded in static full-forward bending position while performing abdominal hollowing. To reduce the bias of EMG measurements between pre-test and post-test, skin temperature was monitored and equal.

**Results.**

For the IO and EO, there was significantly higher activity during the abdominal hollowing in post-test compared with pre-test (p = 0.04 and 0.01, respectively). In static full-forward bending position while performing abdominal hollowing, the IO produced significantly higher activity, while the MT produced significantly lower activity in post-test compared with pre-test (p = 0.04 and 0.01, respectively).

**Conclusions.**

Abdominal hollowing or contracting the TA and IO may increase intraabdominal pressure, enhancing stability around the lumbar spine. Furthermore, the increased intraabdominal pressure may supply the extension force to the lumbar spine, reducing the loads on the lumbar extensors. On the other hand, hot pack may warm superficial muscles and reduce their tone. Our study found that applying a hot pack to the abdomen easily brought out the higher activity of the IO during the abdominal hollowing and minimized that of the MT in static full-forward bending position once the IO was easily activated. Thus, strengthening exercises for the abdominal stabilizers plus thermal modalities for abdominal mobilizers may be effective for the rehabilitation of low back pain.

**THE INFLUENCE OF SKIN-FOLD THICKNESS IN DETERMINING IN DETERMINING**

**Jones, D., Grace, C., Griffiths, T., Kilgour, R., Comtois, A.**

**Concordia University, Canada**

Purpose For this project we evaluated the palpation skill of two experienced athletic therapists (AT) and looked at the influence skin-fold thickness may have on agreement between the two ATs. The two AT’s palpated eight different locations on the upper arm and torso of young women, on two separate occasions. The AT’s were palpating for the presence or absence of a nodule in the muscular tissue that is often associated with a trigger point.

Methods Using a double blind process the two AT’s evaluated 19 subjects for this project. None of the subjects had experienced any upper body pain in the 6 months before the testing took place. The two AT’s agreed on the predetermined locations that would be palpated and marked each site with indelible ink. The AT’s were not given any verbal feedback from the subjects on whether or not a nodule had been located. After the completion of the palpation process, skin fold measures were performed at each location to determine skin-fold thickness.

Results A total of 264 locations were evaluated by each AT, 152 locations on day 1 and 112 locations on day 2. (5 subjects were unable to return between day 1 and day 2) The percentage agreement on day 1 varied from a high of 95% -to a low of 35% depending on the location. The percentage agreement on day 2 varied from a high of 89% -to a low of 65% depending on the location. Skin fold thickness was also measured at each of the testing locations and a significant difference (P<0.05) was found between locations. The location with the lowest skin fold values had the most agreement between the two AT’s as to whether a nodule was present or absent. The location with the second highest skin-fold values had the most disagreement between the two AT’s in regards to nodule status at the site. A comparison was also performed evaluating the intraclass correlation between the AT’s (ICC= 0.537) as to the status of a nodule at each location.

Conclusion Skin-fold thickness appears to be a factor when therapists are evaluating tissue. Locations with greater amounts of adipose tissue required repeated trials in determining nodule status. This was seen with the increase in the percentage of agreement between both AT’s from days one to day two at locations with greater amounts of adipose tissue. The percentage agreement between the AT’s did not really change in the locations with less adipose tissue. The low ICC scores for the palpation of the presence or absence of nodules are consistent with other studies evaluating manual techniques by therapist. The difference between this study and previous work in this area is the rigor at which the data was collected. Often a nodule in the muscular tissue may be associated with pain when pressure is
applied to it. With all of the subjects being asymptomatic of pain the therapist could not rely on some type of twitch response/aversion response by the subject to indicate the presence of a nodule.

**IMPACT OF PHASE CARDIAC REHABILITATION PROGRAM ON MORTALITY IN ELDERLY PATIENTS WITH STABLE CORONARY ARTERY DISEASE**

Department of Cardiovascular Medicine, Japan

Background: Cardiac rehabilitation has numerous benefits in not only modification of risk factors, but also improvement of mortality in patients with coronary artery disease[1,2,3]. However, there are few studies, which investigated the long-term efficacy of phase III cardiac rehabilitation in elderly patients. The aim of this study was to assess the impact of phase cardiac rehabilitation on mortality in elderly patients with coronary artery disease. Method: We included 36 male patients (more than 65 years). All patients participated in the supervising cardiac rehabilitation during 6 months. The cardiac rehabilitation consisted of exercise training, diet therapy, and counseling once a week. We followed up to 8 years after the program. Results: After cardiac rehabilitation, body mass index, %fat, fat weight, muscle strength of lower limb, anterior trunk flexibility, lipid profiles and glucose tolerance, were significantly improved. Five patients died (myocardial infarction: 1, cancer: 3, accident: 1). The value of 60min, 120 min, and area under the curve of 75g oral glucose tolerance test at baseline were significantly higher in the event group than the survival group. The value of %fat, and insulin of 60 min of 75g oral glucose tolerance test after cardiac rehabilitation were also significantly higher in the event group comparing with the survival group. The flexibility of anterior trunk after cardiac rehabilitation was significantly lower in the event group than the survival group. Conclusions: These data suggested that cardiac rehabilitation program in phase in elderly patients with coronary artery disease was effective for physical fitness, lipid profiles and glucose tolerance. Moreover, intensive intervention on deterioration of glucose tolerance and insulin sensitivity caused by fat accumulation may be needed to improve the long term prognosis in elderly patients with coronary artery disease.

**HIP MUSCLE WEAKNESS IN PATELLOFEMORAL PAIN SYNDROME**

Thom, J., Roscoe, S., Lancaster, R., Barnes, M., Jones, J.

School of Sport, Health and Exercise Sciences & North West Wales NHS Trust, United Kingdom

INTRODUCTION: Patellofemoral pain syndrome is one of the most common knee complaints, especially in athletes, with symptoms often being triggered during activities such as walking down stairs. The potential causes of patellofemoral pain are poorly understood and thought to be multifactorial. One of the possible factors that may contribute to the development of patellofemoral pain is hip muscle weakness, particularly of the hip abductors and external rotators. However, there is limited research on the contribution of hip muscle weakness in this patient group. The purpose of this study was twofold, firstly to test the reliability of hip muscle strength measures and secondly to determine if hip muscle weakness is present in patients with patellofemoral pain.

METHODS: To determine the reliability of hip abduction and external rotation maximal torque, 21 healthy volunteers (14 females, 7 males, age: 22.4 (3.4) years, height: 167.7 (7.3) cm; mass: 65.2 (8.6) kg, mean (SD)) were tested on one limb on two separate occasions. Maximal hip abduction and external rotation torque were measured isometrically three times at 10 degrees and maximal concentric torque three times at 50 degrees/s (ROM from 0 to 30 degrees) using a Humac Norm isokinetic dynamometer. The affected limb of 18 patients with patellofemoral pain (age: 26.8 (9.2) years, range 19-50 years, height: 169.3 (9.4) cm, mass: 69.2 (12.5) kg) were then compared with the unaffected dominant limb of 18 matched healthy controls (age: 28.6 (10.3) years, range 18-53 years, height: 168.7 (112.8) cm, mass: 73.6 (112.4) kg). The torque values were normalised to body weight. A subgroup of patients (n=11) and healthy matched controls (n=11) also performed a step-down task with EMG electrodes placed over the posterior fibres of the gluteus medius (PGM) and the vastus lateralis muscles to determine reliability and differences in activation onset/offset times between the groups.

RESULTS: The hip muscle strength tests were found to be reliable (intraclass correlations r=0.85 to r=0.96, P<0.001). The patellofemoral pain patients normalised torque values were 21-22% lower than that of the controls in hip abduction (P<0.05) and 38-41% external rotation (P<0.01), isometric and concentric torque, respectively. The PGM/VL EMG step-down measures were found to be reliable (r=0.73 to r=0.89, P<0.001). However, no significant differences were observed between the groups in duration or onset of the PGM muscle, although the patellofemoral pain patients tended to have lower muscle activity than that of the controls during the maximal contractions.

CONCLUSIONS: Weakness of the hip abductors and external rotators is a problem for patients with patellofemoral pain. These data suggest that, regarding motor function of subjects, there were no significant differences between two groups at base line; however after the treatment, all sub-scales of motor function between two groups were significantly different. In the experimental group, the intervention...
improved all sub-scales of motor function significantly, though, no significant changes observed within the control group. In conclusion, physical therapy in conjunction with standard medical therapy, could affect motor function of people with Parkinson disease positively, and therefore could be beneficial for these patients.

Poster presentations (PP)

PP-SM03 Sports Medicine 3

EVALUATION OF EVIDENCE BASED TRAINING THERAPY IN PATIENTS WITH NON-SPECIFIC BACK PAIN VARIABILITY OF SPINE SHAPE PARAMETERS AND DIFFICULTIES IN SHORT-TERM COMPARAISONS

Schroeder, J., Reer, R., Braumann, K., Mattes, K.
University of Hamburg, Faculty 4, Germany

In an attempt to evaluate the effects of evidence based individually designed training treatment in back pain patients we found significant alterations in pain, health state, trunk muscle peak force and spine posture parameters. But there are some difficulties for reasonable conclusions when you at the variability of back shape analysis parameters in longitudinal short-term interventions.

A sample of 29 back patients (22 females: age 54 +/-15 y, height 1,69 +/-/0,06 m, weight 71,0 +/-14,6 kg, 7 males: age 42 +/-13 y, height 1,89 +/-/0,08 m, weight 88,7 +/-15,2 kg) went through an individualized training intervention (2 units/week, 18 units at all) and were examined before and after the treatment in terms of pain (CR10 pain scale), health state self-rating (SF12 physical and mental score), trunk muscle peak force for back extension, trunk flexion, lateral flexion und trunk rotation (Myoline®) and posture parameters by means of back shape analysis (Formetric®).

There were significant decreases in pain score values (p= .002), significant increases in health state physical and mental scores (physical: p= .020, mental: p=.045 respectively). In addition we found various increases and alterations in peak force and spine shape parameters. Especially, back extension increased significantly (T=26, p<.000) from initially 40.0 kg (59.8/28.3) to 55.0 kg (82.7/43.8). In accordance to other findings there were some alterations in spine shape parameters. A significant increase of lordotic angles (T12-DM & maximum angle) can be observed, in women especially: maximum lordotic angle changes significantly (T=37.5; p=.012) from initially 39.5° (46.3/33.1) to finally 37.0° (44.0/32.3). For females and males there are changes with a tendency for significance (females: T=52; p=.084, males: T=0.0; p=.068) in the lordotic angle T12-DM from 36.8° (39.9/30.3) to 33.5 (38.8/30.5) and from 33.0° (34.0/28.5) to 32.0° (33.5/28.0), respectively.

Analyzing the data pool we recognized that there are angle alterations in both directions and of course more or less extended for the decision if an individual alteration of a spine shape parameter can be judged to be caused by a previous training treatment you have to be aware of the test reliability and the parameter variability in repeated measurements. In case of lordotic angle measurement we found reliability coefficients of rtt=0.92 0.95 (n=157) and a mean range of parameter variability of 2.7° to 3.1° (n=69). That means that individual alterations in lordotic angles should be considered to be induced by any treatment only, if the difference is more than approximately 3°.

Conclusions based on spine shape parameter changes are valid only with regard to these fundamentals. Judging changes in lordotic angles leads to valid information but there are numerous difficulties to rate changes in spine shape parameters like trunk inclination or pelvic tilt or vertebral rotation.

EFFECT OF FOOT AND ANKLE IMMOBILIZATION ON LEG AND THIGH MUSCLE VOLUME AND MORPHOLOGY: A CASE STUDY USING MAGNETIC RESONANCE IMAGING

Grosset, J.F., Onambele-Pearson, G.
Manchester Metropolitan University, United Kingdom

Introduction
Despite the routine practice of ankle joint immobilization after injury, the impact of said immobilization and the rate of recovery of both proximal and distal to the immobilized joint muscle groups is poorly characterized in term of muscle morphology and volume changes. The aim of our current investigation was therefore to systematically describe the changes associated with total ankle immobilization, using the quadriceps, hamstring and triceps surae muscles as models of atrophy and post-trauma recovery.

Methods
A healthy young woman (29 years) had suffered a fracture of the fifth metatarsal of the right foot. MRI scanning of her right thigh and calf muscles were performed on three separate occasions: the first, one month before the injury (Pre) during a scan initially planned as a teaching tool, the second, two days following a 4-week cast immobilization period (Post), and the third, after a two-month recovery period (Post+2).

Results
The results show muscle volume decrements in the triceps surae (TS), quadriceps (Quad) and hamstring (Ham) of 21.9, 24.1 and 6.5% respectively, between the Pre and Post measurements. At Post+2 the Quad and TS muscle volumes were still -5.2 and -9.5% decreased, compared with the Pre data. The Ham muscle volume however, was 2.7% greater than at the Pre phase. Following recovery, hypertrophy in individual TS muscle volume was limited to proximal and medial (with respect to the knee joint) segments of the muscles.

Discussion
The current case study shows that complete ankle immobilization leads to a greater loss of muscle volume than other hypo-activity models including unilateral lower limb suspension (Tesch et al. 2004), bed rest (Allen and Tesch 2004), and spaceflight (LeBlanc et al. 2000), where movements are still allowed though the degree of loading is substantially decreased.

Conclusion
These results indicate very substantial and rapid losses in muscle volumes, both proximally and distally to the immobilization site. The results also show that recovery is far from complete up to two months post cast removal. Moreover, the present study suggests the importance of awareness of the localised aspect of the degree of CSA changes. The results have implications for the requirements for rehabilitation for orthopedic patients.

The analysis of the content gave us a half punctuation 5.49 ± 1.00 while punctuation obtained in the writing was of 5.27 ± 1.19. With regard to the content, all those questions with an inferior punctuation to the half punctuation were revised. However, the questions with an inferior punctuation at 5.8 were restated.

Aim of this work was to identify anthropometric and body composition variables that discriminate among groups of sub-elite male athletes aged 25-3 years ± 4.61 from four different sports (cycling, n=10; swimming, n=10; volleyball, n=10; soccer, n=17) and fitness controls (n=59). The anthropometric variables were weight (74.6 ± 9.07 kg), height (1.80 ± 6.9 cm), skin fold thickness in seven sites, sum of skin folds; body composition variable was % body fat estimated from seven skin folds according to Jackson & Pollock equation. Stepwise discriminant analysis was then applied to the 13 variables measured to develop a model capable of predicting which of the four different sports the athletes participated in. Statistical analysis was performed using SPSS software package. Results showed that the 4 discriminant functions were highly significant (P<0.001 for all). Squared Mahalanobis Distance to Centroid showed a better separation for cyclists and swimmers with respect to the other groups. Indeed, it was found that after cross-validation, 100, 100, 80, 77, and 70% of cyclists, swimmers, volleyball, soccer players, and fitness control, respectively, were correctly classified. The variance among 4 different sports and fitness controls was most explained by body dimensions, not body composition. These results suggest that sub-elite athletes practicing sports with different metabolic requirements can be identified with good accuracy by easy-to-measure anthropometric variables. This finding may be useful to identify talents in different sports.

VALIDATION OF A QUESTIONNAIRE FOR THE REGISTRATION OF INJURIES IN THE PROFESSIONAL SOCCER

Noya, J., Benito, P., Calderon, F., Gómez, P.  
Faculty of physical Activity and Sport Sciences-INEF, Spain

Introduction. 
One of the main concerns in the professional soccer, is the high incidence that suffer [1-3]. The main objective of this work is to infer in the causes, designing a new tool of evaluation of the injuries in the soccer. First step in all investigation for questionnaire is the validation of instrument [4].

Material and methods. 
For the process of validation of the instrument, you elaborates a first questionnaire conformed by 46 questions. That questionnaire was sent by 10 experts which known reputation national in this environment for their evaluation. The experts were distributed in two groups, the first specialists in qualitative statistic and the second group in the evaluation practical aspect.

Experts applied for the evaluation of each question, a scale likert of 6 units, valuing the relevancy, content and writing of each question. The results of each questionnaire of experts’ evaluation were processed in the program SPSS v.14 to carry out a descriptive analysis of three variables to analyze on each article.

Results. 
Of 38 questions included, 11 questions initially were excluded, what final questionnaire is 27 items. After descriptive statistical analysis of each questions, first approach, that you uses, was the relevancy. The obtained half punctuation was of 3.60 a 0.909 being eliminated all those questions with a punctuation <3.5 points. That takes us to exclude 11 questions.

The analysis of the content gave us a half punctuation 5.49 ± 1.003 while punctuation obtained in the writing was of 5.37 ± 1.191. With regard to the content, all those questions with an inferior punctuation to the half punctuation were revised. However, the questions with an inferior punctuation at 5.8 in the writing were restated.

This validation process gives us as a result a questionnaire formed by 27 questions, all of them closed character. Which we will be able to value the injury incidence in competition.

Conclusions.
The obtaining of a perfectly valid tool for registration of injuries in the current professional soccer.

PHYSIOLOGICAL AND ANTHROPOMETRIC CHARACTERISTICS OF ELITE JUNIOR HANDBALL PLAYERS

Noutsos, K., Nassis, G., Varellis, I., Kororos, P., Skoulas, D., Bayios, I.  
National & Kapodistrian University of Athens, Greece

Introduction: Talent identification is the recognition of potential by means of certain measures accepted as markers of future high performance. Players’ anthropometric and physiological characteristics are recognized as important determinants of performance. Consequently, physical and physiological assessment may assist in the identification of young talents (Carter, 1967). The purpose of the present study was to define the physiological and anthropometric characteristics of elite junior Greek handball players.

Methods: Thirty handball players [age 15.5 (0.4) yrs, mean (sd)], all members of the Greek junior national team, participated in this study. The anthropometric measurements included: body mass, height, five skinfolds thicknesses (biceps, triceps, subscapular, suprailiac and
call), three circums (call and biceps relaxed and tensed) and two widths (femur, humerus). Body density was calculated using the equation of Durnin & Womersley (1974). Percent body fat was estimated from the measurement of four skinfolds using the equation of Siri (1956). The somatotype was calculated following the Heath & Carter method (1967). All anthropometric parameters were obtained according to Heyward & Stolarczyk (1996). Physiological assessment included: flexibility (sit and reach), running speed (5-m, 10-m, 30-m sprint from standing position), maximal oxygen uptake (20-m shuttle run) and muscular power (standing long jump and ball velocity at standing position).

Results: Height was 180.3(6.8) cm, body mass 77.8(11.2) kg, BMI 23.9(3.0) kg/m², body fat 14.3(9%), fat free mass 66.2(7) kg, fat mass 11.5(6) kg, endomorphy 3.0(1.1), mesomorphy 4.3(1.2), ectomorphy 2.4(1.3). The results for the fitness assessment were as follows: sit and reach 35.2(7.1) cm, 5-m sprint 1.07(0.0) sec, 10-m sprint 1.82(0.1) sec, 30-m sprint 4.4(0.2) sec, estimated maximal oxygen uptake 48.5(4.1) ml/kg/min, standing long jump 224.4(17.6) cm and ball velocity at standing position 78.3(7.2) km/h.

Discussion and Conclusions: The results of this study show that elite junior Greek handball players, compared with Danish youth national handball players aged 17.9(0.7) yrs had lower body height [188(6) cm], body mass [83.6(8.4) kg], maximal aerobic power [57.5(4.7) ml/kg/min], and standing long jump 35.2(7.1) cm, 5-m sprint 1.07(0.0) sec, 10-m sprint 1.82(0.1) sec, 30-m sprint 4.4(0.2) sec, estimated maximal oxygen uptake 48.5(4.1) ml/kg/min, standing long jump 224.4(17.6) cm and ball velocity at standing position 78.3(7.2) km/h.

EXERCISE MAY PREVENT AMPHETAMINE ADDICTION
Tavares, P., Marques, E., Pereira, F., Silva, A., Macedo, T., Ribeiro, G., Fontes Ribeiro, C.
University of Coimbra, Portugal

The dopaminergic mesocorticolimbic system, which is stimulated by amphetamine and other drugs of abuse, is considered to be involved in reward-related associative learning and reinforcement, contributing to the development of drug dependence. The aim of this study was to verify the influence of chronic exercise in the mechanism of addiction using an amphetamine-induced conditioned place-preference in rats, a popular model of drug-mediated associative learning in humans.

Adult male Sprague-Dawley rats were randomly separated in two groups: with and without chronic exercise (n = 6-10 per group). Chronic exercise consisted in a 8 week running program in a treadmill (Panlab/Letica LE8706, Barcelona, Spain), with increasing intensity (velocity, slope and time); the group without chronic exercise had no contact with the treadmill. The conditioned place preference test was performed in both groups using the procedure and apparatus previously established by others. It has three phases: pre-conditioning (20 minutes with free access to all compartments and registration of the time spent in each one), conditioning (during 8 consecutive days, in every other day a session of 45 min with the intraperitoneal injection of 2 mg kg⁻¹ amphetamine or saline solution (0.9% NaCl), being the compartments associated with one of the conditions for each rat and test phase (same conditions as the pre-conditioning phase). Animals were sacrificed by decapitation 24 h after the last amphetamine or saline injection and brain dissected to obtain the striatum. HPLC with electrochemical detection was used to quantify the total tissue content of DA and its metabolites (DOPAC and HVA).

Since the pre-conditioning phase none of the animals presented preference for a compartment, all the animals were used in the study. The group without chronic exercise showed preference for the compartment associated with amphetamine (p < 0.05), being the opposite observed with the animals with chronic exercise (more time spent in the compartment associated with the saline injection (p < 0.05)). In the group with chronic exercise, significant differences were found between the animals treated with saline or amphetamine for the DA total tissue content, turnover [HVA+DOPAC/DA], DOPAC/DA ratio and HVA/DA ratio; between these groups no significant difference was found for DOPAC and in HVA contents. In the groups treated with saline significant higher values were found for the trained in comparison with the untrained animals for all these variables except DA.

According to the present results, chronic exercise may prevent the drug-dependence behaviour caused by this amphetamine dose and administration protocol in spite of an exercise-induced increase of dopamine synthesis in the striatum.

PHYSICAL ACTIVITY MAY PREVENT OR AMELIORATE MIGRAINE BUT NOT TENSION-TYPE HEADACHE
Ribeiro, G., Rodrigues, C., Tavares, P., Fontes Ribeiro, C.
University of Coimbra, Portugal

Exercise-related headaches are commonly seen but not often associated with significant underlying pathology. The International Headache Society classification (IHS, 2004) describes some forms well, but overall reflects our lack of understanding of how exercise and headache pain are related.

Migraine headache is common, mainly in women, and can be triggered by many factors, including physical activity, which is one of the criteria for diagnosis. In addition, migraine may be worsened by many components of an active lifestyle or specific training, such as resistance exercise, endurance training, or valsava maneuvers while training. Other factors are environmental exposure (heat and cold), dehydration, inadequate warm-up, altitude, fatigue, and dyspnea, which can occur during exercise. Exercise has not been related with tension-type headache, which is the most prevalent form of headache.

This study aimed to compare the lifelong prevalence of headaches in female students of medicine or sports, characterizing the headaches induced or aggravated by physical activity. These two populations were chosen due to the different level of exercise performed, they had similar demographic characteristics. A specific questionnaire was developed and validated.

224 students answered to the questionnaire. 94.3% and 45.6% of the sport and medicine students, respectively, regularly performed exercise. Headaches occur in 94.3% and 97.7% of the sports and medicine students, respectively. Considering the diagnostic criteria of the International Headache Society (2004), migraine, frequent episodic tension-type headache and infrequent episodic affected 11.3%, 50.9 % and 24.5%, respectively, of the subjects in sport sciences, and 20.5%, 63.2% and 17.0% of the medicine students, respectively; chronic tension-type headache occurred in only 2 and 5 sport and medicine students, respectively; primary stabbing or primary thunderclap headaches and primary exertional headache had a low prevalence (less than 2%); Some subjects have more than a type of headache. Routine physical activity is a trigger for migraine in 0.0% and 20.0% of sport and medicine students, whereas moderate to intense exercise-induced migraine in 0.0% and 20.0% of these populations. Routine or slight physical activity aggravated migraine attacks in...
16.7% and 45.7% of the sport and medicine students. For frequent and infrequent episodic tension-type headaches there are no significant differences between the students from sports or medicine for physical activity as an inducer or an aggravating factor. However, in the whole tension-type headaches are significantly less induced or aggravated by physical activity than migraine.

In conclusion, migraine but not tension-type headache is less frequent in subjects who regularly performed physical activity which is also more often an inducer or aggravating factor of migraine attacks than of tension-type headache, namely in subjects who do not perform exercise.

**PHYSICAL CHARACTERISTICS OF ADOLESCENT ELITE FEMALE HANDBALL AND VOLLEYBALL PLAYERS**

Noutsos, K., Koskolou, M., Barzouka, K., Bergeles, N., Bayios, I.

National & Kapodistrian University of Athens, Greece

Introduction: It is often the case that the demands of a sport dictate the morphology of the athlete’s body. The nature and the level of performance are also likely influenced by the physical characteristics associated with training for a sport (Carter, 1990). The aim of this study was to compare physical characteristics between adolescent elite female handball and volleyball players.

Method: Twenty-eight handball players (age 17.8±1.2 years) and 28 volleyball players (age 17.2±1.3 years) participated in this study. The anthropometric measurements included body mass, height, five skinfold thicknesses (biceps, triceps, subscapular suprailiac and calf), three circumferences (calf and biceps girth (both relaxed and tensed) and two widths (femur, humerus). Body density was calculated with the equation of Durnin & Womersley (1974) using the sum of four skinfolds (biceps, triceps, subscapular and suprailliac) for females aged <19 yrs. Percent body fat was estimated according to the equation of Siri (1956). All anthropometric measurements were taken in accordance with Heyward & Stolarczyk (1996) guidelines. Comparisons between the two sports were made using t-test for independent samples. Significance was set at p<0.05.

Results: No significant differences were found between handball and volleyball players in body mass, body fat, fat mass, free mass and endomorphy component (64.7±6.5 kg vs. 67.1±6.3 kg, 17.4±2.3 kg vs. 17.7±2.1 kg, 11.8±2.3 kg vs. 11.6±2.3 kg, 55.3±4.6 kg vs. 53.1±4.4 kg, 3.7±0.7 vs. 3.8±0.5, respectively). However, volleyball players were significantly taller (175.2±6.3 cm vs 166.9±4.7 cm, p<0.001) with lower BMI (21.8±1.8 kg/m² vs. 23.2±1.9 kg/m², p=0.011). In addition, handball players were significantly more mesomorphic (3.7±1.0 vs. 2.7±0.9, p<0.001) and less ectomorphic (1.9±0.9 vs. 3.0±1.0, p<0.001) than the volleyball players.

Discussion and Conclusions. The main findings in this study were that volleyball players were significantly taller with higher value in endomorphic component and lower in mesomorphic than handball players. These findings could be explained for a more strict selection of young athletes in volleyball and by a higher demand for jumping movements. The mean somatotype of the volleyball players was balanced endomorph (3.7-2.7-3.0), whereas handball players were characterized as mesomorph–endomorph (3.8-3.7-1.9). These data could be added to the reference bank of anthropometric characteristics for future testing and evaluation of young female athletes.

ATTENDANCE AT INDOOR CHLORINATED SWIMMING POOLS IS ASSOCIATED TO ASTHMA: RESULTS OF THE SANA (SALUS NATATORUM, SWIMMER HEALTH) SURVEY

Ferrari, M., Mantovani, W., Papadopoulou, C., Tonellotto, L., Posenato, C., Schenk, K., Tardivo, S., Coppo, C., Ferrari, P., Lo Cascio, V.

University of Verona, School of Sports Medicine, Italy

The Sana (salus natatorum, swimmer health) survey was started in 2005 targeting to investigate the possible relationship between indoor swimming pool environment and respiratory, dermatological disorders. Aim of the present analysis was to evaluate the association between attendance at chlorinated pools and asthma prevalence. We examined 1136 subjects (18-55 years of age, 59% women) attending public indoor swimming pools of the city of Verona, Italy. Individuals agreeing to take part in the survey were asked to complete a modified version of the ECRHS questionnaire. Some questions concerned the age at which asthma began, and, eventually, subsided. Participants were divided into two groups on the basis of the median of cumulative hours of pool attendance during life (first group <=320 hours, second group >320 hours). The prevalences of hay fever (22.3%), past asthma (8.7%) (positive answer to the question Have you ever had asthma?, in a subject without symptoms and not taking medicine for asthma in the last 12 months) and current asthma (13.5%) (a positive answer to the question Have you ever had asthma? in a subject having had an attack of asthma in the past 12 months) and/or using asthma medication were similar in the two groups. On the contrary, incident asthma (IA, asthma arisen at least 12 months after the beginning of pool attendance) as well as subsided asthma (SA, asthma present at the beginning of pool attendance, but subsided from at least 12 months at the time of interview) were shown to be significantly higher in the second group. In the multivariate analysis, adjusting for age, sex, family history of allergic diseases and smoking habits, only IA resulted independently associated with pool attendance (p<0.0001).

Our results suggest that the incidence of asthma is associated to the attendance of public indoor swimming pools.

PRESCRIPTION FOR POSITIVE EXERCISE EFFECTS ON IMMUNITY IN CHILDREN

Gleeson, M., Callister, R., Dorrington, M.

University of Newcastle, Australia

Purpose: Exercise is encouraged in children to improve fitness and as an intervention for obesity. Intense exercise is known to impair immunity in high performance athletes, but there is little evidence of how much exercise can be prescribed without impairing immunity in children. The purpose of this study was to determine the effect of exercise at different intensities on the salivary IgA (Sal-IgA) responses to acute aerobic exercise in children. The possible influences of age, maturation status and aerobic fitness level was also investigated.

Methods: Twenty-nine children aged 8-12 years old completed three cycle exercise tests: an incremental (maximal) exercise test to exhaustion, and submaximal exercise tests at workloads that elicited 75% and 50% of the child's VO2peak. Saliva samples were collected immediately before and after each exercise test, and after one hour of recovery. Saliva samples were analysed for Sal-IgA, albumin and osmolality to assess changes in mucosal immune function. The children were classified into groups based on gender (15 boys, 14 girls), stage of maturation (prepubertal or peripubertal), and aerobic fitness level (lower or higher aerobic fitness). Boys with VO2peak values ≤ 41 ml.kg-1.min-1 and girls with VO2peak 37 ml.kg-1.min-1 obtained from the incremental exercise test were classified as having lower aerobic fitness.

Results: There was a significant suppression of Sal-IgA after maximal exercise, with slight recovery one hour after exercise. Exercise at 75%VO2peak caused no immediate change in Sal-IgA, but suppression was observed after one hour of recovery. Suppression of mucosal immunity occurred after 50%VO2peak, with significantly higher Sal-IgA levels that returned to baseline levels after an hour of recovery. Aerobic fitness level influenced the degree of mucosal immune stimulation following exercise at 50%VO2peak. Children with higher fitness levels had greater increases than those with lower fitness levels. Children with higher fitness levels had greater benefit than those with lower fitness levels. Gender and maturation status had no influence on the immune responses to exercise at any intensity.

Conclusion: Exercise at maximal and high intensities suppressed children's mucosal immunity, potentially leaving them at increased risk of mucosal infections. In contrast, moderate intensity exercise stimulated mucosal immunity. Children with higher fitness levels had a greater benefit than those with lower fitness levels. Increased aerobic fitness levels and regular moderate intensity aerobic activity may improve mucosal immune protection in children and can be safely prescribed. Higher intensity exercise has the potential to impair immune protection and if undertaken caution should be advised in the recovery period to avoid potential infection.

THE USE OF CONTACT LENS DURING WATER POLO PLAY: A 15-YEAR PROSPECTIVE STUDY

Komori, Y., Kobayashi, D., Murase, Y., Enomoto, I., Kono, I.

Doshisha University, Japan

Introduction

Water polo is a heavy contact team sport, which is why it is also regarded as rugby football being played in water. The rules of water polo prohibit players from wearing eyeglasses and swimming goggles. This rule forces players with low visual acuity to use contact lenses during play. However, the status of contact lens use in the pool among water polo players has not yet been reported.

The purpose of this study was to investigate contact lens use in the pool with respect to competitive water polo players from Japanese colleges in 1991, 1996, 2001, and 2006.

Methods

We investigated the following four groups of male water polo players from Japanese colleges: a group of 114 players in 1991, 118 players in 1996, 121 players in 2001, and 118 players in 2006. Information about the use of contact lenses during water polo play, the different types of contact lenses, the frequency of losing contact lens, and any previous cases of ophthalmopathy was obtained by administering a self-report questionnaire.

Results

Fifty-four percent of the players were using contact lens during water polo play in 1991; more than 74% in 1996 (p < 0.01); 87%, in 2001 (p < 0.01) and 84%, in 2006 (p < 0.01). While 96% of the contact lenses used by the players in 1991 group were soft type (SCL), 74%, 91%, and 86% of the contact lenses used by the 1996, 2001, and 2006 groups, respectively, were disposable type (DSDL). The problem was that the players using contact lenses during water polo play had sustained significantly higher corneal and conjunctival damage than players using vision correction devices in their daily lives and players without vision correction devices (p < 0.05).
Conclusions
These findings demonstrated that a high percentage of players were using vision correction devices during water polo play between 1996 and 2006. It is regarded that this is related that there were a lot of users of disposable type contact lenses. In conclusion, this study suggests that increasing contact lens use for water polo players may induce beneficial effects in terms of scoring and winning.

MILK PEPTIDE INTAKE MAY REDUCE MUSCLE DAMAGE AFTER ECCENTRIC EXERCISE

Hirose, N., Yanagisawa, O., Sato, M.
Waseda University, Japan

Eccentric exercise causes muscle damage. Treatments for reducing muscle damage have been introduced and a number of nutritional supplement treatments have also been examined. Of these, it has been reported that pre- and/or post-exercise intake of protein sources, which include protein, peptide, and amino acid, might be useful for muscle recovery following exercise. One possible reason for this is that intake of protein sources might attenuate exercise-induced muscle protein breakdown and stimulate muscle protein synthesis. Milk peptide, hydrolyzed casein, is known to be a source of protein with excellent digestive and absorption qualities. Our previous research has confirmed that pre-exercise intake of milk peptide reduced muscle soreness after stepping exercise. However, because the exercise lacked intensity, it did not induce elevations in muscle damage markers. Therefore, in this study we increased the intensity of exercise to induce muscle damage in order to determine whether intake of milk peptide decreased eccentric exercise-induced muscle damage.

Healthy male volunteers performed calf-raise exercise by shouldering a bar with weights, equal to each volunteer’s body weight. Blood creatine kinase (CK) activity and magnetic resonance imaging (MRI) of the calf were measured at pre- and immediately post-exercise (no MRI performed immediately post-exercise), and on day 1, 2, 3, 5 and 7 following the exercise to evaluate muscle damage. Transverse relaxation time (T2) of the calf, used for evaluating intramuscular water content and an indirect measure of muscle injury, was measured from T2-weighted image at proximal 75% of the length between the head of the fibula and the lateral malleolus on the right leg. Muscle soreness was evaluated pre- and immediately post-exercise, and every 2 hours from the night of the exercise to 5 days after the exercise, using a visual analog scale (VAS). The supplement included 5g of milk peptide, taken 13 times for a total of 65g in this test. 1h before exercise and immediately after exercise, and twice a day for 5 days starting the night the exercise was performed. This was a cross over comparison between with and without peptide supplement, separated by at least an 8-week interval. The VAS score of muscle soreness increased from 12 hours after exercise, and it reached a peak in the 60 hours following exercise.

In conclusion, we found that milk peptide intake may be effective for decreasing muscle damage after eccentric exercise.

HORMONAL REACTIONS TO ACTUAL TRAINING IN SWIMMING WITH RESPECT TO SEX AND TRAINING STATUS

Skipka, W., Stoia-Djeska, C., Krakowski-Roosen, H.
German Sport University Cologne, Germany

Hormonal Reactions to actual Training in Swimming with Respect to Sex and Training Status

Skipka W, Stoia-Djeska C2, Krakowski-Roosen H3
1 German Sport University Cologne, Am Schulberg 13, D-50858 Cologne, Germany
2 Dep. Pathophysiology, Univ. Med. Pharmacy Carol Davila, Bucarest, Romania
3 Deutsches Krebsforschungszentrum Heidelberg, Translationale Onkologie (G100), D-69120 Heidelberg, Germany
Mail: Werner.Skipka@gmx.de

Aim of present investigation was to register blood values of the adrenocortical hormone aldosterone (ALDO) and renal excretion rates of the catecholamines during and after an actual swimming training (ST). Beside training reactions a comparison of the results between different sex and performance capacity of the subjects should be done.

With 15 male and 12 female swimmers of different performance capacity an extensive interval training ranging from 3500 to 4200 m in front crawl was conducted in water of 26 °C. Before, at the end and 1.5 and 3 hours after ST blood and urine samples were taken for determination of the hormones. Increase of plasma ALDO concentration induced by ST was less pronounced compared to equivalent exercise on land, a result of the competitive suppressive effect of immersion to ALDO (Skipka et al 1979). In males ALDO is increasing significantly from 161±83 to 263±118 pg/ml, in females however individual changes are differing strongly. Before ST their ALDO is higher than values of males (p<0.05) and only 1.5 hours after end of ST a significant elevation of ALDO can be stated (324±156 to 398±191 pg/ml). In both sexes training induced changes of ALDO are correlating significantly positively with the actual training performance. Basicallly and during ST renal catecholamine excretions display a significant dependence on sex and physical fitness. In males lower trained subjects are reacting during ST with an intensified increase of catecholamine excretions, while in females a corresponding augmentation of values is to be seen in the well trained group. The effects might be explained with similar behaviour of lactate values. Though the Noradrenalin/Adrenalin-quotient in females generally is significant greater compared to males, their training induced elevation of this value is equivalent.

CYCLOSPORIN A DIFFERENTLY AFFECTS CORTICAL BONE AND CANCELLOUS BONE IN EXERCISE TRAINED MOUSE

Lee, HH., Hung, W., Fang, SH., Wu, CL., Chang, YW., Chang, CW., Chiu, YC, Chang, CK.
National Taiwan Sportus University, Taiwan

Immunosuppressive drugs like cyclosporin A (CsA) and FK506 had become a lifesaving treatment after alloplast organ transplantation. Immunosuppressive drugs like cyclosporine A and tacrolimus potently inhibit calcineurin activity which plays an important role in modulating osteoclastic activity and calcified tissues homeostasis. Systematic administration of calcineurin inhibitor such as Cyclosporin A usually performed severe osteoporosis in rat and human. The purpose of this study is to investigate the effects of Cyclosporin A administration on bone mechanical properties and whether exercise can alter such effect.

Methods: Forty-eight BALB/c mouse randomly assign into six groups which treat with 0, 10 or 20mg of CsA daily combine with or without exercise training, respectively. At 8 weeks of age, mouse of exercise groups began running 3 days per week on motor-driven treadmill with initial speed of 10 m/min, 0% grade for 10 min/day. Training intensity gradually increased to 18m/min and maintain 0% grade for 60 min/day within three weeks and maintain such training intensity until the end of training period. After eight weeks of exercise training, left femur and L4 vertebrate of all mouse were dissected and removed all connective tissues for mechanical test. The mechanical strength of the cortical bone tested by three-point bending at the mid-diaphyseal region of the femora and L4 vertebrate were tested by vertical compression test. Load-displacement curve was created for every sample and stiffness, maximal failure load, failure displacement and energy to failure were determined.

Results: Maximal failure load of femora were adjust by body weight. Mouse treated with CsA have higher maximal load/bodyweight ratio (10mg: 72.609±2.651 kgf/kg-bw, 20mg: 81.197±2.651 kgf/kg-bw) compared with untreated groups (0mg: 63.346±2.683 kgf). Stiffness and total energy load of femora also affected by CsA administration but only slightly affected by exercise training. Maximal failure load of vertebrate slightly decreased in mouse treated with CsA (10mg: 3.6164±0.7979Kgf, 20mg: 3.3931±0.7014Kgf) compared with untreated groups (0mg: 3.7977±0.8591 Kgf). Energy to failure significantly and dose-dependently decreased by CsA administration.

Conclusions: Administration of Cyclosporin A shows controversial effects in different bone tissues and such effects are not altered by exercise training.

PSYCHOTROPIC SIDE-EFFECTS OF ANABOLIC STEROIDS

Mueller-Platz, C., Müller, R.
1Federal Institute of Sports Science, 2University of Leipzig, Germany

Anabolic-Androgenic Steroids (AAS) are abused both in high level-sports and in mass sports like leisure sports. The motivation and the attitude of this drug abuse as well as the biomedical side effects of anabolic steroids are widely documented. Here we report on the rather neglected issue of their psychotropic effects.

In this regard it has to be taken into account that for doping purposes anabolic steroid hormones are frequently taken in supraphysiological doses during the so called stacking periods. The link between this abuse of AAS and psychotrophic effects is still under discussion. Therefore we analyzed scientific databases e.g. Medline, Spolit focusing on the description of psychotropic effects correlated to AAS intake. The hits and also related articles detected in review articles, together more than 80 original papers including more than 1200 test persons were evaluated.

The papers were specified into three categories:

- Clinical trials with Abusers and Non-Abusers or defined administration of AAS
- Field studies in fitness clubs comparing the frequency and severity of psychotropic side effects between abusers and non-abusers of AAS
- Case-studies, medical observation and follow-up monitoring

To identify the psychotropic effects the Diagnostic and Statistical Manual of Mental Disorders criteria and other evaluated specific questionnaires were widely used testing the psychological inventories.

The most frequently used methods to examine psychotropic effects by now are to ask the abuser about the abused substance and diagnose the psychotropic effect by a standardized questionnaire. In field and case studies this comprises a high grade of uncertainty because of the mixtures of AAS usually consumed during stacking and the uncertain nature of the preparations administrated (unreliable sources of supply).

During clinical trials like application studies the administered doses have to be ethical maintainable and therefore have to remain from the supraphysiological doses, meaning that they can show only weak effects.

Psychotropic effects like mood alterations, enhanced aggression, depression, some forms of psychoses and dependence are considered to be linked to the abuse of AAS by all papers retrieved by our research except one.

While the alkylation on C-17 position of the steroid and liver toxicity are closely related no evidence of a correlation between a derivative of testosterone and a special psychotropic effect is described.

Further approaches are biological and pharmacological experiments regarding the correlation of AAS, central nervous receptors and behaviour. Further research seems necessary to describe the overall relevance of the side effects of AAS to human health.

ENDOTHELIAL FUNCTION IN ACTIVE INDIVIDUALS WITH AND WITHOUT INDUCIBLE AXILLARY ARTERY COMPRESSION

Stapleton, C., Green, D., Cable, N., George, K.
Liverpool John Moores University, United Kingdom

Background: Some individuals demonstrate inducible axillary artery compression when the arm is placed in overhead positions. Repeated and forceful compression of the axillary artery by the head of the humerus has been linked to case reports of aneurysm and thrombus in overhead throwing athletes. However, the pathological significance of inducible axillary artery compression has not been investigated. Objective: The aim of this study was to investigate the local (3rd portion of the axillary artery) and downstream (brachial artery) effects of inducible axillary artery compression in active, asymptomatic adults. The key outcome variable, indicative of arterial health, was flow mediated dilation (FMD), a non-invasive assay of endothelium-dependent and nitric oxide mediated conduit artery vasodilation. Methods: Following ethical approval and written informed consent, subjects underwent screening for cardiovascular related conditions and upper limb injuries. Individuals previously tested for inducible axillary artery compression were placed in the “compressor group” (COMP: N=8, 2 males, 6 females, mean±SD age: 23±4 yrs) or the “non-compressor” control group (NONCOMP: N=8, 2 males, 6 females, 26±4 yrs). In a supine position with the dominant arm rested at 45° abduction, an 8-10 MHz linear array transducer recorded...
arterial diameter and blood flow velocity via a high-resolution ultrasound machine. A rapid inflation/deflation pneumatic cuff placed distal to the site of measurement, and inflated for 5 min, induced reactive hyperaemia. Custom designed wall tracking computer-software with synchronised Doppler waveform analysis detected changes in arterial diameter and blood flow velocity from baseline to 3 min following cuff deflation. Shear rate and blood flow were calculated continuously and automatically. Results: No differences in FMD were observed locally at the 3rd portion of the axillary artery between COMP (6.3±4.9%) and NONCOMP (10.3±4.5%) groups (P>0.05). However, the downstream brachial FMD response was significantly (P=0.006) diminished in the COMP (6.3±3.2%) compared to the NONCOMP group (10.3±4.2%). Shear rate i.e. the stimulus for dilation was comparable between groups (COMP: 81.9±44.5 s⁻¹, NONCOMP: 83.1±40.0 s⁻¹, P=0.05). A significant negative correlation (r=-0.52, P=0.038) was demonstrated between the FMD response and percentage of arterial compression when groups were merged. Conclusion: The diminished brachial FMD response observed in the COMP group indicates a statistically and clinically significant deleterious effect of transient axillary artery compression on arterial health. The similar shear rate between the groups confirms that this response is not a result of a reduced flow stimulus, but probably represents a chronic change in vascular function. The additive effect of forceful, repetitive overhead motion on arterial health in “compressing” individuals, as well as the long term consequences, needs to be investigated.

**CRITERIA OF SUCCESS OF CHILDREN AND YOUTH SPORT DEVELOPMENT IN RUSSIA**

Beskrovnaya, V.

*Federal State Educational Establishment of Higher Professional Education Velikiye Luki State Academy of Physical Training and Sports, Russia*

**Introduction.**

The number of people involved in sport activities in Russia is increasing but makes not more than 12% total. However, the schoolchildren and youth's health condition and their physical fitness are rated as insufficient. According to the experts, more than 2/3 of the children and youth get to school practically healthy. But only each fifth pupil leaves it in the same condition. The number of children and youth involved into practising sports has decreased by more than 1.5 min.

**Methods.**

The legislation of children and youth sports has not been formed. The children and youth sport school system is supervised by different departments and institutions. It excludes a possibility to conduct an integrated public policy in the sphere of children and youth sport development. The number of professionally trained coaches has half reduced in the last 20 years. Children and youth sport development isn't financed by the federal budget. The children and youth sport basis is developing only at the expense of regional budgets. Shortage of means hinders reconstruction and renovation of the sports institutions material basis. At present, only 57.9% of the institutions are adequately supplied and have a sport basis at their disposal. Degradation of the sport basis leads to deterioration of the educational and training process quality. The children and youth sport schools are not included into the current national project “The Education”. The current system of medical control of young sportsmen’s activities limits the participation of the children with cardiovascular system pathology in sport activities only to some extent.

**Results.**

Small amount of sport events of different level for the schoolchildren, low financing and increase of the transportation fare tariffs can lead to degradation of the present day children and youth sport system. Furthermore, it will entail the qualitative deterioration of sport schools work, loss of interest of the children, youth and trainers to exercising and training since they can’t assess the results of their work as required.

**Conclusions.**

For further successful development of children and youth physical training and sports in the system of education attention should be focused on the following issues: search of new effective ways to attract school children and youth to various sport activities; creation of an integrated policy and implementation of the concept of the schoolchildren and youth sport development in Russia; solving problems of the children and youth sport as a priority of national projects; the usage of the state system opportunities for participation of the popular sport institutions in the improvement of the children and youth's health condition.

**THE COACH’S ROLE IN THE HUMAN RESOURCE MANAGEMENT IN THE PROFESSIONAL PORTUGUESE LEAGUE OF FOOTBALL**

Maçãs, V., Silva, L., Pereira, A.

*Faculdade de Desporto da Universidade do Porto, Portugal*

To be a coach is a complex job and requires flexible competences that can adjust to several situations and professional contexts. The coachman, as a people manager, has an important and a decisive action in sport organization performance.

The general objective of our study goes from the understanding of the football coachman’s role on managing the human resources in the Portuguese professional football teams. From this main objective, several specific objectives emerge, such as: i) to understand the coachman’s role in the players’ attraction and withholding; ii) to identify the main difficulties/obstacles to face to achieve the proposed objectives and produce results and understand the coachman’s role when facing this; iii) to understand the team’s cohesion as a decisive factor in the sportive performance; iv) to understand the importance of the results.

We have interviewed twelve coachmen from Portuguese professional league. Afterwards, we submitted the transcriptions of the interviews and the articles newspapers and magazines to a content analysis. We established four main categories: i) The coachman’s role in the players’ attraction and withholding, II) Difficulties/Obstacles, III) Cohesion, IV) Results.

The main conclusions from this study were: i) every interviewed coachmen have a decisive power when it comes to recruiting and integrating the players, and from these, 34% also have a decisive power when it comes to select the players. In the definition of objectives and in the definition of the most used reward (money), all coachmen’s power is just a consulting one; ii) being pointed by 75% of the interviewed the main difficulty/obstacle is the lack of positive results in a short period of time; iii) the cohesion takes a determinant role in
the coachmen’s work philosophy, it’s always present in their minds and pointing it as a vital factor to face/deal with the difficulties/obstacles; iv) the results are the factor that interfere most with the coaching role.

SPORT MANAGER'S SKILLS AND PROFESSIONAL PROFILE
Maçãs, V., Claudino, R., Serôdio-Fernandes, A., Quaresma, L., Maia, M.
University of Trás-os-Montes e Alto Douro (UTAD), Portugal

The Sport Manager is important in the management of sport organizations. He's activity allows the definition of professional profile. The Sport's Manager human capital assumes a decisive importance in sport organizations. It is considered as one of the most valuable resources in organizations, given its correlation in results and the role in the future organizations competitiveness.

The theoretical model used by Maçãs (2006), able us to characterize the perception of management activities nature developed by 124 Soccer Sport Managers (professional competition n=68) and no professional competitions n=56).

The data was obtained by documentary analysis, interviews and questionnaire (adapted and developed from Danylchuk and Chella-durai, 1999), concerning different activities of management of the Sport Managers. The data treatment was possible through content analysis and statistical procedures in SPSS.

To build the Sport Manager professional profile, was used the INOFOR (2002) recommendations and norms, based in a deductive and interpretative process, from the activities developed for the Sport Managers by considering five items: (i) job referential; (ii) skills mobilized; (iii) education and experience; (iv) work market specificities; (v) prospective elements.

The professional profile is a tool that allows: (1) to guide the educational system; (2) to determine professional itineraries; (3) to guide recruitment politics and careers management; (4) professional certification.

Sport Manager is a new profession of sport, with vital importance in the improvement of the functioning and competitiveness of sport organizations, as well as in strategic definition of its politics and missions.

AN EMPIRICAL ECONOMIC ANALYSIS OF LAW ON ATHLETES’ PROPERTY RIGHTS: TAKE THE PERFORMANCES OF ARCHERS IN TAIWAN FOR EXAMPLE
National College of Physical Education and Sports (Taiwan), Taiwan

Both assistance fund and image rights fall under the property rights. However, what lays the groundwork for the existence of these athlete-concerned rights? Where do their property rights go and how are they divided? People’s answers to these questions remain varied. This research outlined some possible reasons for the existence of above rights in terms of natural rights of property, utilitarianism and economic efficiency through literature review. Players with more than 8-year experiences in participating in national archery competitions held these ten years in Taiwan (including one game of President Cup, Youth Cup, and Master Cup, respectively) were selected for this research, with their competition records about standard outdoor target archery rounds collected. Their statistical data were also arranged on a gender basis. Taking the each athlete’s scores for qualification rounds of each game as response variable, and the athlete thereof as well as his/her coach for the game as two explanatory variables, the researcher conducted an analysis by using General Linear Model. The result indicates a statistical significance observed in three sources the athlete, the coach and the interaction between them, either statistically or practically. This research bases itself on this empirical analysis to draw a conclusion for the bases of justifying these rights: natural rights of property or utilitarianism are merely the necessary conditions of the existence of these rights, while economic efficiency (transaction cost) is the very sufficient conditions. This conclusion can serve as a reference for future legislation.

PORTUGUESE GOLF CONSUMERS’ ECOLOGICAL PROFILE
Baptista, M., Pires, G., Colaço, C.
Faculty of Human Movement, Portugal

This study aims to highlight the relevant features of the Portuguese Golf Consumers (PGC), in order to design the respective ecological profile. The ecological approach to the satisfaction of environmental needs has been largely treated by the green marketing theory [1], [2], [3]. The ecological approach implies an ecological awareness and a practice of choosing the product based on environmental characteristics [1], [2], [3]. Therefore, the authors intend to obtain PGC’s green profile through two consecutive phases: a) the evaluation of the environmental theme in the golfers’ everyday life and b) the assessment of the way the ecological component is perceived in the particular choice of golf consuming. The analysis model is formed by dimensions endorsing golf’s pleasure factors, national problems, ecological information, environmental quality, ecological responsibility and consumers’ ecological behaviour, as well as the perception of golf’s ecological impact, causes of golf’s ecological impact, awareness of golf’s environmental procedures, eco-label and golf’s environmental activities.

Each one encloses characterization variables (age, gender, educational level, type of practice) and dependent variables (organized by the alternative choices given for each pre-defined dimension).

The sample comprises 108 respondents to a questionnaire and represents the universe of the federated golfers who consume the service in the big Lisbon. A data base has been created, using the SPSS statistical programme and the gathered data was treated according to the exploratory character of the study, through descriptive parameters and adequate statistical graphics and tabulations.

Among some of the most important conclusions, the present study reveals that the environmental awareness of the PGC is high and above the average of the Portuguese population, however, they appear to have some difficulty to view the potential of the game’s negative environmental impact and often confuse the artificial green fields as good environment. Therefore, the authors defend that the ecological consciousness is a necessary step to alter golf consumers’ behaviour.

LEADERSHIP OF VOLUNTEERS IN SLOVENIAN SPORT
Jurak, G., Bednarik, J.
University of Ljubljana, Slovenia

Sport in Slovenia represents 2.33% GDP (Bednarik, Kolenc, & Monik, 2001) and its constantly increasing trends are similar to that of developed countries. One of the important characteristics of Slovenian sport in non-governmental sports organizations is a large share of voluntary work (65% of total work). Evaluated economic strength of voluntary work in Slovenian sport, based on the average monthly salary, represents 0.311% GDP (Jurak & Bednarik, 2006); this make volunteers a very important source to manage.

A research about the leadership style has been conducted on the stratified 3% sample (N=190) of leaders in non-governmental sports organizations, which act in various segments of Slovenian sport.

In order to measure the styles of leadership, a questionnaire, based on Hersey-Blanchard situational model of leadership has been used. Questionnaire has been supplemented with questions about the characteristics of sports organization, about the work with volunteers within this organization and about the characteristics of the leaders. Reliability of the questionnaire has been analyzed with Cronbach alpha test. Significance of differences between individual variables has been analyzed with discriminant analysis, variance analysis and Pearson 2 test.

Leaders mainly use selling (in 42% of cases) and participating style of leadership (in 37% of cases). Telling style (12%) and delegating (9%) are used rarely. Leaders quite often adjust their style of leadership according to the circumstances; however, they do not use styles of leadership appropriate to the followers’ readiness.

Leadership style does not have a direct impact on the indicators, which measure the success of sports organizations. Similar conclusions have also been reached by other authors.

Furthermore, characteristics of the leader, type of sports organization or the way in which the voluntary work is being organized do not influence the style of leadership. Analysis of differences and correlations on the general level as well as on the level of particular variables within the listed segments lead to the conclusion that the leadership in sports environment is a rather unnoticed but existing reality.

Research indicates that the styles used for leading and managing the voluntary workers, are unsuitable. It is advisable that Slovenian Olympic Committee Union of Sports Associations prepares and performs expert training and guidance programs for sports organizations about the leadership styles of volunteers.

SPORT LEVEL OF THE EUROPEAN INSULAR REGIONS. SPORTIVE DEVELOPMENT AND POLITICAL AUTONOMY OF THE INSULAR REGIONS OF PORTUGAL, SPAIN, ITALY, FRANCE AND GREECE
Fernandes, F., Colaço, C., Pires, G.
Universidade Técnica de Lisboa - Faculdade de Motricidade Humana, Portugal

Europe is not only made of continental countries. It is also an insular space with hundreds of islands and millions of people. European Union is nowadays formed by twenty seven State-members that have two hundred eighty six inhabited islands, representing 3.2 % of European territory and 3% of all European population. Each insular region has their own social and human development models, influenced in many ways by the autonomy levels and the type of relationship, under the constitutional law, with the continental country it belongs to.

Those social and human development models are not equally and we are faced with the question of knowing if the differences are a consequence of different autonomy levels. This reality motivated a study, in course, in order to determine the Sport Level in the European Insular Regions and compare that level with the same sport indicator of each of the corresponding countries. Sport Level is an indicator which allows a global vision of the sportive development stage reached by a certain country or region. This indicator expresses the connection between elite athletes and common athletes, known as basis.

The study focused on a descriptive analysis of data. It allowed the comparison between the Sport Level of five different countries (Portugal, Spain, France, Italy and Greece) and ten of their regions (Madeira Island, the Azores, Canary Islands, Balearic Islands, Corsica, Martinique, Guadalupe Island, Sicily, Sardinia and Crete). The focus was on differences and similarities through the analysis of human development indicators and levels of political autonomy of each region concerning their countries’ own capital. This last indicator was measured through an original quantification model. That original quantification model of the Autonomy Level regards Regional Competences, State Political Power and type of State Permanent Representation on the island.
The study also will allow to establish a connection between the Sports Level of each region and their sportive assessment concerning their results on the Jeux des Îles promoted by the COJI (Comité d’Organisation des Jeux des Îles). Through the use of Spearman Rho’s correlation technique and Wilcoxon Z’s comparison it will be possible to associate the results of all the variables.

PP-TT03 Training and Testing 3

MONITORING TRAINING IN TEAMGYM GYMNASTS
Minganti, C., Meeusen, R., Capranica, L., De Pero, R., Piacentini, M.
University Institute of Movement sciences, Italy

Introduction
The ability to monitoring training is critical to the process of quantifying and correctly planning training. Session RPE method has proven to be successful in monitoring training load during steady state, high-intensity and multiple types of exercises (Foster C., ‘96, ‘98, 2001). In Teamgym training sessions, gymnasts practice skills or sequence of skills within a specific apparatus (floor, trampoline, tumbling) and work on strength and flexibility. No previous studies were conducted to evaluate the session RPE method capacity to quantifying training in this kind of sport. The aim of this study was to evaluate the ability of the session RPE method to quantifying training during teamgym practice.

Methods
Ten female gymnasts (age=21.7±1.1 yrs; height= 164.9±6.6 cm; weight=54.6±5.4 kg) participated in the study. Three different training session (floor, tumbling, trampoline) were the object of our study. Each subject was monitored during training sessions with an Heart Rate (HR) monitor (Polar Team System); and the RPE rating was obtained using the category ratio (0-10) RPE scale of Borg. The subjects were asked to provide a rating of the overall difficulty of the training session 30 minutes after the end of the session to avoid that different difficulties of the exercises toward the end of the session would influence the subject’s rating. An exercise score for each training session was computed by multiplying the overall difficulty of the training session by the RPE (Session RPE).

As an objective reference method for quantifying each training session the summated HR zone method (Edwards S., ‘93) was used. The HR monitors were downloaded using software that allowed evaluation of the accumulated time in each of 5 HR zones based on 50-60%, 60-70%, 70-80%, 80-90% and 90-100% of theoretic HR peak (220-age). Time in each zone was used to calculate the training score (TRIMP) by multiplying the accumulated duration in each HR zone by different factors (50-60%=1; 60-70%=2; 70-80%=3; 80-90%=4; 90-100%=5) and summating the results.

Results
Pearson’s correlation coefficient was used to evaluate relationship between TRIMP scores generated using the summated HR zone method and the session RPE method of monitoring the training session. Results (Trampoline r=0.87*; Floor r=0.72*; Tumbling r=0.92*; overall r=0.84*; *p<0.05) showed high correlation coefficients between the two methods.

Discussion
Results of this study are consistent with previous observations of high correlated relationship between session RPE and the summated HR zones methods of evaluating training sessions.

Our results suggest that the session RPE method may be used as an easy method of creating a TRIMP score for evaluation of exercise training in teamgym sport.

ENERGY COST AND POLE FORCES DURING NORDIC WALKING UNDER DIFFERENT SURFACE CONDITIONS
Knicker, A., Schiffer, T., Dannöhl, R., Strüder, H.
German Sport University Cologne, Germany

Introduction. The purpose of the study was to identify the effect of three different surfaces on energy consumption and the forces acting on the walking poles during ground contact in Nordic walking (NW).

Methods. Thirteen female NW instructors (age: 26±4 years, weight: 58.5±4.2kg, height: 168.1±4.6cm) volunteered in the study. Each subject walked a distance of 1200m at a constant speed of 2.2ms-1 on each of a concrete surface (C), an artificial athletics track (A) and a naturally grown soccer lawn (G). They used NW poles with inbuilt strain gauge force transducers to measure ground reaction forces acting along the long axes of the poles. Oxygen uptake, capillary blood lactate (La), heart rate (HR) and rate of perceived exertion (RPE) were measured before and after the tests.

Results. Impact forces, maximum forces, force rates during ground contact identified from the registered force time histories displayed significant differences related to the surface conditions. However force time integrals did not show surface related differences. Relative oxygen consumption showed significant differences between NW on C and on G while no surface related differences could be identified between the surface conditions for the parameters i.a. HR and RPE.

Conclusion. Our results suggest that the impulse which is generated by the subjects through the poles is identical between the varying surfaces. Since there are differences for the oxygen uptake between C and G the main regulator for the propulsion must be the musculature of the lower extremities. The work of the upper extremities seems to be a luxury effort for Nordic walkers with a proper technique.

THE DEFENSIVE PERFORMANCE IN HANDBALL ANALYSIS OF THE THREE FIRST-PLACED TEAMS IN MEN'S EUROPEAN CHAMPIONSHIP 2006
Gomes, F., Volossovitch, A.
Technical University of Lisbon, Portugal

Introduction
The defensive performance in handball is considered as one of the most important team efficiency factors. However, the majority of notational studies still focus on game offensive process, limiting the information about defence to few performance indicators. Therefore, this study aims to analyse and describe the Defensive Process (DP) of the best European teams, classified in three first places in the Men’s European Championship 2006.

Material and Methods

In total, 23 matches were analysed (France - 8, Denmark - 8 and Spain - 7). A specific computer program (ORAND) was created to register a total of 1854 defensive actions from 1042 DP. The 68 defensive performance indicators were grouped in 9 categories: defensive process duration, time of the game, game result, player, defensive action, defensive zone, process result, defensive system, phase of game. Data was analysed through descriptive statistic.

Results

The main conclusion drawn from this study was that all teams had some characteristics in common, as well as distinctive particularities. In common was registered the high defensive efficiency: France - 55.6%, Spain - 51.7% and Denmark - 47% and, particularly, the high goalkeeper efficiency: France - 46.4%, Spain - 54% and Denmark - 52.5%. These three teams had a high percentage of their DP in position defence phase: France - 77.2%, Spain - 74.7% and Denmark - 81%. Interruption of ball circulation with fault was the defensive action with highest frequency of registers: France - 35.2% of all defensive action, Spain - 27.5% and Denmark - 37.6%.

The failure percentage in 1x1 was the most frequent reason for the defensive failure: France - 16.2% of all defensive actions; Spain - 22.3% and Denmark - 17.5%.

The defensive success was essentially associated with the interception ability: Interceptions represented 5.4% of all defensive action of France, 6.0% of Spain and 5.1% of Denmark.

The capability to interfere with the opponent-shot was represented by frequency of blocks and shot pressure percentage. France used blocks in 4.3% and shot pressure 12.6% of all defensive action, Spain in 4.3% and 12.7% and Denmark in 2.9% and 10.2%, respectively.

The most important difference between the teams was the diversified interpretation of the defensive system of each one. The dominant defensive system of France was 5:1, during 64.3% of the DP. Spain and Denmark used the 6:0 with 40.8% and 45.6% respectively.

Although Spain and Denmark used the same defence system, they had a very unique realization of the schematic figures. Spain used the second’s defenders of the 6:0, to press the opponents’ throwers; Denmark made this pressing with the central players. The French advanced centre player made a large pressing under the playmaker and the back centre player had the best block percentage.

The results suggest that for assessment of defence play of teams it is necessary to consider their particular defence organization.

REPRODUCIBILITY OF AN ISOKINETIC ECCENTRIC MUSCLE ENDURANCE TASK

De Ste Croix, M., Sauret, J., Deighan, M., James, D., Iga, J.

University of Gloucestershire, United Kingdom

Despite the widespread use of isokinetic eccentric muscle endurance protocols there appear to be no studies that have examined the absolute and relative reliability of such tests. The aims of this study were to examine the reliability of a repeated isokinetic eccentric knee muscle endurance task. Fifteen healthy untrained males volunteered to take part in the study and written informed consent was obtained.

The study received ethical approval from the University Research Ethics Committee. Subjects visited the laboratory on 3 separate occasions; 2 weeks prior to testing to familiarise them with the experimental procedures, and on 2 separate occasions, 2 week apart and at the same time of day. Isokinetic eccentric knee extension and flexion of the dominant limb were measured using a calibrated Biodex system 3. Range of motion during testing was set using voluntary maximal full extension (0 rad) to 1.57 rad of knee flexion and testing occurred at 1.56 rad/s-1. Subjects performed four maximal efforts to determine maximal peak torque (PT). A 120s rest period was then given before the endurance test of 50 continuous eccentric repetitions. Subjects were encouraged to give a maximal effort for each action. Data were gravity corrected and windowed to only include constant velocity periods. Data were analysed using SPSS for Windows. Repeated measures ANOVAs were used to investigate differences in maximal peak extension and flexion torque and the maximal torque measurement recorded during the endurance test. Reproducibility was assessed through calculation of intra-class correlation coefficients (ICC), repeatability coefficients (RIC) and 95% limits of agreement (LOA) using the methods described by Bland and Altman for torque fatigue index (TFI), work fatigue index (WFI) and total work (TW).

PT difference between the strength test and the endurance trial were found to be non-significant for both quadriceps (323 Vs 323 Nm) and hamstrings (1183 Vs 178 Nm). ICCs indicated significant (p < 0.05) positive moderate to strong correlation between test 1 and 2 for all pain thresholds except hamstring torque fatigue (p = 0.11) and hamstring work fatigue (P = 0.08) index. RCs and LOA indicated systematic bias for both TFI and WFI for extensors and flexors, ranging from -3 to -10, with less fatigue evident in the 2nd test. There was also systematic bias for TW with more work performed during the 2nd test compared to the 1st. The random error was large for all variables and there was greater variability in the hamstrings compared to the quadriceps. Along with moderate to strong ICC’s, these data suggest that there is small systematic bias in repeated eccentric muscle actions for both the quadriceps and hamstrings, however the random error is large despite extensive habituation procedures.

Therefore, data from an isokinetic eccentric muscle endurance task should be viewed with a degree of caution.

CONSEQUENCES OF SWIM, CYCLE, AND RUN PERFORMANCE ON THE OVERALL RESULT IN OLYMPIC-DISTANCE TRIATHLON

Sandig, D., Fröhlich, M., Klein, M., Pieter, A., Emrich, E., Gießing, J.

University of Saarland, Germany

Purpose: Olympic triathlon is a multidisciplinary sport that comprises three different modalities (swim, cycle and run) which are conducted in succession. Overall triathlon time consists of the three legs and the two transition times between the three legs. In order to achieve the fastest overall time possible, the times needed for each leg have to be minimized and athletes have to consider the aspect of marginal return when deciding how to use their resources in training and competition. The purpose of this analysis was to find out which of the three disciplines is of superior significance for overall finishing times and rankings.

Methods: Overall times and rankings as well as rankings and times for each of the three modalities of all athletes who competed in the Olympic-distance triathlon world championships in 2007 (junior women, n = 59, junior men, n = 77, U23 women, n = 30, U23 men, n = 62, elite women, n = 60, elite men, n = 66) were analysed. By calculating correlations and multiple linear regressions beta weights for each of the three modalities were calculated. Calculations were carried out for all athletes who participated in the above mentioned competitions as well as for the 20 highest-ranked finishes.
Results: There was a significant correlation between the times of all modalities and overall finishing times for all finishers (all p < 0.01: junior women: swim 0.61, cycle 0.84, run 0.84; junior men: swim 0.81, cycle 0.88, run 0.85; U23 women: swim 0.47, cycle 0.66, run 0.83; U23 men: swim 0.47, cycle 0.80, run 0.80, elite women: swim 0.62, cycle 0.83, run 0.83, elite men: swim 0.51, cycle 0.76, run 0.85. For the junior athletes the highest beta weights were found for the cycle (Beta ≥ 0.50), for the U23 athletes as well as for elite women and men the highest beta weights were found for the run (Beta ≥ 0.57). When limiting the analyses to the 20 best overall finishers, no significant correlation between modality times and overall finishing times could be found for junior athletes whereas for U23 athletes as well as elite athletes there was a significant correlation between run time and overall time. The highest beta weights for the 20 best overall finishers were on the run (Beta ≥ 0.82) in all subgroups.

Conclusions: Since drafting is allowed in Olympic-distance triathlon races, the run has been upvalued whereas the swim and the cycle have been devalued. Except for junior athletes it can be stated that the most decisive factor for winning or not winning an Olympic-distance triathlon is the time needed for the run whereas an athlete’s placing after the swim or the cycle has no prognostic relevance for his or her final placing. Judging from an efficiency-oriented perspective, triathletes should emphasize training the run rather than emphasizing the swim or the cycle.

**INFLUENCE OF VARIABLE RECOVERY INTERVAL PATTERNS ON FATIGUE DURING REPEATED SWIMMING SPRINTS**

Theoas, A., Bogdanis, G., Evangelidis, P., Stavarou, P., Maridakis, M.
Faculty of Physical Education and Sports Science, University of Athens, Greece

The effect of recovery duration on repeated short cycling sprints has a significant effect on performance (2). A recent study (1) has shown that during repeated 6s cycling sprints, an increasing recovery interval results in a smaller decline in peak and mean power output, but lower total work compared to decreasing recovery intervals. Although variable recovery intervals are commonly used in swimming training, there is a lack of informing performance. Moreover, the drop in performance during repeated sprints is much less in swimming compared to cycling (3)(2). Therefore, the purpose of the present study was to examine the influence of two different recovery interval patterns on performance and fatigue during repeated swimming sprints. Ten male elite water polo players (age: 24.5 ± 1.8 yrs, height: 183.3 ± 1.8 cm, body mass: 85.7 ± 4.9 kg, mean±SE) participated in this study. Participants performed 6x50m sprint swimming test in two different occasions in random order. On one occasion, the recovery interval after each sprint was decreased from 30s to 10s in 5 s steps (condition D) while on the other occasion the interval was increased from10s to 30s (condition I). Differences between the two conditions in performance time for each sprint and fatigue during each protocol (percent increase of performance time from the first to the last sprint) were analyzed using two-way ANOVA. Results are presented as mean ± SE. There was a condition vs. sprint number interaction in performance time (p<0.01). Performance time in the 6th sprint was better maintained in the I compared to the D condition (31.8 ± 0.3 vs. 34.6 ± 0.6, p<0.001). Consequently, the drop from sprint one to sprint six was half in the I compared to the D condition (10.2 ± 1.6 vs. 21.0 ± 3.4%, p<0.01). The results of this study suggest that the recovery patterns influence performance despite the fact that the total recovery time was the same in the two conditions. An increasing recovery interval may be more effective in maintaining higher performance during swimming training, while a decreasing interval may be used when a greater stress is desirable.

**IL-6 AND TNF-α RESPONSE TO HIGH VOLUME TRAINING PERIOD IN HIGHLY TRAINED MALE ROWERS**

Maastu, J., Rämsö, R., Jürimäe, J., Jürimäe, T.
University of Tartu, Estonia

Excessive musculoskeletal stress associated with insufficient rest and recovery may induce a local acute inflammatory response that may evolve into chronic inflammation and produce systemic inflammation and is suggested as a cause of overtraining and further the overtraining syndrome (Smith 2000). It has been shown that IL-6 and TNF-alpha increase during endurance exercise, as an acute inflammatory response (Ostrovski et al 1999). Robson-Ansley et al (2007) indicated elevated IL-6 levels after intense interval training program. In contrast, Stewart et al (2007) showed that a 12 week training program had no effect on fasting concentrations of IL-6 and TNF-alpha in physically active and inactive subjects. Limited data is available on the cytokine response on high volume, low intensity trainings that are prevalent during the preparatory period. The aim of the study was to investigate the response of the IL-6, TNF-alpha and leptin concentrations during high volume training period in male rowers.

Eight male rowers (age 20.2±1.6, height 183.9±4.6, body mass 81.0±5.4) participated. During the four week period of high volume low intensity, training volume increased from 587.3±149.9 min/week, with the intensity kept constant. Long distance rowing at 80% of anaerobic threshold for 2 hours was carried out after the day of full rest at baseline (T1), after high two weeks of high volume period (T2) and after recovery period (T3). Venous blood samples were obtained before (PRE), immediately after (POST) and 30 minutes after (POST30) long distance rowing. Leptin concentration significantly decreased at POST and POST 30 compared to PRE during T2. At T2 POST 30 leptin concentration was significantly decreased to POST 30 value at T1. IL-6 concentration increased significantly at POST and POST 30 test compared to PRE test values during all the tests. POST 30 level of IL-6 at T3 was significantly higher than POST value during T1. TNF-alpha concentration increased significantly at POST compared to PRE only during T2.

In conclusion, high volume training decreases exercise-induced leptin concentrations and increases TNF concentrations, with no effect on IL-6 concentration.

DYNAMIC VISION OF TOP ATHLETES

Jendrusch, G., Engel, D., Ehrenstein, W., Platen, P.

*Ruhr-University Bochum, **University of Dortmund, Germany

Due to their high motion and action speeds most sport activities demand an outstanding capacity and precision of vision. Especially dynamic visual functions are required in successful sports performance, but also in accident and injury prevention. Conversely, visual performance might benefit from physical strain (1).

PURPOSE: The present study aims to assess dynamic visual performance of top athletes compared to visual reference values of non-or-leisure-time athletes. Recent findings suggest improvement of dynamic vision following physical exercise (cycle ergometer), an activity largely unrelated to particular visual demands (1). Here we ask whether dynamic visual performance might be more specifically linked to the respective sport activity or profession.

METHODS: A total of 152 male top athletes (29 baseball players, average age: 24.2 ± 3.9 years, 56 football players, average age: 25.4 ± 4.4 years, and 67 hockey players, average age: 21.1 ± 3.0 years) of different German national or first league teams participated. Dynamic vision was tested by a form-from-motion analogue to the Landolt test as developed by Wist et al. (2). Within a random-dot display, Landolt rings of the same average luminance as their surrounds become visible only when the dots within the ring are moved briefly while those of the surround remain stationary. Thus detection of gap location is based upon motion contrast (form-from-motion) rather than luminance contrast. With the size and exposure duration of the centrally presented ring held constant, motion contrast is manipulated by varying the percentage of moving dots within the ring. Subjects report gap location (left, right, bottom, top).

RESULTS: Compared to the reference sample (299 unselected, non-or-leisure-time athletes, healthy males between 20 and 34 years), taken from a previous study (3) with a mean score of 81.9 (± 2.26 SE), baseball players and hockey players showed a better performance (87.3 ± 2.41 SE; 83.3 ± 1.60 SE), whereas football players resembled the reference (81.7 ± 1.74 SE). Thus, with the reference set to 100%, the raise in performance level for baseball players amounts to 6.6%. The difference between baseball players and football players was significant (p < 0.05). The three groups did not differ with respect to static visual acuity (p > 0.70; VA between 2.03 and 2.11).

CONCLUSION: The data provide the basis for applications which include differential assessment of dynamic vision of athletes. They further suggest that the improvement of visual performance is specifically related to the respective sport activity.

COMPARISON OF TWO BODY FAT PERCENTAGE MEASUREMENT METHODS (BIA VS SKIN FOLD) ACCORDING TO SEX IN SWIMMERS

Ertas, D., Koz, M.,

Gazi University, Turkey

This research is carried out in order to determine the differences between two body fat percentage (BF%) calculation methods, that are Bioelectrical Impedance Analysis (BIA) method and skin fold (SF) measurement tests. The data of 32 swimmers (22 male and 10 female), who are at top 10 in Turkey among their age groups and attended the competition of Selection of National Team which was held on January 19-20, 2008, Ankara are collected. The age, height, weight and BMI measures for female and male swimmers are 17,00±3,16 years, 166,00±5,58 cm, 56,80±5,89 kg, 20,62±1,91 kg./m2; 16,22±1,77 years, 176,14±7,61 cm., 67,54±10,76 kg. 21,68±2,38 kg./m2 respectively.

The data are taken 15 minutes prior to the performance. Tanita BC-418 body composition analyzer and Holltain brand skin fold caliper, which provides 10 g/m2 pressure in all angels, was used for BIA method and skin fold measurements respectively. BF% with SF is obtained by using Jackson-Pollock(U-Pi) formula. Repeated measurements ANOVA test was used to investigate the differences between two methods of BF% measurements. The difference between two measurement methods is evaluated with DUNCAN test. Consequently, according to BF% measurement with BIA method, no statistically significant difference was found between male and female subjects (M=14,39±3,92; F=20,10±3,05 (P<0,05). On the other hand, there was found statistically significant difference in SF method (P<0,05). It is found that, M subjects’ BF% values (12,26±6,00) are lover than the F subjects’ (24,23±3,24).

EFFECTS OF A SPECIFIC TRAINING PROTOCOL ON BODY COMPOSITION AND BALANCE IN HEALTHY ELDERLY WOMEN

Bellaﬁore, M., Battaglia, G., Bianco, A., Palma, A., Farina, F.
University of Palermo, Italy

Equilibrium disorders are frequent symptoms of aging because of both sensorial perceptive and neuromuscular system decay [1,2]. They might be responsible for the postural control failure and falls of elderly subjects under adverse environmental factors. Physical activity is one of factors that contribute to improve postural control and reduce the risk of falls [3]. The aim of our study was to evaluate the effects of short-balance-training-program (SBTP) on body composition (BC) and several balance control indicators (BCI) in elderly women.

Ten healthy and active elderly female subjects (age: 68.67 ± 5.50 year; mass: 63.74 ± 7.83 Kg; height: 1.50 ± 0.03 m) were trained for 5 weeks by SBTP that consisted of 2 sessions/week in the first three weeks and 3 sessions/week in the last two weeks. Training intensity increased in the forth and fifth week by the addition of new exercises. Every session included a warm up pattern for 15 minutes (min); a circuit of balance training including a standard sequence of exercises performed with the hands along hips and cool down model for 10 min. Subjects followed the training circuit once in the ﬁrst week and twice in the next weeks. BC was analysed by a multi-frequencies (5, 50 and 250 kHz) bioelectrical impedance analysis system (inbody320). Balance control indicators such as mean speed (MS), anterior-posterior mean speed (MS-y), sway path (SP) and ellipse surface area (ESA) of the BMC were analysed by Sway Test (unipedal or bipedal test with eyes open or closed) on the stabilometric platform. All data were acquired before and after the experimentation. Results were compared using nonparametric and paired Student’s t-test and the statistical signiﬁcance was set to value of P<0.05.

BC did not change in response to SBTP. Instead, impedance index (height squared divided by impedance) of both lower limbs showed a signiﬁcant increase in trained subjects. All BCI decreased after the SBTP; however only MS, MS-x, MS-y, SP in bipedal condition with eyes open and ESA in left and right unipedal conditions with eyes open and closed were statistically signiﬁcant. Our results suggest that SBTP may develop the eye-foo coordination in elderly women. Moreover, the increase in lean body mass of lower limbs may contribute for improved postural stability. Therefore, SBTP appears to be suitable for improving the balance control systems in elderly women and may be an efficacious method to decrease equilibrium disorders.

OPTIMISING THE EVALUATION INSIDE PHYSICAL EDUCATION THROUGH INTERDISCIPLINARY METHODS

Niculescu, I.
University of Piesti, Romania

Introduction

The sport performance is determined by multiple factors and no one can say for certain which factor has a greater balance when its numbers are reaching the superior limits of the sportsmen’ capacity. The novelty of this research will consist of the following:

A new approach of the work methods inside the new female volley players’ training.

Elaborating a test containing the psycho-motrical elements which are the object of research inside ball work.

Using a new method of evaluation-the method of the genetic algorithm, for evaluating the psycho-motrical aptitudes;

The appeal to Mathematical improved methods for calculating efficiency inside the game of volleyball.

The basic idea for choosing and structuring this paper is the fact that under the actual conditions, the complex study of the sport activities becomes interdisciplinary, being realized both with the help of classical research methods, but also by using those methods borrowed from other fields of activity. Thus, the genetic algorithms method was used to evaluate some components of the psycho-motricity. Coordination, balance and space orientation are taken into account, being included in a test created in such a way as to include all of them, inside ball work. In order to calculate the efficiency inside the volley game there already existed some mathematical formulas applied by considering the number of ball-touching inside a set or a game. As a novelty element, an improved mathematical formula was used by introducing the time parameter, the number of ball-touching-s being reported to the time spent on the fi eld. It is considered that the efficiency value is much closer to reality, being this way objective.

Conclusions

The three psychomotricity components treated during this research are very little used during the selection process, but there are many means of instruction which can be used with a view to educating the psycho-motrical components, the psycho-motical components-coordination, balance, space orientation-contribute to the efficient learning of the volley game as a whole. For the final evaluation of the game, there are means to calculate the efficiency of the players in function of their evolution. The method of the genetic algorithm was adopted by our system on the background of having an evaluation as complex as possible of the above mentioned relation. Its use contributed to an increase of the efficiency and quality of the training, especially in what concerns the operational strategies applied.

OPTIMISING THE EVALUATION INSIDE PHYSICAL EDUCATION THROUGH INTERDISCIPLINARY METHODS

Charakterization of 32 swimmers; Association between anthropometry and performance

Morouço, P., Cruz, J.
Polytechnic Institute of Leiria, School of Education, Portugal

The aim of this study was to analize possible relationships among anthropometric data and performance in age group swimmers. The best 32 swimmers were selected out of the best performance in 400Free and 200Medley of Leiria’s district. The sample comprised 16 girls (9-11-y-o) and 16 boys (10-12-y-o). A total of 38 measurements were taken in a weekend. Differences among genders were obtained in span/weight, length of upper extremity length, upper body flexibility, hand strength (p<0.01) and in span, biacromial breadth, curl-ups
%fat mass, critical velocity and slide (p<0.05). To analyze correlations Pearson factor was used. Positive correlation was found between: (i) weight and span, length of hand and foot (p<0.01) showing that taller boys and girls have bigger propulsive segments; (ii) body mass index and the sum of 6 skinfolds (p<0.01), slide (p<0.01) and horizontal fluctuation (p<0.05) showing that fatter swimmers increase their buoyancy getting bigger fluctuations; (iii) length and width of hand with hand strength (p<0.01) measured with a dynamometer. Negative correlation was found in: (iv) 50m freestyle time and hand width (p<0.01) and span (p<0.05) making us assume that width and length of the propulsive segments play an important role in short distance events; (v) this assumption is even more evident when analyzing the negative correlation among hand strength and time in short events (50F, p<0.01, 100F, p<0.01, 200F, p<0.05, 400F, p<0.09). As expected (vi) critical velocity showed a negative correlation (p<0.01) with time in 50F (-.767), 100F (-.794), 200F (-.866) and 400F (-.991). These results are similar to Papoti et al. (2005) with 17-y-o swimmers. As the distance increase, so does the association between critical velocity and aerobic capacity, meaning that the latter plays a major role in longer distance performance. Critical velocity is an easy method of evaluation. However studies developed with this range of age are scarce and must be taken in order to assume these conclusions.

A NEW LOW COST GADGET DESIGN TO MEASURE THE WEIGHT BAR VELOCITY IN A BENCH PRESS USING CHRONOJUMP

Buscà, B., De Blas, X.
Ramón Llull University, Spain

The proposal of the present study was to determine a new gadget validity to assess the average velocity and the displacement of a weight bar using Chronojump (De Blas, González-Gómez, 2005). The new design is based in a contact bar simple and low cost mechanism that detects the conductivity of electrical potentials (Svala) through a precision chronograph (Skypic 1.0). This system allows the coaches to assess speed, power and strength parameters to control the training process. The validation study was carried out between a Chronojump (ChJ) utility (chronopic and software) and MicroMusclelab® engine (mML®) to measure the concentric action parameters of bench press bar displacement. A number of 75 actions from 13 subjects were recorded using the two methods in the same action and some values were compared: bar displacement with the new gadget (Displ. B), time with ChJ (T CJ), bar displacement with mML® (Displ ML), time with mML® (T ML), power with mML® (W ML), average velocity with mML® (Av V ML). Besides, the work, power (W ind) and the average velocity (Av V) were calculated taking the ChJ time values and the displacement statically measured with the new contact gadget. The Pearson correlation between T ML and T CJ was r=.964 (p=.00), between W ML and W ind was r=.945 (p=.00), between Av V ML and Av V was r=.966 (p=.00) and the correlation between Displ ML and Displ B was r=.922 (p=.00). We also take into account the correlation as the displacement statically pre-measured with the new gadget and the values obtained from mML®. The high correlation values are not as high as the other parameters but high enough to be worth studying the error in the measures for the whole sample and each different loads. Relative error of 2.26% (+ 1.04%) was found. Observing the correlation values for each load, a high assessment problem was detected in the lowest one (20kg). According to this fact, a new relative error of 1.83% (+ 9.8%) was calculated excluding the 20kg actions. According to these findings, same correlation and error magnitudes were reviewed in Weiss et al. (1998), Markovic et al. (2004) and other authors. For the future, more sensors to assess new mechanical parameters are developing. In addition, new applications has been included in the latest software version available ChJ web site.

TRENDS IN THE APPLICATION OF PUNCHES AND KICKS IN K-1 SPORT

Kapo, S., Cikatic, B., Radjo, I., Kajnovic, H.
Faculty of Sports and Physical Education, University of Sarajevo, Bosnia and Herzegovina

Various observations and analyses of fights by experts of different profiles have resulted in broadening and strengthening knowledge of different possibilities for applying and making technical components of K-1 sport more concrete (Kapo, 2006, Kapo, 2007). The research has been carried out on a sample of 96 top level super heavyweight (over 91 kg) male fighters participating in final K-1 tournaments in Japan from 1993 to 2004 (in 84 matches and 205 rounds). The objective of the research was to analyse the application of technical elements during the fights of the most successful K-1 fighters in the world. This paper is based on an explorative approach to K-1 phenomena in situational conditions. The situational aspect has been provided through video recordings of all fights. This resulted in a thorough sectional view of the most successful fighters, helping to determine an absolute criterion for defining what a quality fighter is, as the final tournament gathers only the 8 best fighters in the world. The gathered data on technical elements have been processed with the descriptive static method and presented according to the total frequency of their application. By means of trend analysis we examined the development trends in the application of technical elements (delivered both with hands and legs) in the sense of their increase and decrease in the period of 12 years, as to obtain data on the average application of technical elements. By analysing fights at the final GP K-1 tournament in Tokyo Dome we obtained information on which techniques are frequently applied in K-1 (low kick right, direct left, techniques rarely applied (kakato geri, direct punches in the stomach) and those applied very rarely or almost never. These findings are highly important as they not only point out the arsenal of the most efficient techniques and its hierarchy, but they can also indicate the only methodologically right manner of teaching K-1 fighting techniques. These data help shorten the time period needed to create a top quality K-1 fighter (as we all know, in all martial arts and, consequently, K-1 a fighter is at its best usually around the time when his age is already becoming a problem, forcing him to stop fighting) by only informing the fighter about inefficient techniques, not teaching him these techniques at all. The most efficient techniques in K-1 are direct punches, hooks, uppercuts, low kicks, knee kicks, etc. Trend analysis indicates that the application of following variables tends to increase: left and right direct punch, right hook and right uppercut, and high and lower circular kicks as well as knee kicks.

ASSESSMENT OF THE EFFECT OF INSTABILITY RESISTANCE TRAINING ON BALANCE, MOVEMENT SPEED, AND STRENGTH IN ATHLETES WITH PREVIOUS ACL INJURY: A FIELD-TEST APPROACH

Zemkova, E., Hamar, D.
Faculty of Physical Education and Sport, Comenius University Bratislava, Slovakia

The assessment of efficacy of instability resistance exercises, that have become a part of both athletic training and rehabilitation, is based namely on laboratory techniques. However, experience showed that coaches prefer easily applied field-tests that may provide actual information on effectiveness of exercise program. The study deals with alternatives of such evaluation of balance, movement speed, and strength prior to and after instability resistance training in athletes with previous ACL injury. A group of 14 soccer players (age 21.8±3.4 y, height 182.2±5.6 cm, and weight 76.7±4.8 kg) underwent two months after rehabilitation combined resistance and balancing exercises (in duration of 30 min) for a period of 12-weeks (4-5 sessions/week). Postural stability was evaluated under both static and dynamic conditions (wobble board and antero-posterior / medio-lateral tilted platforms) during bipedal and one-legged stance. COP velocity was recorded at 100 Hz by means of posturography system FITRO Sway check based on dynamometric platform. Speed of FTO Dyne initiation and the soccer kick was measured using FITRO Force plate was applied to measure height of the squat and counter-movement jump. Pre-training measurements showed the non-injured-to-injured leg percent differences of 15.7% for static and 24.5% for dynamic balance. Following the training there were no changes in static balance on both legs (from 18.2±3.3 mm/s to 15.8±2.8 mm/s), on non-injured leg (from 41.3±8.8 mm/s to 38.2±7.8 mm/s), and on injured leg (from 49.0±8.9 mm/s to 43.2±7.7 mm/s). Likewise, the dynamic balance did not change while standing on both legs (from 93.2±19.0 mm/s to 86.7±17.8 mm/s) and on non-injured leg (from 112.3±25.0 mm/s to 101.2±21.8 mm/s), however a significant (p<0.01) improvement on injured leg has been found (from 148.7±22.8 mm/s to 138.0±20.0 mm/s). In addition, sway velocity significantly (p<0.05) decreased during bipedal stance on ML tilted platform (from 134.2±20.1 mm/s to 110.6±18.2 mm/s) but not on those A-P tilted (from 120.6±19.7 mm/s to 104.7±18.0 mm/s). Moreover, mean run-out speed significantly (p<0.05) increased on injured leg (from 347.4±42.3 cm/s to 385.3±38.8 cm/s) but not on non-injured leg (from 378.1±42.1 cm/s to 371.8±47.1 cm/s). In contrast, no changes in mean kick-off speed on injured and non-injured leg have been found (from 474.0±38.5 cm/s to 515.6±43.3 cm/s and from 475.9±40.7 cm/s to 499.5±37.6 cm/s). Unfortunately, no information on changes in jumping performance is provided because during pre-training testing most of the subjects were not able to perform SJ and CMJ. It may be concluded that evaluation the efficiency of instability resistance training in dynamic conditions more sensitively reflect adaptation changes in postural control system than on stable platform. Also measurement of movement speed seems to be suitable method, whereas using explosive power tests in an early stage of post-rehabilitation is limited.

EVALUATION OF K-1 FIGHTERS’ APPLICATION OF TACTICAL MEANS

Kapo, S., Cikaltic, B., Radijo, I., Kajmovic, H.
Faculty of Sports and Physical Education, University of Sarajevo, Bosnia and Herzegovina

From the structural point of view, K-1 is a combination of different martial arts: Karate, Kempo, Kickboxing, Taekwondo, Kakutogi, Box, Muaythai. The best characteristics of those motion structures have been merged and that resulted in a dominant, top-of-the-pyramid motion structure called K-1. All advantages of martial arts have been shaped in unique K-1 rules which do not limit fighters from fully employing all available technical and tactical elements. K-1 sport requires the application of rapid, perfect and efficient techniques and complex technical and tactical combinations, leaving out slow techniques and passive defending (Hong, 2003., Kajmovic et al., 2005., Kapo, Radijo, Kajmovic, & Bonacini, 2006). This research has been carried out on a sample of 96 top level super heavyweight (over 91 kg) male fighters participating in final K-1 tournaments in Japan in 84 matches and 205 rounds. The age of the examinees varied from 21 to 39 years. The objective of the research was the evaluation of tactical means applied during the fights by the most successful K-1 fighters in the world and identifying dominant tactical means on the basis of achieved results. The gathered data on technical elements have been processed with the descriptive statistic method and presented according to the total frequency of the ratings and average ratings of individual variables. By means of trend analysis we examined the development trends in the application of technical means in the sense of their increase and decrease as to obtain data on average behaviour of fighters. The research results indicate that the following variables have the highest level of application in K-1 fights: distance (which allows a fighter to both defend himself and attack the opponent efficiently), feinting (used in order to confuse the opponent, as well as to divert his attention from the actual intentions i.e. the blow that is to be delivered), and combination. The richness and possibilities of the latter are considered to be the strongest tactical weapon among the factors essential for attaining success in K-1 sport. Trend analysis indicates that the application of following tactical means such as speed of FTO Dyne initiation and the soccer kick was measured using FITRO Force plate was applied to measure height of the squat and counter-movement jump. Pre-training measurements showed the non-injured-to-injured leg percent differences of 15.7% for static and 24.5% for dynamic balance. Following the training there were no changes in static balance on both legs (from 18.2±3.3 mm/s to 15.8±2.8 mm/s), on non-injured leg (from 41.3±8.8 mm/s to 38.2±7.8 mm/s), and on injured leg (from 49.0±8.9 mm/s to 43.2±7.7 mm/s). Likewise, the dynamic balance did not change while standing on both legs (from 93.2±19.0 mm/s to 86.7±17.8 mm/s) and on non-injured leg (from 112.3±25.0 mm/s to 101.2±21.8 mm/s), however a significant (p<0.01) improvement on injured leg has been found (from 148.7±22.8 mm/s to 138.0±20.0 mm/s). In addition, sway velocity significantly (p<0.05) decreased during bipedal stance on ML tilted platform (from 134.2±20.1 mm/s to 110.6±18.2 mm/s) but not on those A-P tilted (from 120.6±19.7 mm/s to 104.7±18.0 mm/s). Moreover, mean run-out speed significantly (p<0.05) increased on injured leg (from 347.4±42.3 cm/s to 385.3±38.8 cm/s) but not on non-injured leg (from 378.1±42.1 cm/s to 371.8±47.1 cm/s). In contrast, no changes in mean kick-off speed on injured and non-injured leg have been found (from 474.0±38.5 cm/s to 515.6±43.3 cm/s and from 475.9±40.7 cm/s to 499.5±37.6 cm/s). Unfortunately, no information on changes in jumping performance is provided because during pre-training testing most of the subjects were not able to perform SJ and CMJ. It may be concluded that evaluation the efficiency of instability resistance training in dynamic conditions more sensitively reflect adaptation changes in postural control system than on stable platform. Also measurement of movement speed seems to be suitable method, whereas using explosive power tests in an early stage of post-rehabilitation is limited.

RELATIONSHIPS BETWEEN THE PHYSICAL ABILITY AND GAME INTELLIGENCE OF YOUNG ELITE WATER POLO PLAYERS

Enomoto, I., Haru, A., Omoto, Y., Kobayashi, D., Takahashi, M., Kawakami, T., Komori, Y., Kono, I.
Kamakura Women’s University, Japan

In order to assess the physical ability of water polo players, many types of battery tests have been developed. On the other hand, game intelligence, which refers to the ability of athletes to effectively solve the problems faced during sports activity, is routinely assessed by coaches. However, little is known about the relationships between the parameters of physical ability and game intelligence. This study aims to clarify the relationships between the physical ability and game intelligence of young elite water polo players. Twenty-six experienced male water polo players (aged 18-20) excluding goalkeepers, participated in this study. 11 players were members of the Japanese national junior team (JUN) and 15 were unseated group of the JN (JUC). The physical abilities included the following: multi-
stage shuttle swim test (MSTT), ball-throwing distance in water (BTD), 30 m sprint swim including jumps anddouble back movements (30S), and vertical floating with 20 kg weights (VFW). Game intelligence parameters included perimeter offensives (POI), man-up offense (WO), counter offense (ICO), perimeter defense (PDI), man-down defense (WMD), and counter defense (CDI). In each situation, four water polo experts including national team coaches assessed every player on a scale of 0 to 5 in an official water polo match.

The result of the paired t-test or Welch’s test (p < 0.05) revealed that the results of MSTT (99.9 ± 8.9 vs. 88.5 ± 13.6), VFWM (37.0 ± 15.0 sec vs. 21.6 ± 9.0 sec), and 305 (44.5 ± 4.5 sec vs. 53.6 ± 6.1 sec) were statistically significant in both groups. However, BTD (30.0 ± 1.9 m vs. 28.8 ± 1.8 m) did not reveal any statistical difference. The scores of the game intelligence parameters for both groups were as follows: PO (17.0 ± 1.8 vs. 11.1 ± 4.7), WO (15.0 ± 1.1 vs. 11.0 ± 4.6), CO (16.0 ± 1.4 vs. 11.2 ± 4.7), PD (15.5 ± 1.5 vs. 10.8 ± 4.5), MD (14.0 ± 1.0 vs. 10.5 ± 3.74), and CDI (14.6 ± 1.1 vs. 10.6 ± 3.4). All regard to the correlation between physical abilities and game intelligence in all participants, Spearman’s correlation coefficient indicated that VFWM (r: 0.59 for PO, 0.45 for MO, 0.63 for CO, 0.61 for PD, 0.64 for MD, and 0.72 for CDI) and 305 (r: -0.55 for PO, -0.52 for MO, -0.54 for CO, -0.42 for PD, -0.47 for MD, and -0.53 for CDI) had significant relationships (p < 0.05) with all parameter. BD had a significant relationship with PO (r = 0.40). MSTT had a significant correlation with MD (r = 0.41). These results revealed that the parameters that were assessed in this study were good criteria for assessing the physical ability and game intelligence of young water polo players. It should be noted that parameters such as leg strength for keeping the body vertical in water and 30 m sprint swimming with specific movements have strong relationships with game intelligence. Ball-throwing ability is associated with game intelligence in the perimeter offense, while aerobic ability is connected with game intelligence in the man-down

**FITNESS CHARACTERISTICS OF A NATIONAL GREEK ALPINE SKIING TEAM: CORRELATION WITH RACING PERFORMANCE**

Nikolopoulos, D., Zafeiridis, A., Manou, V., Saraslaniadis, P., Kellis, S. Aristotle University of Thessaloniki, Greece

Alpine skiing performance depends on several fitness parameters such as aerobic and anaerobic capacity as well as lower limb strength. This study aimed to characterize the aerobic and anaerobic power and strength parameters of the Greek men’s national alpine skiing team and to investigate the correlations of these fitness parameters with their racing performance in slalom (SL) and giant slalom (GS), as assessed by the International Ski Federation (FIS) points.

The Greek national alpine skiing team (height=174.9±7.2 cm, body weight=73.4±6.6 kg, body fat%=11.1±1.8%) performed a maximal incremental test on a treadmill for determination of VO2max and a Wingate test for determination of peak and mean anaerobic capacity. Participants also underwent isokinetic (angular velocity 60°/s) and isometric testing as well as various types of vertical jumps for the assessment of lower limb strength. All data were analyzed using descriptive statistics and Pearson correlation coefficient.

The mean value for VO2max was 56.5±5.3 ml/kg/min (45.8-65.2 ml/kg/min) and for peak power, mean power, and fatigue index were, 10.4±0.7 W/kg (8.5-11.2 W/kg), 8.1±0.5 W/Kg (6.8-8.8 W/kg), and 42.6±6.2% (28.1-48.8%), respectively. The relative maximum force that developed during isometric testing averaged to 68.8±5.9 N/kg extensors knee muscles ratio of 67.4%. Therelative maximum force that developed during isometric testing averaged to 68.8±5.9 N/kg extensors knee muscles ratio of 67.4%. The relative maximum force that developed during isometric testing averaged to 68.8±5.9 N/kg extensors knee muscles ratio of 67.4%. The relative maximum force that developed during isometric testing averaged to 68.8±5.9 N/kg extensors knee muscles ratio of 67.4%. The relative maximum force that developed during isometric testing averaged to 68.8±5.9 N/kg extensors knee muscles ratio of 67.4%. The relative maximum force that developed during isometric testing averaged to 68.8±5.9 N/kg extensors knee muscles ratio of 67.4%. The relative maximum force that developed during isometric testing averaged to 68.8±5.9 N/kg extensors knee muscles ratio of 67.4%. The relative maximum force that developed during isometric testing averaged to 68.8±5.9 N/kg extensors knee muscles ratio of 67.4%. The relative maximum force that developed during isometric testing averaged to 68.8±5.9 N/kg extensors knee muscles ratio of 67.4%. The relative maximum force that developed during isometric testing averaged to 68.8±5.9 N/kg extensors knee muscles ratio of 67.4%. The relative maximum force that developed during isometric testing averaged to 68.8±5.9 N/kg extensors knee muscles ratio of 67.4%.

The result of the paired t-test or Welch’s test (p < 0.05) revealed that the results of MSST (99.9 ± 8.9 vs. 88.5 ± 13.6), VFWM (37.0 ± 15.0 sec vs. 21.6 ± 9.0 sec), and 305 (44.5 ± 4.5 sec vs. 53.6 ± 6.1 sec) were statistically significant in both groups. However, BTD (30.0 ± 1.9 m vs. 28.8 ± 1.8 m) did not reveal any statistical difference. The scores of the game intelligence parameters for both groups were as follows: PO (17.0 ± 1.8 vs. 11.1 ± 4.7), WO (15.0 ± 1.1 vs. 11.0 ± 4.6), CO (16.0 ± 1.4 vs. 11.2 ± 4.7), PD (15.5 ± 1.5 vs. 10.8 ± 4.5), MD (14.0 ± 1.0 vs. 10.5 ± 3.74), and CDI (14.6 ± 1.1 vs. 10.6 ± 3.4). All regard to the correlation between physical abilities and game intelligence in all participants, Spearman’s correlation coefficient indicated that VFWM (r: 0.59 for PO, 0.45 for MO, 0.63 for CO, 0.61 for PD, 0.64 for MD, and 0.72 for CDI) and 305 (r: -0.55 for PO, -0.52 for MO, -0.54 for CO, -0.42 for PD, -0.47 for MD, and -0.53 for CDI) had significant relationships (p < 0.05) with all parameter. BD had a significant relationship with PO (r = 0.40). MSTT had a significant correlation with MD (r = 0.41). These results revealed that the parameters that were assessed in this study were good criteria for assessing the physical ability and game intelligence of young water polo players. It should be noted that parameters such as leg strength for keeping the body vertical in water and 30 m sprint swimming with specific movements have strong relationships with game intelligence. Ball-throwing ability is associated with game intelligence in the perimeter offense, while aerobic ability is connected with game intelligence in the man-down

**EFFECTS OF OFFICIAL TAEKWONDO COMPETITIONS ON ALL-OUT PERFORMANCES OF ELITE ATHLETES**

Chiado, S., Tessitore, A., Ammendolia, A., Cortis, C., Lupo, C., Iona, T., Capranica, L. University of Catanzaro, Italian Taekwondo Federation, IUSM of Rome, University of Molise., Italy

Introduction

Official Olympic Taekwondo competitions include qualifying sessions, semi-finals and finals organized during a day. Each session consists of three 2-minute rounds with a 1-minute rest in between. Since research focused on simulated competitions only (Bouhlel et al., 2006, Buitos & Tisaka, 2007), this study aimed at investigating the Taekwondo athletes’ capability of all-out performances during a National Championship in relation to the load of their matches.

Methods

The physical load of the Italian Taekwondo Championship was evaluated in 15 (4 women and 11 men) elite athletes by means of heart rate (HR) recordings during the match and blood lactate (La) measurements performed before and at the end of the three rounds. In relation to the percentage of individual HRmax five activity categories were considered: 1) maximal effort (>95% HRmax), 2) high-intensity (86-95% HRmax), 3) low-intensity (76-85% HRmax), 4) active recovery (65-75% HRmax), and 5) passive recovery (<65% HRmax). Counter-movement jump (CMJ) and handgrip performances were measured before and at the end of the competitions. A preliminary analysis ascertained that no difference (p<0.05) emerged between qualifying (i.e., six-teen, eighth, and fourth rounds) and final (semi-final and final) competitions. Then, a 4 (intensity) x 3 (round) analysis of variance for repeated measures was applied to time (s) spent at the activity categories. A 2 (gender) x 2 (session) analysis of variance for repeated measures was applied to CMJ (cm) and handgrip (N) performances, and La values (mM).

Results

During the competition, a difference (p<0.01) emerged for intensity and for the interaction intensity x round (p<0.01), with higher frequency of occurrence for the high intensity category (7±10%) with respect to low intensity (9±4%) and maximal effort (20±13%) ones. After the match, La values increased (p<0.01) to 5.2±2.0 mM and 7.0±2.6 mM for female and male athletes, respectively. Jump performances showed main effects (p<0.01) for gender and session, with best performances after the competition (men pre: 40.8±4.9 cm, men post: 43.9±5.2 cm).
cm; women pre: 28.2±2.5 cm; women post 30.8±2.3 cm). Grip strength showed main effects (p<0.01) for gender and session, with worst performances at the end of the competition.

Discussion
The results showed that Taekwondo competitions impose a high load on athletes. The lack of difference between qualifying and final sessions indicates that athletes are able to recover between matches. The better jump performances observed at the end of the matches might be due to the effect of an increased arousal from the intermittent activity of the lower limbs during the match. Instead, the decreased grip strength might be due to fatigue developed by the athletes continuously competing with clenched fists to defend and to be ready to attack.

PREDICTION OF MAXIMAL OXYGEN UPTAKE IN 12 - 18 YEAR-OLD ADOLESCENTS: DEVELOPMENT AND CROSS VALIDATION OF A NEW EQUATION, AND COMPARISONS WITH OTHER PREDICTION EQUATIONS
Tsiaras, V., Zafeiridis, A., Zilogas, G., Patras, K., Georgoulis, A., Kellis, S.
Aristotle University of Thessaloniki, Greece

The aims of this study were: 1) to develop and cross-validate a generalized equation to predict VO2max in adolescents 12-18 yrs. based on a maximal running exercise test, 2) to compare the new equation with the previously published ones for the prediction of VO212 and VO2max in adolescents, and 3) to cross-validate the previously published equations.

Eighty-eight male adolescent athletes performed a maximal exercise test on a treadmill to assess the actual VO2max and a 20m shuttle-run test. The incremental exercise protocol started at 6 km/h and the speed was increased by 1km/h every 2min until exhaustion. Then, the subjects were divided into a derivation (n=70; age=14.9±1.4 yrs.) and a cross-validation (n=18; age=14.8±1.7 yrs.) groups. Multiple-regression analysis was used to develop the equation from the derivation group using combinations of age, height, body weight, running velocity and exercise duration as independent variables. The derived equation was cross-validated using: correlation coefficient (R) between the actual and predicted VO2max, constant error (CE=actual VO2max - predicted VO2max), standard error of estimate (SEE), total error (TE), and the similarity between SEE and TE.

The following equation best attained the above criteria and most accurately estimated VO2max: VO2max [ml/min] = -597.9 + 73.5 x Exercise Duration(min) -45.7 x BW[kg]. Cross-validation statistics are: R=0.94, mean difference (CE) = -24 ml/min, SEE =157 ml/min (4.8%), and TE = 164 ml/min (5.1%) between the actual VO2max and predicted VO2max. When the absolute values of VO2max were converted to relative values, CE = -0.5 ml/kg/min (1.1%), SEE = 2.4 ml/kg/min (4.5%), and TE = 2.6 ml/kg/min (4.8%). The cross-validation analysis for the 4 published equations showed CE from -1.3 to 4.8 ml/kg/min, SEE from 3.0 to 3.9 ml/kg/min and TE from 3.6 to 6.1 ml/kg/min. Tukey tests revealed differences between the actual and Bonnen’s predicted VO2max (53.6±2.6 vs. 48.7±3.1; p<0.01), while there were no differences between the actual and the Bonnen’s predicted from equations of this study [54.1±2.9], Shuttle-test (51.7±3.4), Walker’s (54.9±4.4), and Leger’s (51.2±3.6). Mean CE was different from zero in Bonnen’s and Shuttle-test equations (p<0.05).

In conclusion, the equation of this study accurately predicts VO2max in 12-18 yrs. males demonstrating lower values of CE, SEE, and TE vs. other equations1-4. The equations of Walker et al. and Leger et al.1 are also suitable for the prediction of VO2max in children 12-18 yrs., despite that they were developed for prediction of VO2 at lower velocities, while the Bonnen’s equation appears to underestimate VO2max.

VENTILATORY RESPONSE DURING A MAXIMAL BOUT OF 400 M IN CRAWL SWIMMING: ASSOCIATIONS WITH PERFORMANCE
Marinho, D., Reis, V., Meira, O., Silva, A., Carneiro, A., Reis, A.
1: UBI (Covilhã, Portugal), 2: UTAD (Vila Real, Portugal), 3: CIDESD (Portugal), 2: State University of Montes Claros (Brazil), Portugal

Introduction
The direct assessment of ventilatory indicators during swimming with breath-by-breath portable gas devices is a recent issue. Gas ana-lysers and specific valves for swimming have been designed as an attempt to improve the validity of field measures and minimize their influence in the technique. However, the data available is still scarce. The energy cost based on ventilatory measurements during the 400 m front crawl event is unknown, as well as its association with performance. Therefore, the purposes of this study were to determine the relative contribution of the aerobic and anaerobic metabolism during the 400 m front crawl event and to determine the relationship between the performance in the event and ventilatory and metabolic variables.

Methods
The sample comprised 8 national level competitive male swimmers. Each subject performed one submaximal and one supramaximal test, with 48 hours recovery between them in an indoor 25 m swimming pool. In both tests expired air was analysed by a K4b2 attached to an AquaTrainer® valve (Cosmed, Italy) and the VO2 values were registered every 20 s. The submaximal test comprised 5 intensity bouts with 6 min duration and recovery time between them. Blood samples were collected at the end of each bout. In the supramaximal test, each swimmer performed an all out 400 m front crawl swimming at maximal exertion. At the end of the 400 m bout blood lactate was measured each 2 min, until levelling-off.

Results
The swimming velocity corresponding to the lactate threshold of 2 mmol/l and the lactate threshold of 4 mmol/l were 1.04±0.11 m/s and 1.20±0.08 m/s, respectively. In the 400 m front crawl swimming the aerobic and anaerobic fractions of energy were 93% and 7%, re-spectively. No significant differences were found between the energy cost in the submaximal test (0.58±0.06 ml/Kg/m) and in the supramaximal test (0.62±0.06 ml/Kg/m). Significant correlations between the mean velocity in the supramaximal test and the ventilatory and metabolic variables measured in this test were not verified. Nevertheless, we found that estimated fat mass correlated with the swim-ming performance (r=0.78; p<0.05). Moreover, accumulated oxygen deficit correlated negatively with the velocity associated to the lactate threshold (r=0.82; p<0.05).

Conclusion

458
13TH ANNUAL CONGRESS OF THE EUROPEAN COLLEGE OF SPORT SCIENCE
The ventilatory response does not seem to determine the 400 m front crawl swimming performance among a homogeneous group of trained subjects. However, estimated fat mass does seem to play some role in this event. Other factors (i.e. biomechanical) may help to understand differences in the performance.

ONTogenetic Variability of Dynamometric Properties in the Jumping Ability in Girls Practising Rhythmic Gymnastics
Polischuk, T.
The Jozef Pilsudski Academy of Physical Education in Warsaw, Poland

Rhythmic gymnastics is one of the most difficult, and at the same time one of the most spectacular sport disciplines. For rhythmic gymnastics the level of jumping ability is of crucial importance. It is indispensable during the execution of complex arrangements and constitutes a condition for efficient and effective sport contest, correct execution of technical exercises, and furthermore it allows achieving good sport results. A high sport class gymnast executes on average from 8 to 12 jumps in each arrangement, which are evaluated by the jury who take into account the height of the leap, the technique and choreographic performance. High score is granted to a combination of a few complex jumps with simultaneous manipulation of accessories.

The conducted study was aimed at finding an answer to the question: how does the dynamometric structure of jumping ability change with age, does it depend on the degree of fitness coordination of the subjects, and do changes take place in the level of jumping ability endurance in the ontogenesis?

The study comprised 32 gymnasts, who were divided into two groups, each with 16 subjects. The first group was consisted of gymnasts aged 9-12 years (training period experience 3 to 5 years). The second group was composed of girls aged 13-16 years (training experience - from 6 to 10 years). Tests of the level of jumping ability was performed using the tensodynamographic method, which is used to evaluate parameters that characterize strength and speed capabilities of the human motor system on the basis of a vertical leap off on a dynamometric platform. The tested persons performed 3 tests: leap off with sweeping arm motion, leap off without sweeping arm motion, performing a series of ten single vertical leap offs - without sweeping arm motion with an interval of 3 seconds between the jumps. The course of component force of base reaction was used to calculate the following height of body mass centre elevation - height of upward leap off, maximum strength, maximum speed, maximum and average power, range of sweeping arm motion, force drive and performed work. The obtained results have shown that values of particular parameters: maximum and average power and maximum strength and force drive depend on the age of gymnasts at the significance level of p<0.05. The obtained correlation indices demonstrated rather significant relations (r = 0.83) between the level of jumping ability, and coordination abilities of the subjects. Considerable differences between groups were recorded also in an executed leap off series. In gymnasts of the older age group a high level and stabilization of values of particular indices (including also the height of jump) during performance of a series of 10 jumps was observed, while gymnasts from the younger group were characterized by a trend of decreasing values of the tested parameters.

Identifying Levels of Peripheral Vision Abilities and Complex Reactions in Basketball Players
Poliszczuk, D., Polischuk, T.
The Jozef Pilsudski Academy of Physical Education in Warsaw, Poland

The role and importance of motor coordination abilities is much differentiated in each particular sport discipline. In sport games they ensure an effective realization of technical and tactic performance in varying conditions and constantly changing situations and tasks. Peripheral vision and the ability of quick reaction are closely related to sensor-motor functions of the psycho-physiology of the competitors such as: simple and complex reaction time to visual stimulus, as well as the accuracy of the reactions to the moving object.

A basketball player during the match has not only to cooperate with his fellow partners in the team but also has to effectively break in the rival's actions and undertake optimal decisions within a limited space of the playing field and under the constant pressure of the opponent. In contemporary team games, sport success is delimited by the control of the course of rivalry within the peripheral field of vision and by the quick and accurate technical and tactic operations.

The aim of the research was to evaluate the range of the peripheral vision and complex reactions of competitors practicing basketball through the use of the Vienna Test System.

This research was based on 42 male basketball players aged 18 to 26, who were members of the Polish National League's second and third division. The Test of Peripheral Vision of the Vienna Test System was applied.

The study revealed that in the group of players a big difference in the missed reactions was recorded, since the minimum number of missed stimuli is equal to 0 and maximum to 12, which accounts for 30% of all stimuli.

The analysis of the results of the research showed that the median of the reaction time and the number of correct reactions of the right eye, despite the smaller angle of vision, are larger than the values of such indexes in the case of the left eye.

The results of the field of vision of the tested players correlate with the median of the reaction time. The correlation shows high level (r = 0.723).

It was ascertained that the eye of the examined individuals, on the side of the dominating hand, has a smaller angle of vision. Whereas the time of reaction and the relevancy of the decisions taken on the emerging stimuli are better. This may be the effect of the character of the discipline, when since the throws are executed during the match, the vision of the eye on the side of the dominating hand is limited, as a result of which it does not possess a big angle of vision.

Indicator’s Differences in Situation Efficiency Among Junior Male and Female Competitors at the European Judo Championship U-20
Kajmovic, H., Radjo, I., Kapo, S.
Faculty of Sports and Physical Education, University of Sarajevo, Bosnia and Herzegovina

Judo is a sport of balance in which fighter has to maintain balance with his opponent who on the other side has his own balance. Fight in judo is developing into two main areas: standing and floor combat. Both areas of fight request different approaches in the process of training fighters for the championships and necessity for the analysis of the situation's efficiency monitoring in judo can give quality information about acting manner of the fighters and their efficiency during the matches. Researches analysis of the indicators of situation's
efficiency, which competitors realize during the competitions represent good base for the applying researching results of training in judo (Kajmovic and al., 2007). Main goal of this research represents confirmation of indicator’s differences of situation’s efficiency among junior male and female competitors at the European championships in judo held in Sarajevo, 2003. Specimen contents total of 246 male fights and total of 179 female fights in all seven categories for male and female juniors. Initial results were carefully recorded through watching of VHS tapes, what made the situational aspect of the research really credible. Analysis of the parameters of situation’s efficiency is based by 4 groups of judo techniques: 1)Groups of judo techniques: 2)Subgroups of judo techniques: 3)Quantitative indicators of judo-fights: technical points and penalties. 4)Efficiency of the separate throwing and grappling techniques. Comparisons were made trough Chi square test at the level of statistical importance (p<0,05) with contingency tables. For testing the importance of correlations between the used variables, the coefficient of contingency was used (C). The results of the Chi square test showed statistically important differences between male and female in groups of judo techniques (Chi square=12,4;df=1;p<,000;C=,13), in subgroups of judo techniques (Chi square=34,4;df=7;p<,000;C=,20) and in quantitative indicators of judo-fights points and penalties (Chi square=13,0;df=6; p<,042;C=,10). Techniques mostly used by male juniors is: Kata Guruma (15,7%), Sukui Nage (9,4%), Tani Otoshi (6,2%), Uchi Mata (6,1%), Ippon Seoi Nage (5,9%), O Uchi Gari (4,9%) etc., and techniques by female juniors is: O Uchi Gari (9,2%), Kesa Gatame (7,6%), Ippon Seoi Nage (7,6%), O Soto Gari (7,0%), Kata Guruma (7,0%) etc.

Monitoring and controlling of the efficiency of the relevant technical-tactical parameters in judo that are expressed by juniors could be directly applied into training process so that optimal choice of content and load for training could be assured. On that way it could be also compared with higher demanding levels of competitions, all in terms of achieving better quality of judo, as a martial art.

DOES CALLISTHENIC EXERCISE AFFECT THE RELATIONSHIP BETWEEN BODY COMPOSITION AND LUNG FUNCTION IN WOMEN?

Karacan, S., Atalay Guzel, N., Colakoglu, F., Akyüz, M. Erikoğlu, G.

Selçuk University, Konya, Turkey

Introduction

Body composition changes with exercise, increases in skeletal muscle mass and declines in fat mass and visceral fat. On the other hand, lung function also increases with exercise. It was reported that respiratory muscle strength and lung function are closely associated with body weight and lean body mass in patients with chronic obstructive pulmonary disease (COPD). A central pattern of fat distribution is negatively associated with lung function in healthy adults2,4. The purpose of this study was to investigate the effects of relations between body composition parameters and lung functions including VC, FVC, FEV1, FEV1/VC, FEV1/FVC after 6-months callisthenic exercise program in healthy women.

Methods

Mean age and height of 35 healthy subjects were 41.69±7.69 yrs, 156.51±4.72 cm, respectively. All subjects took 50-minutes/sessions, 3-day per week and 24-week callisthenic exercises were performed to. The intensity of the exercise was determined with 80 % of heart rate reserve and contacts with each foot on a separate force plate (Kistler, Switzerland) and should be performed as soft as possible simultaneously with both feet. VGRF was measured (sampling rate of 1000 Hz) for each foot during drop-landing. For the peak and valley of the force-time-curves in drop-landings related to injuries reference data must be available. The current literature does not give a satisfying review on such data for vertical ground reaction forces (VGRFs) during a drop-landing. Therefore the purpose of the study was to evaluate the reliability of VGRF in a drop-landing series to have a basis for collecting a reference data pool. It was found that a negative relative in the BMI and FVC and MVV of subjects (p<0,01, r=- .03,. r=-.49). Also it was found that the reliability of VGRF in a drop-landing series to have a basis for collecting a reference data pool.

Discussion / Conclusions

In conclusion, there were positive effects as evident on women lung volume and capacity with callisthenic exercises. This study showed that the decrease level of fat percentage and BMI would be affected the lung functions in a negative way.

Key Words: Body Composition, Lung Volume, Exercise, Women.

FUNCTIONAL TESTING: DO FORCE PLATES DELIVER RELIABLE PARAMETERS TO ANALYSE DROP-LANDINGS?

Koplin, S., Schnittker, R., Baumann, J., Jöllenbeck, T., Weiss, M.

University of Paderborn, Germany

Purpose: Landing from a jump is often reported to be the cause of noncontact injuries in competitive sports. To find characteristics in the force-time-curves in drop-landings related to injuries reference data must be available. The current literature does not give a satisfying review on such data for vertical ground reaction forces (VGRFs) during a drop-landing. Therefore the purpose of the study was to evaluate the reliability of VGRF in a drop-landing series to have a basis for collecting a reference data pool.

Methods: Eight male volunteers (27.5±6.14 years, 85.4±13.8 kg, 183.6±8.8 cm) participated in the study. Inclusion criteria required that all subjects were free of pain. The participants were asked to execute 40 drop-landings barefooted from a height of 25 cm. The ground was contacted with each foot on a separate force plate (Kistler, Switzerland) and should be performed as soft as possible simultaneously with both feet. VGRF was measured (sampling rate of 1000 Hz) for each foot during drop-landing. For the peak and valley of the force-time-curves the time points (Ipeak, Ifalley) and forces (Fpeak, Fvalley) were analysed. The test series was split in four sessions (M1-M4) each consisting of ten drop-landings. After normalising the VGRF by body mass, the coefficients of variation (CV) for force and point in time were calculated for each session. Statistical comparisons of sessions were done using an one-way ANOVA with repeated measures.

460

13TH ANNUAL CONGRESS OF THE EUROPEAN COLLEGE OF SPORT SCIENCE
Results: The mean CV for tpeak was 5.5% (SD 1.0%) while it was 15.90% (SD 3.4%) for Fpeak. The variability index of tvalley was higher with 10.1% (SD 3.2%) as well as 19.8% (SD 1.6) for Fvalley. The highest CVs of all parameters were consistently in M1. Statistical analysis revealed a significant difference of CV for tpeak of the left leg between M1 and M2 (p=0.02) and between M1 and M3 (p=0.02). No further differences in variability of all described parameters throughout the test series could be detected.

Conclusion: Force plates do deliver reliable parameters of vertical ground reaction forces in a drop-landing series related to time points (tpeak, tvalley). The significant differences in these parameters at the left leg between the initial session and the two following sessions were discussed as a familiarization effect. In summary the time characteristics during drop-landings could be a basis for reference values, but future studies should also focus on other force characteristics, the influence of gender and the instruction of the task to prepare the ground for a reference data pool.

A MODEL OF THE PROCESS OF REGAINING BALANCE AFTER PERTURBATION FROM QUIET STANCE: WITH APPLICATION TO TRAINING IN ELITE JUDO

Lopez Diaz de Durana, A., Stirling, J., Zakynthinaki, M., Cordente Martinez, C., Sillero Quintana, M., Sampedro Molinuevo, J.
Technical University of Madrid, Spain

Using tools from dynamical systems [4] we investigate stability and the maintenance of balance in elite Judokas. We model and analyze the ground reaction forces resulting from an athlete being perturbed from quiet upright stance, for the two legged and single legged condition [1,2]. The maximum correctable angles between the resultant ground reaction forces and the vertical in the anteroposterior and mediolateral directions are obtained via a force platform. A closed critical curve [4] is fit through these maximum correctable angles outside which the perturbations cannot be corrected and the motion of the body back to the position of quiet stance is analyzed. We then analyze the curve to identify non-symmetric behavior caused by muscle imbalances, postural problems, structural problems and differences in the ranges of motion on either side of the body. We also show how the model can be used in elite judo regarding injury prevention [3] and identifying competitive strengths and weaknesses which may be addressed and corrected via training [5] once they have been discovered.

FLEXIBILITY TRAINING AND PHYSICAL FITNESS PERFORMANCE IN YOUNG HIGH-LEVEL SOCCER PLAYERS

Hadjicharalambous, M.
University of Nicosia, Cyprus

The present study examined the effect of specific static long-term flexibility training on selective physical fitness components in young high-level soccer-players. Twenty three players (mean +/- sd) were randomly assigned into Experimental (E) and Control (C) groups (E group: n = 12, age 16.1 +/- 0.6 years, height 1.71 +/- .06 m, body mass 62.4 +/- 7.5 kg, peak oxygen uptake (V˙O2 peak) 55 8 +/- 4.1 ml kg-1.min-1); (C group: n = 11, age 15.9 +/- 0.6 years, height 1.73 +/- .07 m, body mass 61.5 +/- 5.6 kg, peak oxygen uptake (V˙O2 peak) 54 2 +/- 5.2 ml kg-1.min-1). The E group performed a specific static stretching-training-program before and after each training session, for four weeks (4 days/week). The two groups performed two series of anthropometrics and physical-fitness tests prior to and following the application of the stretching-training performed on the E group. Anthropometric characteristics, body composition, aerobic capacity, 10m sprint and standing horizontal-jump were not different between the E and the C groups. However, flexibility ([F(1-21) = 4.850, p = .039], 35m sprint ([F(1-21) = 4.962, p = .037]) and agility (U = 15.000, N1 = 12, N2 = 11, p = .001) performance as well as Deltas flexibility ([F(1-21) = 4.293, df = 21, p = .005]), agility (t = 8.15, df = 21, p = .005) and standing horizontal-jump ([U = 29.000, N1 = 12, N2 = 11, p = .002]) scores were significantly improved in E group compared with C group. Only in the E group, a significant negative correlation between post-training flexibility and post-training agility scores was observed (r = -.46, n = 23, p < 0.028, two tailed). In conclusion, the present results suggest that regular application of static flexibility training is effective in improving flexibility, short-distance maximum sprint and particularly agility performance in high-level young soccer-players.

EFFECT OF ADDITIONAL MENTAL WORK ON BLOOD LACTATE DISAPPEARANCE AFTER MAXIMAL EXERCISE

Brás, R., Esteves, D.
University of Beira Interior, Portugal

The active recovery process plays an essential role in determining subsequent sports performance. The purpose of this study was to investigate the effect of additional mental work on the rate of blood lactate disappearance during recovery from maximal exercise. Eighteen sport students (both male and female) from the University of Beira Interior (mean age 20.7 +/- 1.6 years) participate in this study. Maximal exercise was performed on a treadmill with loads about 90-95 % FCmax during 5 minutes. After that, the students are divided in 2 groups. Group A completed an active recovery session performed at 40-50% FCmax for 10 minutes. Group B was submitted to the same recovery session, but with an additional task: response to simple mathematical calculations (involving the four operations and numbers 0-9), on an average rhythm of one per two seconds. Blood samples were drawn at the end of maximal exercise, at 3 and 6 min after recovery period. The results showed that at the end of active recovery, the blood lactate concentrations of the Group B (6.8 +/- 2.9 mmol/L) were higher than Group A (5.4 +/- 3.5 mmol/L). Furthermore the results indicated that an additional mental effort did affect significantly (p
less 0.05) the rate of blood lactate disappearance measured during active recovery. The decrease of the rate blood lactate disappearance can be attributed to the greatest demand of blood flow to nervous system, and in this way principal lactate removal processes (oxidation and gluconeogenesis) were not optimized. Our results suggest that coaches should consider avoid exercises or another test (conference, mental preparation) that require additional mental work during recovery among training sessions.

CHARACTERIZATION AND EVALUATION OF YOUNG RING HOCKEY TEAM
Madeira, R.
Universidade Lusófona de Humanidades e Tecnologias, Portugal

The purpose of this study was to evaluate a ring hockey team, determine the strong and weak trainable capacities, and compare the results of the same protocol with and without roller skates.

Eleven 15,86 ± 0,54 year old boys took part in the study. Basic anthropometry determined body mass (BM), height (H), body surface area (BSA), body fat percentage (%BF) and fat free mass (FFM). Maximal aerobic power (VO2max), maximal heart rate (HR max), average heart rate (HR a), percentage of maximal theoretical HR and covered distance were determined with the 20 meters shuttle run test (Luc Leger, 1982) with (WRS) and without (WORS) roller skates. Average HR standard deviation, maximal and minimal value for all variables were determined. Mean values WRS were compared with those WORS using t tests for paired data. A correlation grid (person product – moment correlation coefficient) was established between results WRS and WORS. All the studies were performed by the same investigator.

Results of all statistical testes were considered significant if p< 0.05. The evaluated group (BM: 67,06 ± 7,18 Kg; H: 173,45 ± 5,42 m; BSA: 1,79 ± 0,10 m2; %BF 9,75 ± 2,25; FF M: 60,50 ± 6,48 Kg) obtained cover distance WRS (135,63 ± 17,07), and VO2max (64,36 ± 3,88 mlKg-1 min-1). The average HR was significantly higher WORS (172,91 ± 9,02 beats/min) than WRS (163,36 ± 7,57 beats/min). No difference was observed between HR max. In both groups only 98,01 % of the maximal theoretical HR was obtained. The 20 meter shuttle run test WRS, in the variables number of courses and VO2max, was highly correlated (p<0,01) to the test WORS. In terms of covered distance and VO2max the athletes reached better performance in the test WRS than WORS but higher HR WORS than WRS. No difference was observed in the HR max. The 20 meter shuttle run test, with roller skates, could possibly be used as a specific test to determine the cardiorespiratory capacity of ring hockey players.

DIFFERENTIAL STRENGTH AND NEUROMUSCULAR ADAPTATIONS FOLLOWING COMBINED SENSORIMOTOR AND STRENGTH TRAINING IN YOUNG SHORT TRACK ELITE ATHLETES AND STUDENTS
Behrens, M., Mau-Möller, A., Laabs, H., Bruhn, S.
University of Rostock, Germany

Introduction
It has been proved that high-intensity strength training (HST) enhances maximum voluntary contraction (MVC), rate of force development (RFD) and neuromuscular activation (NA). Improvements in MVC, RFD and NA were induced by sensorimotor training (SMT) as well (Bruhn et al., 2006). The present study investigated neuromuscular adaptations of combined SMT and HST at different strength training levels.

Methods
14 subjects (male and female) were assigned to two groups of 7 persons respectively (young short track elite athletes, G1; age 17,0 ± 1,3, weight 67,7 ±7,0, height 176,4 ±8,2, students, G2; age 27,6 ±4,7, weight 75,3 ±7,1; height 179,9 ±6,9). Both groups had to go through a combined SMT and HST, which were performed successively in each training session twice a week for twelve weeks. Every training session consisted of 30min SMT followed by 45min HST. Before and after the training period MVC (in N), RFD (in Ns) were evaluated by standardized bilateral isometric strength testing on the legpress. The activations of mm. vastus medialis (VM), rectus femoris (RF) and soleus (S) were recorded unilaterally by surface electromyography (EMG) during the test. The parameters root mean square (RMS in mV) and median frequency (MF in Hz) were used to evaluate neuromuscular adaptations.

Results
Strength adaptations and EMG in G1. After the training period MVC was significantly enhanced (2332,7 ± a798,6 vs. 2620,5 ± 708,7; p = 0,037) accompanied by increased RMS in So [19,5 ± 10,76 vs. 22,37 ± 11,75], VM [53,96 ± 25,82 vs. 62,54 ± 30,12] and MF in So [50,83 ± 19,49 vs. 80,89 ±22,71], p = 0,021, RF [90,50 ± 33,96 vs. 93,33 ± 25,54]. RFD was also enhanced (10,12 ± 5,67 vs. 11,46 ± 4,33) as well as RMS in So (28,70 ± 31,38 vs. 37,11 ± 44,43). RF (52,27 ± 48,10 vs. 70,14 ± 46,57), VM (69,99 ± 29,84 vs. 81,99 ± 34,25). Strength adaptations and EMG in G2. After the training period MVC was enhanced (2482,4 ± 1002,9 vs. 2601,5 ± 736,1i) accompanied by major increased RMS in RF (38,66 ± 14,13 vs. 42,76 ± 12,91) and MF in So (78,57 ± 17,73 vs. 82,25 ± 22,66), VM (79,48 ± 27,16 vs. 83,39 ±17,35) RFD remained nearly unmodified [11,97 ± 5,41 vs. 11,76 ± 5,71] and RMS was decreased in RF (43,11 ± 20,02 vs. 35,37 ± 12,62), VM (69,57 ± 41,98 vs. 55,66 ± 30,95).

Discussion
In G1 increased MVC was likely induced by enhanced recruitment of VM motor units (MU) and improved firing frequency of the So motoneuronpool (intramuscular coordination). G2 revealed a moderate enhancement of RMS and MF. Therefore the improved MVC was likely induced by increased intramuscular coordination. Only G1 showed an improvement of RFD, which was probably induced by better recruitment of the MU of all three muscles.

Conclusion
Combined SMT and HST evoked different strong and neuromuscular adaptations in elite athletes and normal subjects.

THE INFLUENCE OF DRIBBLING ON REPEATED SPRINT TEST PERFORMANCE AND PHYSIOLOGICAL RESPONSES IN YOUNG BASKETBALL PLAYERS
Meckel, Y., Kasorla, T., Eliakim, A.
Zinman College for Physical Education & Sport, Israel

The study examined the effect of basketball dribbling on performance indices and physiological responses during repeated sprint tests (RST). Thirteen young (mean age 18 ± 0,7 years) male basketball players (7 backline players and 6 frontline players) performed two forms of RST. The RST included 6 X 30m maximal runs departing every 30s, with and without dribbling, in random order. Maximal heart rate and blood lactate concentrations were significantly higher in the RST without dribbling compared to the RST with dribbling (180 ±2,8 vs 171,5 ±2,2 b/min and 9,9 ± 0,8 vs 6,5 ±0,8 mMol/L, respectively, p<0,05). The fastest 30m sprint time and the total sprint time (sum of all 6
CHARACTERIZATION OF A SO-CALLED VELOCITY TRAINING SERIES IN SWIMMING

Sampaio, A., Fernandes, R., Colaco, P., Figueiredo, P., Sousa, M.

Higher Education Institute of Maia, Portugal. University of Porto - Faculty of Sport, Portugal

Velocity training is not a simple task to be accomplished in swimming. As well as the other bioenergetics areas, developing velocity implies specific planning and periodization plus accurate training control. There is relatively less information on the response of swimmers to maximal exercise of very short duration, namely because the methodologies used for the evaluation of the effort supported by the immediate energy production system are scarce. However, velocity training series are widely spread in the technical community, evidencing that this conditional capacity is important for the overall development of swimming performance.

The purpose of this study consisted in the characterization of a typical swimming velocity training series, testing the contribution of the anaerobic glycolysis in a alleged "alactic" exercise. Since it is accepted that the time to maximal contribution of the phosphagenic energy system is about 6-8s (Di Prampero, 1981), it was hypothesized that there is an increase in the blood lactate concentrations [La-] within the training series, which lead to a decrease of velocity between repetitions.

Seven good level swimmers (5 males and 2 females) were studied. Subjects main physical characteristics were: 19.0±1.5 years old, 174.2±6.7cm, 67.4±5.1Kg, 20.0±1.4 years old, 175.5±12.0cm and 62.5±10.6Kg (male and female swimmers, respectively). The protocol consisted in a front crawl training set of 4x25m at maximal intensity, with 2min interval. Capillary blood samples were collected from ear lobe at rest and after each repetition (1, 3, 5 and 7min of recovery) to assess rest and post exercise peak [La-] Lactate Pro, Akrayl. After the normality of the distributions were verified, mean ± SD computations for descriptive analysis were obtained for all variables. Velocity and [La-] differences were tested using Friedman and Wilcoxon non parametric test. Statistical significance criterion was 0.05.

[La-] mean value increased significantly from rest to the first 25m repetition and throughout the training series: 1.7±0.4, 2.82±1.02, 6.51±1.02, 8.92±1.61 and 11.61±2.88 (respectively for rest values and 1st, 2nd, 3rd and 4th reps, all in mmol/l), which evidences a clear contribution of the glycolytic metabolism in supporting this specific type of effort. Regarding swimming velocity, it was not observed any differences during the protocol: 1.89±0.13, 1.92±0.11, 1.90 ± 0.10 and 1.90 ± 0.10, respectively for the 1st, 2nd, 3rd and 4th reps (all in m/s).

This fact seems to indicate that the installed muscle acidosis, and the consequent fatigue state, was not sufficient to inhibit the maintenance of very high swimming velocities.

The studied training series seems to be more appropriated for developing the glycolytic power bioenergetic capacity. For training velocity swimming coaches should diminish the duration of each repetition and/or increase the rest interval.

ISOKINETIC FATIGUE PROTOCOL: ASSESSMENT OF SHOULDER ROTATOR MUSCLES

Forthomme, B., Maquet, D., Lehanne, C., Wingtens, N., Crielard, J., Croisier, J.

University and CHU of Liege, Belgium

Introduction

Up to now, resistance fatigue protocols were classically devoted to lower limb. Interestingly, it has been suggested that fatigue affects upper limb proprioception and entails impairment in movement accuracy [1]. Therefore, resistance fatigue assessment should also investigate shoulder muscle groups, which requires a methodological analysis. Shoulder isokinetic assessment is characterized by many possibilities of installation and protocols, without actual consensus into the literature.

Aim

To accurately design a protocol, our study aimed to clarify the influence of shoulder position on the isokinetic results, immediate and differed pain and cardiac frequency during isokinetic resistance fatigue evaluation.

Patients and methods

Twelve healthy male subjects (21.5 +/- 1 year old) sustained an isokinetic resistance fatigue assessment of the external (ER) and internal (IR) rotators of the dominant shoulder. Subjects were installed in lying supine position, the shoulder installed at 45° or 90° of abduction (Abd) in the frontal plane (order randomly assessed). The protocol consisted in 30 maximal contractions (range of motion - ROM = 120°) in the concentric mode at 180°/sec. Subjects also underwent Borg scale appraisal, shoulder ROM measurements, clinical tests and doliorometry evaluation on shoulder muscles. The cardiac frequency was measured during the isokinetic test and during recovery.

Results

The total Work IVN in JI developed by the IR was significantly higher (p<0.001) than VI measured on ER, whatever positioning. The ER WI increased at 90° Abd in comparison with 45° Abd (> 20%). The ER/IR ratio was higher at 90° Abd but remained relatively constant during the 30 repetitions. There was no difference in the evolution of heart rate between both positions. The start level was recovered one minute after the end of the assessment. Exercise at 90° Abd only entailed some delayed side effects. Being more specific of sport gesture, 90° Abd position may be recommended for isokinetic fatigue protocol. Nevertheless, therapists have to be knowledgeable of possible side effects on shoulder status.

SUBMAXIMAL ENDURANCE MARKERS OF ELITE SOCCER PLAYERS DURING PRESEASON TESTING

Ziogas, G., Patras, K., Stergiou, N., Georgoulis, A.
University of Ioannina, Greece

BACKGROUND: VO2max has been traditionally used to explain physiological differences among soccer teams of different ranking. However, the degree of predictive ability of VO2max in endurance events has been challenged, with velocity at lactate threshold being more strongly correlated with performance and running economy affecting performance even when VO2max remains unaltered. Thus, submaximal endurance markers may have greater discriminatory ability and provide additional information that will affect preseason training planning in soccer.

PURPOSE: To examine if velocity at lactate threshold and running economy can be used to better discriminate endurance characteristics of soccer teams of different level along with VO2max during preseason testing.

METHODS: One hundred twenty nine professional soccer players from the top three leagues participated in the study and underwent an incremental treadmill test to exhaustion with simultaneous expired gas analysis and blood lactate measurements. Velocity at lactate threshold was determined using the Dmax method and running economy was measured at 12 km/h. A one-way ANOVA with Tukey-Kramer adjustment for multiple comparisons was used to determine significant differences.

RESULTS: VO2max was 58.8 ±3.3, 56.4 ±3.7 and 57.6 ±3.2 ml/min/kg, velocity at lactate threshold 13.16 ±0.7, 12.61 ±0.7, 12.28 ±0.8 km/h and running economy 44.6 ±2.9, 44.4 ±2.8, 46.4 ±3.9 ml/min/kg for divisions A (First Division), B (Second Division) and C (Third Division) respectively. Velocity at lactate threshold was the only variable which was statistically different in between any two leagues. In every comparison, the higher division had the higher velocity at lactate threshold. VO2max was statistically different only between the top two divisions. Running economy was statistically different between leagues with similar VO2max, with better running economy for the higher league in each comparison. Lactate at threshold, heart rate at threshold and maximal heart rate did not differ between divisions with values 3.95 ±1.2, 3.77 ±1.2, 3.68±1.8 mmol/l, 170 ±10, 167 ±11, 168 ±11 and 191 ±9, 191 ±9, 191 ±8 beats/min for the three leagues respectively.

CONCLUSION: Velocity at lactate threshold revealed additional significant differences among divisions even when VO2 max failed to do so during preseason soccer fitness testing. Running economy can differentiate between divisions with similar VO2max. Preseason training programs should give more emphasis on lactate threshold training especially of the lower division teams as compared to top division teams, since velocity at lactate threshold appears to reflect the preseason training status of professional soccer players.

WINNING IN MIXED MARTIAL ARTS- A COMPARATIVE WEIGHT CATEGORY BASED MATCH-ANALYSIS

Garcia, B., González-Haro, C.
National Institute of Physical Education of Catalonia (INEFC), Pharmacology and Physiology Department, School of Medicine (U2), Spain

Background. Mixed Martial Arts is a combat sport the proponents of which use techniques from various martial arts. The ‘Ultimate Fighting Championship’ or UFC®, which is one of the highest profile events on the sporting calendar, involves five competition weight categories (i.e. Lightweight (L): 66-70 kg, Welterweight (W): 70-77 kg, Middleweight (M): 77-84 kg, Light Heavyweight (LH): <84-93 kg, and Heavyweight (H): <93-120 kg). These categories have been monitored by the Nevada State Athletic Commission since 2001.

Purpose: To conduct a comparative investigation, by weight-category, of how fighters win competitions within the UFC®. Methods: A total of 52 consecutive competitions, conducted within the period 2001-2008, and involving a total of 437 combats, 308 fighters and an average of 87.2 ± 5.4 fights within each weight category, were included in the analysis. This involved an examination of the extent to which round, and which scores (i.e. decision, disqualified, knock-out KO, Submission or Technical KO) of a fight were most commonly associated with victory. The data were obtained from the official UFC® results as well as from ‘pay per view’ videos. Both a frequency analysis of qualitative variables and a Student’s t-test, for which the level of significance was set at P<0.05, were used to compare data.

Results. The median fight duration of weight category L exceeded that of H (367 ± 395 vs. 460 ± 381 sec, p<0.05). No significant difference in fight duration was shown in the remaining categories (i.e. W: 465 ± 313 sec, LW: 508 ± 353 sec, LH: 529 ± 381 sec). Category L and W fights most commonly finished within the 3rd round (47.5%, and 40.2%), in contrast to M, LH, and H fights, which usually finished in the 1st round (41.1%, 37.3%, and 51.6%). Within categories L, W, M, and LH, fights were most often won by 3rd round Judges’ Decision (L: 42.5%, W: 31.5%, M: 23.3%, and LH: 25.3%), and least often by first round Technical KO (L: 13.8%, W: 13.0%, M: 18.9%, and LH: 21.7%) and Submission (L: 12.5%, W: 15.2%, M: 16.7%, and LH: 10.8). However, combatents in category H most frequently won their fights via a 1st round Technical KO (19.8%) or Submission (14.3%), or Submission (16.5%).

Conclusion. In UFC®Light and medium weight fighters most commonly finish a fight within the 3rd round (47.5%, and 40.2%), in contrast to M, LH, and H fights, which usually finished in the 1st round. However, combatants in category H most frequently won their fights via a 1st round Technical KO or Submission, whilst heavier weight fighters most often do so via a 1st round Technical KO, Submission or KO.

CYCLOKEROGRANT TESTS IN THE ANAEROBIC CAPACITY DIAGNOSIS OF FOOTBALL PLAYERS

Gabrys, T., Stanula, A., Szmatlan-Gabrys, U., Szczerbowski, M.
University of Physical Education Warsaw, Academy of Physical Education Katowice, Poland

Introduction. The contemporary football is characterized by the interval effort and training. The key element of players preparation is anaerobic endurance (Bangsbo 1994, Reily 1986, VdVtappen & Borens 1989). The methods of anaerobic endurance training in football player should include appropriate and specific tests. The aim of this study was the comparison analysis between three tests performed on cycloergometer (10 seconds Test, Wingate Test and 3760 seconds Test). Measurements used in the study allow for estimation of anaerobic lactate and non-lactate power and capacity. First test is designed to measure the peak anaerobic power based on anaerobic non-lactate metabolism. The two latter tests measure anaerobic lactate power and capacity.

Material and methods. Subject group was composed of 28 football players aged between 17-18 years (they had 5 to 6 years of training experience). The laboratory measurements of anaerobic endurance were conducted in three consecutive days, in the following order: 10 seconds test an effort with maximal intensity during 10 seconds and with the 10% of body mass workload, 30 sec test - Wingate test protocol with the 9% of body mass workload, 60 sec test an effort with maximal intensity during 60 seconds and with the 7.5% of body mass workload.

We measured the concentration of the lactic acid in subjects blood in the fourth minute after the cessation of an effort with the use of photometric method Dr Lange LP 20 and LKM 140 l.

Results. Statistically significant differences (p>0.001) were found between peak power (Pmax) and mean power (Pav) registered in 10s test and 30s, the same differences occurred between 10s test and 60s test. These differences indicate that one need to differentiate tests
depending on what area of metabolic changes one wants to evaluate. However such differences occurred in case of LAmax and DLA values (p<0.01). The 30 seconds effort is too short for the activation of the anaerobic, lactate metabolism. Therefore it is not an appropriate measure of metabolic potential of football players in the discussed range of metabolic changes.

Statistically significant dependencies (p>0.001) were found between all test in aspect of peak power. Significant dependencies between the registered values of 30 and 60 seconds test, such as: Pmax (r=0.656, p<0.01), WTOT (r=0.526, p=0.05), Pd (r=0.742, p<0.001), TUZ (r=0.588, p<0.05) and WOT1/SWOT1 (r=0.526, p<0.05), indicate that these tests assess similar range of metabolic adaptation of examined football players.

Conclusion. An interesting observation of this study is the statistically significant difference (p<0.05) in time the subjects reached their peak power in the 10s test comparing it to the 30 and 60 seconds tests. In case of the first one the time was shorter. Conducted comparison analysis of registered parameters in 30 and 60 seconds tests did not show statistically significant differences of Pmax, TUZ and TUT values.

EVALUATION OF ANAEROBIC EFFICIENCY OF ICE-HOCKEY PLAYERS WITH THE USE OF OFF-ICE TEST AND ON-ICE TEST

Szmatlan-Gabrys, U., Stanula, A., Gabrys, T.
University of Physical Education Warsaw, Academy of Physical Education Katowice, Poland

The evaluation of ice-hockey performance is based on parameters registered during laboratory test, eg. Wingate (WAnT) [Watson & Sargant 1986] and on-ice test (Kostka et al. 1986, Volkov 1982). Off-ice tests allow for accurate registration of endurance parameters. On-ice tests are considered also very appropriate due to the specificity of the effort. During those test the analyzed parameter is the speed. The main aim of this study was the comparison of anaerobic endurance parameters of the off-ice and on-ice tests.

Material and methods. The experimental group was composed of 25 national team, ice-hockey players, aged between 19-20 years. Wingate test was performed on a cykloergometer the subjects were supposed to skate five times: the distance of 54m. The lever of lactic acid (LA) was estimated before and three minutes after the effort. The change in LA concentration was estimated (DLA), with the use of LKM reagent set 140 and photometer LP 20 Or Lange.

Results. Peak Power registered during the Wingate test in offence ice-hockey players was 11.21 W/kg-1 and in defense players 11.36 W/kg-1. Attack players work capacity reached the level of 275.64 J/kg-1 and defense players 274.13 J/kg-1. The change of the lactic acid level in attack players and defense players were accordingly 11.34 mmol/l-1 and 11.83 mmol/l-1. The time of the on-ice test performance for attack players was 42.74s and 43s for defense players. Even though the on-ice test duration was 13 seconds longer, there was no statistically significant differences in DLA between off-ice and on-ice tests. The statistically significant differences in Pmax between 30s and 60s cykloergometer tests were observed (p<0.001), such differences did not occur between offence and defense players. Statistically significant differences of DLA in both tests were observed (defense players p<0.05, offensive players p<0.001). There was significant dependency between LAmax in both player groups (r=0.328 r=0.370) and DLA (r=0.436 and r=0.537), and DHF (r=0.373 r=0.113). Significant dependencies were found between offence and defense players in the parameter of 30-s and 60-s tests: Pmax and Tw (r=0.894 and r=0.444), WTOT and Tw (r=0.894 and 0.444).

Conclusions. We showed statistically significant relations between endurance parameters registered with the use of cykloergometer which is the peak power (Pmax) and total work (WTOT) and parameters of on-ice skating on a specific distance 5x54m (1) W. However we did not noticed any relations between the range of body reactions as a result of an effort in both tests. This can indicate that even though both tests are supposed to measure the anaerobic endurance in consequence these tests could measure different areas of anaerobic metabolism. Wingate test assess power and volume of the anaerobic glycolysis and on-ice test estimates its effectiveness.

MAXIMAL POWER, MAXIMAL WORK AND HEART RATE OF THE SWIMMERS AGED BETWEEN 14-15 YEARS DURING THE ENDURANCE TEST PERFORMED WITH ARMS AND LEGS

Arkidusz, S., Gabrys, T.
(1) Academy of Physical Education, Katowice. (2) Almamer, University of Economics, Warsaw, Poland

Introduction
The energy needed for the execution of the movement in swimming is based on the anaerobic and aerobic metabolism. Every type of metabolism is assessed with the use of different methods. Measurements of the functional state of the organism and maximal power measurements on the cykloergometers are very common (1).

The main aim of this study was an assessment of the differences between groups of female swimmers aged between 14-15 years. In this age one can observe accelerated development of anaerobic abilities in the aspect of the amount and characteristics of performance with maximal power performed in 30 seconds.

Material and methods
The examination was conducted on 16 female swimmers between 14 and 16 years old. They participated in regular swimming training and had approximately 5 to 7 years of training experience. The subjects have undergone an endurance test which was the modified Wingate test lasting 30 seconds. They performed it with their arms and legs in separate trials. The cykloergometer Monark 881 and Monark 824 was used in the study (2). The workload was assigned to every subject individually as the 5% of the body mass for arms and 7.5% for legs. The heart rate was registered with the use of Sport-Tester Polar Vantage.

Results
The statistically significant higher indices of peak power 3.27 W/kg, mean power 2.74 W/kg and overall work 82.21 J/kg as well as longer times of peak power maintenance reaching 0.26s (all p<0.001) were observed in case of legs performance when compared to arms. The high increase of heart rate (8.84-9.58%) in both tests during the first 3s of trials was observed. Between 3rd and 15th second we observed continuous increase of the heart rate with the decreasing gain tendency. It is characterized by the percentage values from 5.38% to 4.15%.

During the first 12 seconds the differences between arms and legs performance in the aspect of heart rate were statistically insignificant. The statistically significant dependencies were found in 15th second (r=0.454, p<0.05) of the trials, this is the point of decrease of peak power. Further time points which showed statistically dependencies in the aspect of heart rate were the following: 21st second (r=0.466, p<0.05), 24th second (r=0.434, p<0.05), 27th second (r=0.496, p<0.05) and 30th second (r=0.464, p<0.05).

Conclusions
High statistical dependency (p<0.01) between consecutive values of heart rate indicates that the test effort induced an expected cardiovascular reactions in the examined subjects. The reactions were independent of the muscle group. Therefore, cardiac adaptation to
increased effort performed only with arms or legs is similar in the groups of female swimmers that present approximately the same sports expertise.

METABOLIC AND VENTILATORY ANAEROBIC THRESHOLD DURING RESISTANCE EXERCISES
Fontana, K., Rocco, G., Junior, S., Molina, G.
University of Brasília, Brazil

Physiological effects from non resistance dynamics exercise such as running and cycling are well known. However, the resistance exercises still need more scientific studies to clarify its metabolic responses. The resistance exercises commonly use weight workloads and establish the base of strength, hypertrophy and power training, besides its importance in training program of almost all sports. The accurate identification of the ventilatory (V-AT) and metabolic (LAC-AT) anaerobic threshold (AT) is important to support exercise prescription due the change in the source of energy expenditure from oxidative to glycolitic pathways. The aim of this study was to analyze the ventilatory and metabolic AT of resistance exercises during the arm curl (BIC) and leg press (LEG) exercises. Thirty five healthy active male subjects had the fat mass determined by skinfold protocol and aerobic power (VO2peak) measured on a maximal treadmill graded exercise test. The maximal workload for one repetition (1RM) was identified for each exercise and applied on a discontinued and incremental workload resistance exercise protocol. The protocol consisted of several 20 repetitions/minute stages, starting at 10% of 1RM with increases of additional 10% in each stage. A two minutes rest interval was used between the stages when 25μL venous blood sample was collected from ear lobe. LAC-AT was determined by the point of abrupt increase in lactate levels and the non-linear rise in blood lactate concentration. Oxygen uptake (VO2), CO2 output (VCO2), and minute ventilation (VE) were measured with a portable telemetric system (K4B2). The V-AT was obtained from the non-linear rise in VE and ventilatory equivalents of O2 and CO2. High values of correlation were found between LAC-AT and V-AT for BIC and LEG exercises based on absolute (kg) (0.870-0.701), relative (%1RM) workload (0.750-0.534), and relative VO2 (0.964-0.796). LAC-AT was reached at 26.1 ± 5.6% of 1RM (10.5 ± 3.2 kg) for BIC exercise and 27.6 ± 7.1% of 1RM (84.0 ± 27.1 kg) for LEG exercise. Higher values of LAC (2.0 ± 0.8 mmol/L) were found on LEG exercise when compared to BIC exercise. Fatigue workload (FW), the load of concentric failure, also showed higher values for LEG (51.1 ± 12.9% of 1RM) when compared to BIC exercise (15.1 ± 5.5 mmol/L e 44.1 ± 10.1% of 1RM). This difference can be explained due a higher muscle mass used to perform multi-joint exercise in which others muscle groups certainly will be activated for exercise effort maintenance. There seems to be high correlations between LAC and V-AT for LEG when compared to BIC exercise. Therefore, it is possible to determine V-AT and LAC-AT during resistance exercise, which was reached at approximately 30% of 1RM in this study. It also appears that LAC and FW are muscle mass dependent. However, different incremental resistance exercise protocol should be tested to better understand the AT during resistance exercise.

THE DEFENSIVE ORGANIZATION IN FOOTBALL - A COLLECTION OF KNOWLEDGE OF PROFESSIONAL FOOTBALL COACHES
Gonçalves, D., Costa, J., Santos, A., Sequeira, P.
Sport Sciences School of Rio Maior, Portugal

This survey aims to create a series of representative enough premises that might be part of the training and competition system of a Football team Defensive Organization. The sample used on this research includes four professional coaches of the First and Second Portuguese football leagues, designated as A, B, C and D. They all have the professional UEFA license (4th Level). B and C coaches have a University degree in Physical Education and Sport Sciences. A and D coaches have acquired a relevant experience as professional and international players. All of them have a significant and large experience as coaches, but coach C has shown evidence of a larger experience in National Team. The data was collected through a questionnaire and the answers were analysed using a qualitative methodology concerning the practical knowledge.

Among other conclusions it was found that it is as difficult to coach the Defensive Organization as it is to coach the Offensiva Organization. The difference is based upon the willingness the players might have for their training. Concerning issues, such as where do I want to put pressure on, how do I want to put pressure on, and when do I want to put pressure on? along with the correct execution of the rules of the game may constitute themselves as an excellent reference of the evaluation for the Defensive Organization. The individual training of the tactic and technical actions of the first defense player may constitute an essential variable for the success of the Defensive Organization.

ENDURANCE TRAINING HISTORY INFLUENCES INDIVIDUAL RESPONSIVENESS TO RESISTANCE TRAINING
Sampson, J., Groeller, H., McAndrew, D., Britton, A., Taylor, N.
University of Wollongong, Australia

Individual responsiveness to a resistance training program is influenced significantly by physical status and prior resistance training experience. The purpose of this investigation was to assess neuromuscular adaptation in untrained males (N=28) following 16 wks of progressive biceps brachii resistance training. Subjects completed a 4-wk progressive resistance exercise control period, and were evenly distributed among three experimental groups on the basis of one repetition maximum (1RM) strength gains: (EC) attempted explosive concentric and controlled 2-s eccentric; (SSC) attempted explosive concentric and controlled 2-s eccentric; and (C) controlled 2-s eccentric and concentric training. No significant differences in 1RM strength gain existed among groups: (SSC) 16.4 (±3.2%); (EC) 19.0 (±2.6%); (C) 15.6 (±3.5%). During experimental training, each group exercised 3 days per wk for 12 wk at 85% 1RM. ICI performed four sets of elbow flexion to repetition failure. IE2 (C) performed four sets of four repetitions. 1RM and MVC elbow flexion strength were assessed. Filtered electromyographic (EMG) data were sampled at 2 kHz (Digitimer, Neurolog). Peak and average root mean square (RMS) and mean frequency (MF, Spike 2 Ver5.13) were calculated over scrolling 250 ms windows with a 50% overlap. Data are means ±SE, with alpha set at 0.05. After the 4-wk control period, 1RM and mean biceps RMS significantly increased in high (24.7 ± 1.4%, 28.7 ± 0.8%) and low (9.2 ±1.5%, 5.4 ±6.3%) responders, respectively. Low responders were significantly more active generally (31.8%), of work (33.3%), engaged in endurance exercise more frequently (66.6%) and vigorous exercise more often (60%), despite no significant difference in resistance train-
ing history among the groups. No significant difference was observed in IRM strength between high [29.6 ±6.5%] and low [31.4 ±10.1%] responders after 12 wks of training. Low responders displayed significantly greater peak biceps RMS (28.9 ±34.7%) and mean biceps RMS (37.8 ±50.6%) compared to high responders [4.7 ±24.2] and [6.5 ±23.8%], respectively. High responders displayed significantly greater total IRM strength adaptation over 16 wks [62.1 ±9.4% versus 43.6 ±9.9%]. No significant group differences in peak or mean RMS were observed. These observations show that, since the rate of neuromuscular facilitation is affected by current and past exercise, pre-experimental (control) training is required to identify high and low responders prior to subject allocation within experimental groups.

THE EFFECTS OF TRAINING ON SPORTS PERFORMANCE IN ADOLESCENT VOLLEYBALL AND FOOTBALL PLAYERS

Atalay Güzel, N., Çalışak, F., Karacan, S., Öz, E., Akżyüz, M. Aslanolu, E.
Gazi University, Turkey

Introduction

The performance tests are very important to follow the development some physical and physiological changes in adolescents who are interested in sports at this period and to evaluate sports performance for talent selection [1]. The purpose of this study was to determine performance differences in volleyball and football with comparing sports performance including some physical, physiological and anthropometric parameters in volleyball and football players between aged 13 and 16 girls.

Method

Mean age of all 33 subjects were volleyball players n=11,15.18±0.98yrs, football players n=11,14.91±1.04yrs and controls n=11,14.55±0.93yrs voluntarily participated in this study. Height, weight, body fat percent, fat weight, lean body weight, body mass index (BMI), somatotype, vertical jump, anaerobic power, sit ups test, press ups test, hand grip strength, flexibility, standing long jump, 30 m sprint, hexagonal obstacle test and zig zag test of volunteers were measured for all subjects at Sports Physiology Laboratory on behalf of School of Physical Education and Sports, Gazi University. Data's were analyzed with Kruskal-Wallis test.

Results

This study showed that height and body weight of volleyball players were significantly higher than the football players (p<0.05). Meso-morphy values of footballers were significantly higher than in volleyball players and controls. There were significant differences in sit ups, 30 m sprint, hexagonal obstacle test and zig zag test between football players and volleyball players (p<0.05). Except for flexibility and vertical jump performances, all the parameters of athletes were significantly higher than the controls (p<0.05).

Discussion / Conclusions

Melrose et al found that volleyball players (VPl) had lower body fat percentage (football players (FP 5.92±2, VP 4.6±1.6), higher flexibility values (SP 19.00±4.77, VP 32.7±5.96cm) and FP had higher hand grip power values than SP (35±7.6, VP 19.6±5.13kg). The results of this study are similar with our study. It can be concluded that higher performance parameters in volleyball and football adolescent players between aged 13 and 16 years reveal the positive effects of regular exercises done in this period. It might be mentioned that football match takes more time than volleyball, playing in greater field and continuously and speedily making attack. Also, defense players in football would be provided more improvements of speed, agility and some anthropometric parameters.

CARDIORESPIRATORY AND METABOLIC RESPONSE TO INTERVAL TRAINING OF VARIOUS DURATIONS USING MAXIMAL WORKLOAD FROM SPIRO-ERGOMETRIC EXERCISE

Tschakert, G., Groeschl, W., Schwabeger, G., Hofmann, P.
Karl-Franzens-University Graz and Medical University Graz, Austria

Interval Training seems to get more important in the future as high intensity training was shown to be superior to constant load exercise in athletes and patients [Hawley, J. A. J Physiol 2008, 586 1-2]. However, there are no standard guidelines about how to set the optimal mode of intervals. Astrand, I. (Acta Physiol Scand Suppl. 1960; 49(169):1-92) presented that using the same workload intervals with 1:2 work to rest ratio (WRR) gave a completely different metabolic response dependent on the length of the work phases. Aim of the study was to investigate the cardio-respiratory and metabolic response to different intervals applying a WRR of 1:2 and using maximal power output from an incremental exercise test (IET).

Six young healthy male sports students (age: 26.2±4.4yrs; height: 180.3±4.2cm; weight: 74±6.0kg, VO2max: 53.2±7.0mlkg-1min-1) participated in the study. A maximal IET (40W, 20Wmin-1, 1min) was performed on an electronically braked cycle ergometer (Monark 839E, Monark, Sweden). Maximal power output was used as target workload for subsequent interval tests on the same cycle ergometer. Intervals applied were 10/20s (A), 20/40s (B) and 30/60s (C) for 30min each. Sessions were randomly assigned and interspersed by at least two days to guarantee sufficient recovery in between.

Results: Relative oxygen uptake (%VO2maxIET) was not significantly different both between treatments (A: 58.3±6.2%; B: 55.4±5.8%; C: 59.4±8.1%) and between treatments and IET at PmeanInterval (55.2±6.1%). Depended on workload duration relative heart rate (%HRmaxIET) differed significantly between interval types [A: 76.2±5.5%, B: 79.6±2.2%, C: 83.7±2.0%] as well as blood lactate concentration [A: 2.65±0.88mmol-l-1, B: 4.06±1.14mmol-l-1, C: 5.11±0.66mmol-l-1]. However, all subjects presented steady state lactate values throughout all interval sessions.

Conclusions: Maximal work load from IET may be used to apply hard interval training sessions maintaining lactate steady state as long as a WRR of 1:2 and a maximal interval of 30s is used. Even in 30/60 intervals, lactate presented a steady state indicating safe and steady state lactate values throughout all interval sessions. From a theoretical point of view hard aerobic interval training must be set at a mean workload below LTP2 (maximal lactate steady state), a recovery workload below LTP1 (maximal rate of muscular lactate elimination) and a WRR adapted to the maximal workload applied in the intervals. This theoretical concept will be evaluated in further investigations.
TOP VOLLEYBALL PLAYERS’ JUMPING ABILITIES

Dolenec, A., Sattler, T., Coh, M.
University of Sport, Slovenia

Volleyball is a fast game with a ball. A player usually does 60 jumps per game. So to satisfy the needs of a modern playing style the players must be good in starting acceleration from zero velocity and have good jumping abilities. Jumping abilities can be measured in concentric conditions as a squat jump (SJ), slow eccentric-concentric conditions as a countermovement jump (CMJ), and in fast eccentric-concentric conditions as a drop jump (DJ). Players one of the best teams in past (USSR) had an average values for SJ 55 cm, for CMJ 61 cm, and 54 cm for DJ from 40 cm bench (Bosco, 1999). The aim of this paper was to find jumping abilities of top volleyball players. Eight players (height 195.5 ± 6 cm, mass 91.5 ± 5 kg, and age 24.5 ± 4 y) participated in this study. We measured SJ, CMJ, and DJ from 25 cm bench. In SJ we analyzed height of jump (SJH), take-off time (SJTO), starting power (mean acceleration in first 100 ms) (SJPP), and ratio between the velocities obtained during the second and the first half of take-off (SJIR). In CMJ we analyzed height of jump (CMJH), mean deceleration during braking phase (CMJD), mean acceleration during acceleration phase (CMJA). In DJ we analyzed height of jump (DJH). We calculate ratio between height of jumps in CMJ and SJ (CMJSJ). We calculate mean values and standard deviation for each parameter. We exclude the libero player since his tasks are different from other players. Mean values obtained in SJ were 43 cm (+-4 cm) for SJH, 341 ms (+- 34 ms) for SJTO, 1.6 m/s3 (+-0.9) m/s3 for SJP, 150 (+-50) for SJR. The mean values for CMJH were 47 cm (+-2 cm), while the mean values for DJH were 34 cm (+-5 cm). Mean values obtained in SJ were 43 cm (+-4 cm) for SJH, 341 ms (+- 34 ms) for SJTO, 1.6 m/s3 (+-0.9) m/s3 for SJP, 150 (+-50) for SJR. The mean values for CMJH were 47 cm (+-2 cm), while the mean values for DJH were 34 cm (+-5 cm).

Mean values obtained in SJ were 43 cm (+-4 cm) for SJH, 341 ms (+- 34 ms) for SJTO, 1.6 m/s3 (+-0.9) m/s3 for SJP, 150 (+-50) for SJR. The mean values for CMJH were 47 cm (+-2 cm), while the mean values for DJH were 34 cm (+-5 cm). We can see that jumping heights in each condition are much lower in ACH Volley players than USSR players (Bosco, 1999). Players from ACH Volley have poor starting acceleration from zero velocity which means they probably struggle to catch the ball when the ball is 1 or 2 m in front of the player. Poor starting acceleration cause long take-off time. So the player with poor starting acceleration need longer time to jump and block the attack. In playing situation this means that a player has less time to make a decision which action and in which position he has to do. Since the value of SJR is high we can speculate that front leg kinetic chain is dominant in SJ execution. The ratio CMJSJ shows that jump heights in CMJ are within the range that can be expected according to SJH so players works in slow eccentric-concentric conditions within the range that can be expected according to concentric conditions. From the height of jumps in DJ we can conclude that players have weak ankles. This is dangers for knee and hip since many landings with heel contact can cause knee and hip injuries. No matter the players involved in this research are top Slovenian players they were not in good jumping conditions.

THE IMPORTANCE OF SOME DIMENSIONS OF ANTHROPOMETRIC STATUS IN POLICE OFFICERS

Zorec, B.
Faculty of Criminal Justice and Security, Ljubljana, Slovenia

Our research is focused on some anthropometric measures in police officers that represent the characteristics of their body structure and composition, taking into account that appropriate morphological status and at the same time good physical fitness are not only an individual’s concern. Pealo (1993) finds that in police officers, the efficiency in terms of work and movement is to a large extent determined by morphological characteristics. Police officers with inappropriate morphological structure (obesity, muscle atrophy etc.) as a consequence of bad living habits are easier to attack and injure. After their arrest, robbers told, for example, that they decided to attack police officers on the basis of their overall image that conveyed vulnerability. Some anthropometric measures and relations between them were studied on a sample of police officers (162) aged between 25 and 48 years. In order to obtain relevant morphological information on the body, variables defining longitudinal (1) and transversal parameters (6), circumferences (6), skin folds (8) and body mass were used. The values obtained were compared with the respective values for workers engaged in machine maintenance covered by another study. The data were statistically processed with the SPSS programme of the Institute of Kinesiology at the Faculty of Sport in Ljubljana. For all variables, basic statistical parameters: the arithmetic mean, maximum and minimum results, standard deviation were calculated. Body density and subsequently the percentage of fat tissue were evaluated by regression equations according to Loeman, Sloan and Weir, Durnin and Womersley. It was found that workers have thinner skin folds on active segments (triceps and biceps), as a result of the nature of their work involving numerous operations performed by upper extremities, above all upper arms. Due to often very rapid operations there occur submaximal muscle stresses, resulting in the reduction in the biceps and triceps fat tissue, which reflects in a thinner subcutaneous fat layer. We conclude that larger circumferences and thinner skin folds in workers in production compared with police officers are a result of hypertrophy of the muscle tissue in the active segments of their upper extremities. The most obvious difference between the two samples is the difference in the mean values of the belly skin fold. A thinner skin fold in police officers is attributed to self-defence techniques training and other special training (final grips, floor fighting, tying and handcuffing, etc.) where repetitive power of the trunk dominates.

THE LACTATE MINIMUM TEST PREDICTS MAXIMAL LACTATE STEADY STATE, BUT IS DEPENDENT UPON THE METHOD OF LACTATE ELEVATION

Johnson, M., Sharpe, G., Brown, P.
Nottingham Trent University, United Kingdom

Surprisingly, the agreement between lactate minimum (LM) and maximal lactate steady state (MLSS) cycling powers has yet to be examined and was the first aim of this study (series 1). LM cycling power is insensitive to the blood lactate concentration ([LaB]) elevation protocol when the same exercise mode is used throughout the test (Smith et al 2002). However physiological responses to exercise differ depending on whether prior exercise is performed using like or unlike muscle groups (Fukuba et al 2002), thus the second aim of this study was to examine the effects of [LaB] elevation mode on [LaB] responses to the LM test (series 2). In series 1, 32 male subjects performed a LM test comprising a [LaB] elevation phase, 8 min recovery phase at 60W, and incremental phase at 45, 50, 55, 60, and 65% of the maximum power achieved during the [LaB] elevation phase. During the [LaB] elevation phase power was increased every 15 s by a constant increment chosen to elicit exhaustion in approximately 10 min. LM power was determined from the zero gradient tangent to a cubic spline function fitting the [LaB] (measured at the end of each stage) vs. power data. MLSS was determined using 30 min constant
power trials with [La]B determined every 2 min from 16-30 min. MLSS power was defined as the highest power at which a positive gradient of a linear regression fitted through the plot of [La]B against time was not observed. In series 2, 10 male subjects performed two identical lactate minimum tests (see series 1) (test 1 = LMLEG, test 2 = LMARM), except that during the second test the [La]B elevation phase comprised arm-cranking exercise with power increasing every 15 s by 4 or 5W until exhaustion. The powers performed during the incremental phase were identical in LMLEG and LMARM. In series 1, LM power (mean ± SD); (205 ± 22) W was not different from MLSS power (208 ± 21) W, with which it was correlated (r = 0.89, P < 0.01). The 95% limits of agreement were 24W and -20W. In series 2, all subjects demonstrated a U-shaped [La]B vs. power profile during LMLEG and LM power was 168 ± 21 W. Conversely, a clear U-shaped [La]B vs. power profile was not observed during LMARM. LM power during LMARM (157 ± 29) W was lower than that in LMLEG (P < 0.05). Although [La]B at the end of each stage of the incremental phase was not different between LMLEG and LMARM, the trial x stage interaction effect was significant (P<0.05). In conclusion, the LM test protocol utilised in this study provides a valid estimate of MLSS cycling power. Furthermore, our data suggest that the LM power is dependent on whether the [La]B elevation phase utilises like or unlike muscle groups. This latter observation may be explained by the dissimilar effects of prior exercise performed with like or unlike muscle groups on physiological responses to subsequent exercise.

RELATION BETWEEN BASICS AND SPECIFICS FACTORS OF SELECTED MORPHOLOGICAL, MOTOR AND BIOMECHANICAL VARIABLES IN SKIJUMPERS

Jost, B., Coh, M., Pustovrh, J.
University of Ljubljana, Faculty of Sport, Slovenia

The purpose of the research study was to establish in a sample of elite Slovene ski jumpers (N=67) a relation between basic’s and specific’s factors of referentiality of manifest area of the selected biomechanical (n=8), morphological (n=14) and motor variables (n=13). The research was conducted on 15 October 2004 on a sample of 67 Slovene ski jumpers. In ski jumping it is hypothetically assumed that the higher the value of specific factors is, the higher will be the potential performance. The factor analysis was made on the basis of the Principal Component Analysis. Six factors were ruled out. In the first dominant factor, accounting for 55% of total variance is the GENERAL MORPHOLOGICAL-MOTOR FACTOR OF SKI JUMPERS. The variables of the push-off explosive power formed a homogeneous structure of the second specifics factor of EXPLOSIVE PUSH-OFF POWER. On the third factor of ASYMMETRIC AERODYNAMIC CAPABILITY, the projection of morphological aerodynamic index (0.98) was prevalent. In the fourth factor of ASYMMETRIC PUSH-OFF POWER, accounting for 5.3% of total variance, the variables of asymmetric push-off power prevailed. In the fifth factor MORPHOLOGICAL INDEX OF TAKE-OFF ROTATION the following projections of morphological variables were predominant: morphological take-off index (0.93) and the related variables of the longitudinal dimension of legs. The projection of the variable AGE (0.95) was strongly prevalent in the last the sixth factor.

The results of the factor analysis made on a sample of 67 Slovene ski jumpers, aged 15 years and more, showed that the manifest structure of 35 variables was reduced to two basic and four specific factors. The results are interesting primarily because they reflect the specificity in expressing of skijumping factors, as it is conditioned by ski jumps i.e. their specific movement technique. The success rate in ski jumps is only in one part affected by the general morphological-motor factor and factor of age. All others specific morphological factors of ski jumpers have a strong impact on the success of ski jumping technique.

SONIFICATION OF THE BOAT MOTION TO IMPROVE THE BOAT RUN DURING TECHNIQUE TRAINING AND RACING IN ROWING

Schaffert, N., Mattes, K.
Faculty of Human Movement, Germany

Introduction
Sonification of the production of movement defined sound sequences has become increasingly interesting for the technique control and optimisation in elite sport. Empirical motor learning studies of the movement sonification were already able to show effects of the complex movement acoustics information for learning new techniques (e.g. ergometer rowing) (Effenberg et al. 2007). The ability to perceive small deviations from the ideal motion are easier to detect with the auditory than purely visual sensors. Also, free perception capacity in the auditory sensors open more possibilities for receiving information. The following study utilises the rowing technique to investigate disconected hearing possibilities by filtering out deliberate and unaware perception differences of acoustic information and their influence on the boat motion in a single stroke and on the stroke by stroke basis.

Also, kinematic and dynamic movement parameters will be sonified to a polyphonic sound sequence to indicate differences to the athlete in regards to the calculated ideal motion.

Methods
Preliminary on-water rowing tests are planned in March 2008 (four male junior athletes (U-23) from the German national team), where the sound (sound pressure level and frequency composition) will be recorded close to the ear of the athletes with a precision-sound level meter (Narco 118). The boat motion (boat velocity and boat acceleration) will be collected with GPS (AstReX 1), velocity transducer, resolution 2cm/s and accelerometer (KB MMF 12F) at different stroke rates. Additionally, video will be taken. In the second set of testing the hearing perception of the athletes will be prevented by sound damping ear plugs and special hearing protections to determine the changes in the boat motion. The kinematics of the boat motion will be determined later in order to add sound overlays.

Expected results
The temporal trace of the sound pressure level and the frequency composition will be audibly disseminated and split into its various components of content to filter out areas/shares of the deliberate and unaware perception. Boat velocity and acceleration traces can detect faulty appearances of the boat motion to then calculate an idealised boat run. The ideal boat run produces a set music, which will be applied in training as acoustic reference. Synchronised with this there is the actual value of the boat movement as another set music fed back to the athlete.

Discussion

The complex movement-acoustics information is a new approach to add to the technique analysis and optimisation for rowing and to describe the ideal boat run. The additional information opens up new opportunities for technique training and racing tactics.

RELATIONSHIP BETWEEN LACTATE TURN POINT AND MAXIMAL PERFORMANCE IN YOUNG HEALTHY MALE AND FEMALE SUBJECTS OF DIFFERENT EXERCISE PERFORMANCE LEVEL

KF-University Graz, Medical University Graz, University of Vienna, Austria

Usually, the percentage of power output (P) or oxygen uptake (VO2) at the anaerobic threshold (AnT) was described to increase with exercise performance. This relationship is dependent on the method of AnT determination. Aim of the study was therefore to investigate the relationship between the second lactate turn point and maximal exercise performance in an age homogeneous group of healthy male and female subjects.

45 male (M) (age: 27.2 +/- 3.5 yrs, height: 180.2 +/- 6.8 cm, weight: 74.1 +/- 8.5 kg) and 30 female (F) (age: 26.6 +/- 2.4 yrs, height: 166.7 +/- 6.8 cm, weight: 61.4 +/- 7.0 kg) subjects were randomly recruited from routine diagnostics. All subjects performed maximal incremental cycle Ergometer exercise (40 (M) / 20 (F) W; 20 W.min^-1 (M) / 15 W.min^-1 (F)) until subjective maximal effort. Heart rate (Sporttester PE4000, Polar Electro, Finland), gas exchange variables (MetaMax I, Cortex Biophysik, Germany) were obtained at rest, throughout exercise and during recovery. Blood lactate concentration (Biosen S-line, EKF Diagnostik, Germany) was obtained from blood samples collected from ear lobe at rest, after each work load increase and during recovery. The first (LTP1) and the second (LTP2) lactate turn point were determined within defined regions. All calculations were performed using a computer supported analysis by means of a linear regression turn point model (Hofmann et al. Med Sci Sports Exerc 1997; 29: 762-768). Subjects were recruited according to maximal power output and divided in groups of low (Lo), medium (Med) and high (Hi) maximal exercise performance level (M-Lo: 256 +/- 24 W, M-Med: 341 +/- 114 W, M-Hi: 423 +/- 18 W, F-Lo: 167 +/- 10 W, F-Med: 209 +/- 8 W, F-Hi: 260 +/- 20 W) and maximal oxygen uptake (M-Lo: 3.4 +/- 0.4 l.min^-1, M-Med: 3.4 +/- 0.2 l.min^-1, M-Hi: 4.3 +/- 0.1 l.min^-1, M-Hi: 5.2 +/- 0.4 l.min^-1, F-Lo: 2.2 +/- 0.2 l.min^-1, F-Med: 2.7 +/- 0.1 l.min^-1, F-Hi: 3.2 +/- 0.2 l.min^-1).

Mean percentage of Pmax at LTP2 was found at comparable levels in male and female subjects (M-Lo: 67.8 +/- 3.8 %, M-Med: 71.1 +/- 2.8 %, M-Hi: 74.2 +/- 3.3 %, F-Lo: 72.4 +/- 4.3 %, F-Med: 71.2 +/- 2.1 %, F-Hi: 72.9 +/- 2.6 %). No sign. differences were found in F but in M where %Pmax at LTP2 increased with Pmax. The percentage of VO2max at the LTP2 was also found similarly (M-Lo: 71.2 +/- 4.0 %, M-Med: 73.6 +/- 5.5 %, M-Hi: 78.5 +/- 4.8 %, F-Lo: 75.9 +/- 4.0 %, F-Med: 74.4 +/- 4.0 %, F-Hi: 75.6 +/- 8.2 %). No sign. differences were found in F but in M where %VO2max at LTP2 increased with Pmax.

Mean percentages of power output and oxygen uptake at the LTP2 were found in a very narrow range around LTP2, a theoretically supported individual threshold concept, in an age homogenous group of male and female sports students. There were only slight gender differences and the mean whole group values for %Pmax and %VO2max were not significantly different between genders. Overall values were found at 71.5 +/- 3.8 % Pmax and 74.8 +/- 5.6 %VO2max which offer some possibilities for easy to apply performance diagnostics.

COMPARISON OF THE PHYSICAL AND PHYSIOLOGICAL PARAMETERS OF ELITE TURKISH SWIMMERS AND FINSWIMMERS

Odabas, I., Alemdar, O., Pelvan, O.
Marmara University, Turkey

In this research, we studied athletes who have reached elite performing stage in swimming and finswimming. The aim of the study was to compare the differences and similarities on physical and physiological parameters of these two different branches.

8 elite male swimmers and 8 elite male finswimmers took part in this study. Bone width and length, skinfold thickness, circumference measurements and some proportions were measured for physical characteristics while aerobic performance, anaerobic performance, vital capacity, force vital capacity and flexibility were tested for physiological and motor characteristics. Bruce protocol was applied using ergospirometer sensor medix 29 C in MaxVO2 measurement. Wingate test (Monark ergometric bicycle) was used for anaerobic power test and data spirometer was used for vital capacity. The results were evaluated in SPSS programme. Mann Whitney-U test was applied in order to determine the differences between groups.

As a result, it has been determined that there were significant differences in the parameters of weight, quadriceps circumference, biceps circumference, fat mass, lean body mass, vital capacity (VC), % vital capacity (%VC) at p< 0,05 level while there were significant differences in the parameter of shoulder circumference at p< 0,01 level. It has not been found any significant differences between the aerobic and anaerobic power and flexibility values of the athletes (p>0,05).

RELATIONSHIP BETWEEN ANTHROPOMETRIC, CORPORAL COMPOSITION AND PERFORMANCE IN YOUNG SWIMMERS, BOYS AND GIRLS

Madeira, R., Conceição, A.
University Lusófona of Humanities and Technologies, Portugal

The purpose of this study was to compare the differences in anthropometric and corporal composition (body mass (BM), height (H), body surface area (BSA), body fat percentage (%BF) and fat free mass (FFM)) between boys and girls, both young swimmers, and to analyse the relationship between those and the best times performed in 100/200 meters free style and 100/200 meters best stroke.
Anthropometric measurements, body composition estimation, the lap of 100/200 meters free style and best stroke (25 meters swimming pool) seven girl swimmers (GS) (12.57 ± 0.54 years of age) and nine boy swimmers (BS) (12.99 ± 0.33 years of age). All the studies were performed by the same investigator.

Mean values for GS were compared with those for BS using t-tests for unpaired data. Pearson product moment correlation coefficient was calculated to evaluate the relationships between anthropometric and body composition data and the performance on freestyle and best style. Results of all statistical tests were considered significant if p< 0.05. GS and BS were of similar age but different in their anthropometric and body composition characteristics. The BS group was significantly taller, had greater FFMs, owing to significantly reduced %BF (p<0.01) and showed greater BM, BSA and BMI, when compared to GS. BS had better performance on 100 and 200 meters free style (p<0.05). BM, H, FFMs and BSA correlated negatively and significantly (p<0.01) with the performance on 100/200 meters. Swimmers of this age, who are heavier, taller, with greater body surface area and FFMs had better performance, better time during 100/200 meters freestyle and best stroke.

COMPARISON OF THE INDIVIDUAL ROWING PERFORMANCE IN JUNIOR AND SENIOR WOMEN IN THE EIGHT
Schaar, H., Draper, C., Mattes, K.
University of Hamburg, Germany

Introduction:
To secure a long-term improvement of performance in young rowers, detailed specifications and standards for training fitness and rowing technique at each development level are of great importance. While such specifications already exist for strength and endurance training, from the rowing ergometer (Steinacker et al. 1998), such data are missing for individual rowing performances and technique in the boat. An analysis and assessment of these factors over 2000m in an eight are crucial: (1) for the selection of junior teams for the junior world championships, (2) to set and evaluate training goals for the crew and each athlete in preparation for the competition period, (3) to suggest prospects for development that exceed training recommendations. The study’s purpose was to compare individual rowing performances in the eight of elite senior and junior rowers by utilising cross and longitudinal section analysis.

Methods: From 2005-07 the national German Women’s Eights at the senior ((Ws), n=24) and junior level (Wj), n=24) were tested three times over 2000m at comparable times of the year (Ws): during international rowing regattas in Germany, (Wj): before the pre-competition phase in Berlin (July). The boats were equipped with a mobile measuring system (FES, Berlin). Handle force, footstretcher force and oar angle were recorded for each individual. The individual’s rowing performance, comprising handle pulling force, handle velocity, stroke length, and other selected technical characteristics were assessed and statistically analysed for mean differences (t-test) for all strokes over 2000m.

Results:
Body height (181±0.5m (Ws) vs. 178±0.5m (Wj)) and body mass (73±4.3kg (Ws) vs. 72±5.4kg (Wj)) between the two age groups were comparable. Significant differences were found in stroke rate (35.4±0.7str/min (Ws) vs. 33.4±0.5str/min (Wj)), handle power (238±21.5W (Ws) vs. 206±18.6W (Wj)), handle work (403±36J (Ws) vs. 371±34J (Wj)) and handle force (302±21N (Ws) vs. 270±21N (Wj)) during the drive phase and in footstretcher forces and handle velocity in the recovery. (Ws) obtained higher values and a better rowing technique during the catch and in connecting motions of the leg-hip extension, upper body exertion and arm pull. The outcomes of the cross section analysis were confirmed in the longitudinal section.

Summary and Conclusion:
The results of the anthropometrical and biomechanical parameters showed general and individual trends from the junior up to the senior level. Collated data provided recommended standards for the rowing performance and technique - guiding each athlete in their on-water training, regarding their fitness and rowing technique towards their season’s peak. Optimising an individual’s improvement could lead to maximising the performance of the crew boat.

ELECTROMYOGRAPHIC PROFILES OF EXERCISES IN STRENGTH TRAINING AND STRENGTH DIAGNOSIS WITH ELITE RACE ROWERS
Schaar, H., Mattes, K.
University of Hamburg, Germany

Introduction:
Strength enhancing training measures in race rowing like training at rowing machine ergometers or barbell training have long since effectively served to develop specific strength proficiency [1, 2, 3, and 4]. Along with these training measures special performance tests have established themselves. To meet the increased demands for ever more effective training and testing methods the definition of an electromyographical profile of training- and training diagnosis exercises recommends itself to more precisely disclose a correlation pattern between training, diagnosis and the motor requirements profile of the target motion in contest rowing.

Methods:
During a training camp (in January 2008) the data of nine male senior elite athletes were acquired. By means of a biovision-EMG and a PEAK Motus 9 analysing soft-ware the surface electromyographic activities of nine chosen, power relevant mus-cles were evaluated with regard to the phased coordination pattern, the succession, the length and intensity of their activation in the motion in selected strength training exercises and exercises of strength diagnosis. The main focus was on 5 maximum arm pull and leg push movements at a Concept 2 rowing ergo meter (FES, Berlin, Germany) and a Concept 2 Dyno (FES, Berlin, Germany) both equipped with sensor technology. In addition, a medicine-ball-throwing test and a trunk-muscles test were performed as well as a 2000-meter-trial at the rowing machine ergo meter. Training exercises such as bench pull, knee squats with arm lift, counter-movement jumps, pull-ups and body lifts were also analysed.

Results and Discussion:
The coordination patterns generated by the training and diagnosis exercises have been used to establish some basic electromyographic coordination profiles, which reveal correlations with the movements at the rowing ergo meter. Based on this fact new potentialities will be shown which lie in categorising the training exercises as to general strength training on the one hand and special exercises on the other. Sec-ondly the functional coherence and independendence of the postulated aim in rowing and the diagnosis and training methods with which to achieve it will be dis-cussed.
HANDBOOK AND TIME OF PHASES OF A FULL SWING IN GOLF
Hansen, S., Amatulli, F., Herwegen, H., Liesen, H.
University of Paderborn, Germany
The comprehension of motion analysis of the complex move of a golf-swing can be facilitated by stable and reliable parameters. The pattern of single phases during the full swing is therefore not only for the beginner, but also for the skilled player of big importance. The times of different sequences of a full-swing depend on performance and sex.
32 golfers different levels: 11 players with low handicap (Mean 1.8), 10 players with medium handicap (Mean 18.4) and 11 beginners (no handicap). Full swing was recorded by a camera. 3 phases were defined (backswing, downswing and follow-through) and analysed. Duration in total was 1.71 +/- 0.26 seconds. The backswing took the longest time of the hole swing (approximately 1 second). Downswing was as long as the sequence of follow-through with shaft parallel to the ground (0.35 seconds). With rising performance-level the total time of the hole swing decreased significantly (p = 0.000, r = 0.412).
A comparison of sexes revealed highly significant difference in the backswing (p=0.000, r=0.268): this phase as well as the total of the swing is longer in female than in male golfers. Higher performance levels lead to shorter times of the full-swing and particularly the back- and down-swing.
Comparing male to female golfers the latter phase as well as the total time of the swing is longer in male athletes. To establish and strengthen a possible triple connection between handicap, swing-time and sex more golfers have to be examined. However, the phase of the back-swing seems to be of decisive importance for the whole swing as there were the biggest differences between 'good' and 'bad' golfers apparent.
The performance-level of a golfer as well as the sex influence times of the total swing and single phases of the swing.

APPARATIVES MEASUREMENT OF STRENGTH AND FLEXIBILITY OF GERMAN ELITE GOLF PLAYERS
Hansen, S., Herwegen, H., Liesen, H.
University of Paderborn, Germany
Unilateral strain in sport may be responsible for imbalances in strength and flexibility. Due to unilateral strain in golf sport golf players are supposed to have a specific profile in strength and flexibility of the trunk muscles. Knowledge of these profiles may lead to the development of training plans for strength and flexibility training especially for golf players.
Apparative measurement of trunk flexibility and strength are made. Tests were carried out in sagittal, frontal and transversal planes. The results are given in % of a given index value. 132 golf players of the German A and C national squads were tested. The golfers had an average age of 18,5 and an average handicap of 1,1.
On the average, a specific profile in trunk flexibility and strength was observed for the tested golf players. They were least flexible in the sagittal plane. The flexibility increased from the frontal to the transversal plane where the best flexibility was observed. The strength profile was exactly converse. Here, the best rates in strength were noticed in the sagittal plane, whereas the lowest rates occurred in the transversal plane.
The results of the study support the hypothesis that (first-class) golf players have specific abilities in trunk strength and flexibility. Hence, the current tendency to additional strength and flexibility training, especially of the trunk muscles, is highly supported.
The tested golf players showed a specific profile in strength and flexibility of the trunk. The imbalanced profile, which was identified for all tested players, illustrates the importance of accompanying strength and flexibility training as health protection.

COMPARISON OF THREE COMMERCIALLY AVAILABLE FACEMASK ON-LINE GAS ANALYSIS SYSTEMS THROUGHOUT IVO2MAX AND VO2MAX MEASUREMENTS
Queiroga, M., Barbieri, R., Barbieri, F., Moura de Ferreira, R., Kokubun, E.
Centre-West State University - UCN/CENTRO - Guarapuava - PR - Brazil
Maximal oxygen consumption (VO2max) and maximal intensity of VO2max (iVO2max), criterion measure of cardiorespiratory fitness and physical performance are most commonly measured by indirect calorimetry during an incrementally graded exercise test to exhaustion using treadmill or bicycle protocols. Different commercial facemask models are used to estimate VO2max and iVO2max though indirect test, however, doesn't know influence on results. Therefore, this study proposed to verify different facemasks (mouthpiece, silicone and neoprene), developed by the MedGraphics VO2200® which is a portable metabolic measurement system (Medical Graphics Corp., St. Paul, MN), influenced on the VO2max and its iVO2max. Thirty 18 males, 5 females) healthy young subjects (age 20.8±2.5 years, body mass 62.2±10.8 kg, 166.5±8.6 cm) volunteered for the study. The subjects performed three maximal incremental tests using mechanically braked cycle ergometer (Monark88), until voluntary fatigue, changing the facemasks in randomly order. Prior to each test, the VO2200 was calibrated according to the manufacturer’s instructions which consisted of performing an auto-calibration routine to the oxygen and carbon dioxide analyzers. At the first stage subjects cycled at 50-60 rpm unloaded during one minute followed by 30 watts with increment in each minute. The great workload performed was used as iVO2max and the VO2 30-s average during the last stage of exercise was considered as VO2max. The one-way ANOVA for repeated measures did not show differences among the facemasks either to VO2max or to iVO2max: mouthpiece (44.1±7.7 ml.kg-1.min-1; 246.9±46.1 W), silicone (45.0±6.8 ml.kg-1.min-1; 244.6±42.2 W) and neoprene facemask (45.0±7.7 ml.kg-1.min-1; 244.6±45.6 W), respectively. In conclusion, the facemasks for this metabolic measurement system used to collect VO2 data did not influence on the VO2max neither on the iVO2max.
MAXIMUM DYNAMIC STRENGTH AND ENDURANCE RELATIONSHIPS IN TWO DIFFERENT RESISTANCE EXERCISES

Boullosa, D., Iglesias, E., Dopico, X., Carballeria, E.

University of A Coruña, Spain

The relationship between % of load and number of repetitions changes with training (Braith et al. 1993). Also, it was suggested an influence of muscle mass involved in exercise (Shimano et al. 2006). The purpose of this study was to examine maximum strength and exercise load influence on the number of repetitions in two different upper body resistance exercises like bench press (BP) and seated arm curl in dominant side (AC).

Thirteen male participants (mass = 77.81 kg, and height = 178.77 cm), experienced in resistance training, were evaluated in repetition maximum (RM) in BP (MBP) and AC (MAC). The following days, with a minimum of 48 h between evaluations, they performed endurance tests in randomized order. The low-intensity endurance tests consisted of performing the maximum number of repetitions at an intensity of 70% of RM with 2 s rest intervals between repetitions until failure in both exercises (N70BP and N70AC). The high-intensity endurance tests consisted of performing the maximum number of repetitions at an intensity of 90% of RM with 30 s rest intervals between repetitions until failure in both exercises (N90BP and N90AC).

MBP was 93.62 ± 18.89 kg, and MAC was 20.19 ± 4.85 kg. N70BP resulted in 16.31 ± 2.59 and N70AC in 8.77 ± 3.01 repetitions. N90BP resulted in 21.85 ± 11.07 and N90AC resulted in 18.54 ± 12.85 repetitions. The CV values reflect a high variability between subjects, higher in high-intensity tests (CV = 0.506; CV = 0.693, in N90BP and N90AC, respectively; vs. CV = 0.159, 0.34, in N70BP and N70AC, respectively). A significant difference was found between N70BP and N70AC (p<0.05), reflecting a lesser number of repetitions in AC. Also, a significant correlation was found between endurance tests in AC (N90AC-N70AC, r= 0.714; p=0.006), with a trend in BP (r= 0.516, p=0.071). Finally, regarding maximum force parameters, only MAC and MAC divided by body weight (MACbw), correlated with endurance performance at low-intensity test IMAC-N70AC, r= -0.574, p=0.04, MACbw-N70AC, r= -0.596, p=0.031, showing an inverse relationship between maximum strength and endurance in AC in the low-intensity condition.

In summary, this study has shown that the number of repetitions at the same % of RM is exercise dependent. From these observations, it is suggested the use of the number of repetitions for training monitoring in contrast to the traditional %RM for a better effort characterization.

MONITORING OF ANTHROPOMETRIC AND BIOMOTOR ADAPTATIONS AND STRUCTURE MODELING OF SPORT PERFORMANCE ON VOLLEYBALL ATHLETES DURING A MACROCYCLE

Dourado, A., Stanganelli, L., Gaya, A., Petersen, R., Oncken, P., Mançan, S.

(1) State University of Londrina, (2) Federal University of Rio Grande do Sul, (3) Brazilian Confederation of Volleyball, Brazil

This study had as objective to determine the structure of sport performance through the anthropometric and biomotor adaptations on the athletes from the male volleyball team during the macrocycle of under-19 Brazilian National Team in preparation to the 2005 world championship. The sample was composed of 12 athletes (17.76±0.71 years old). Training volume analysis was according to the manuscripts recorded by the coaches. The athletes were tested in three different moments and the measured variables were organized as follows: Training volume quantification, anthropometry (height, body mass, sum of seven skinfolds, % body fat), muscle power of the upper extremities (3 kg medicine ball throwing); muscle power or the lower extremities (squat jump, countermovement jump, attack and block height).

The relationship between % of load and number of repetitions changes with training (Braith et al. 1993). Also, it was suggested an influence of muscle mass involved in exercise (Shimano et al. 2006). The purpose of this study was to examine maximum strength and exercise load influence on the number of repetitions in two different upper body resistance exercises like bench press (BP) and seated arm curl in dominant side (AC).

Thirteen male participants (mass = 77.81 kg, and height = 178.77 cm), experienced in resistance training, were evaluated in repetition maximum (RM) in BP (MBP) and AC (MAC). The following days, with a minimum of 48 h between evaluations, they performed endurance tests in randomized order. The low-intensity endurance tests consisted of performing the maximum number of repetitions at an intensity of 70% of RM with 2 s rest intervals between repetitions until failure in both exercises (N70BP and N70AC). The high-intensity endurance tests consisted of performing the maximum number of repetitions at an intensity of 90% of RM with 30 s rest intervals between repetitions until failure in both exercises (N90BP and N90AC).

MBP was 93.62 ± 18.89 kg, and MAC was 20.19 ± 4.85 kg. N70BP resulted in 16.31 ± 2.59 and N70AC in 8.77 ± 3.01 repetitions. N90BP resulted in 21.85 ± 11.07 and N90AC resulted in 18.54 ± 12.85 repetitions. The CV values reflect a high variability between subjects, higher in high-intensity tests (CV = 0.506; CV = 0.693, in N90BP and N90AC, respectively; vs. CV = 0.159, 0.34, in N70BP and N70AC, respectively). A significant difference was found between N70BP and N70AC (p<0.05), reflecting a lesser number of repetitions in AC. Also, a significant correlation was found between endurance tests in AC (N90AC-N70AC, r= 0.714; p=0.006), with a trend in BP (r= 0.516, p=0.071). Finally, regarding maximum force parameters, only MAC and MAC divided by body weight (MACbw), correlated with endurance performance at low-intensity test IMAC-N70AC, r= -0.574, p=0.04, MACbw-N70AC, r= -0.596, p=0.031, showing an inverse relationship between maximum strength and endurance in AC in the low-intensity condition.

In summary, this study has shown that the number of repetitions at the same % of RM is exercise dependent. From these observations, it is suggested the use of the number of repetitions for training monitoring in contrast to the traditional %RM for a better effort characterization.

DIFFERENCES IN DEVELOPMENT OF MOTOR SKILLS AND PHYSICAL FITNESS BETWEEN A SPORT CLASS AND A REGULAR CLASS IN AN AUSTRIAN SECONDARY SCHOOL: A 3 YEAR LONGITUDINAL STUDY

Leitner, C., Raschner, C., Platzer, HP., Patterson, C., Mitterbauer, G.

University of Innsbruck, Austria

Introduction

Physical fitness of 10 to 13 years olds in Austria has been declining [Sandmayer, 2004]. The need for more physical education in schools should be examined. In Austria regular classes have physical education 2 hours per week, while sport classes have up to 8 hours per week. This study analyzed the differences in motor skill and fitness development between sport and regular pupils over three years.

Methods

53 school children (regular class (RC) n=26, sport class (SC) n=27) have been tested with a comprehensive motor skill and fitness testing battery twice annually since 2004. The tests are: 15 m sprint, counter movement jump (CMJ), maximal unilateral isometric leg press, maximal isometric core strength, complex reaction test, hurdle boomerang run, balance test (IMFT 53 Check), stand and reach, and...
Cooper test. Anthropometric data (height, weight and BMI) were also collected. A 2 factor ANOVA (SPSS 15.0 for Windows) was carried out to analyze differences between classes.

Results
As the children aged, the performance generally improved in the tests except in sprint, hurdle boomerang run and relative isometric leg strength left/right. These 3 tests showed no significant main effect for time. BMI was consistently significantly higher in RC, and the increase in BMI from year to year was also greater in RC. SC had significantly higher scores on all other tests except for stand and reach and absolute isometric leg strength and absolute core strength.

The sport class significantly improved in CMJ (p < 0.001), relative isometric core strength (p < 0.007) and Cooper test (p < 0.005) over the three years.

Discussion
The increased physical education in SC had a positive effect on the motor skills and fitness levels of the children. This study confirms other work (Ziroli et al. 2003) which stress the effect of activity level on BMI and fitness. If children do not have the necessary motor skills and strength for sport, they will eventually choose sedentary activities in their leisure time. This will in turn lead to even worse fitness levels. The strong correlation between physical inactivity and bad health (Dencker et al. 2006) suggests that RC pupils will be more susceptible to health problems in the future. The education system should seriously consider increasing the exposure of pupils to physical education.

THE EFFECTS OF PLYOMETRIC TRAINING ON JUMPING STRENGTH AND SOME ANTHROPOMETRIC FEATURES IN VOLLEYBALL PLAYERS AGED BETWEEN 14-16

Kose, S., Onarc Gungor, E.
Anadolu University, Turkey

The aim of the present study is to determine the effects of plyometric training on jumping capacities of female volleyball players aged between 14 and 16. 22 Female volleyball players licensed at 2. Division. The subjects were given a pretest, a pre-mezosiklus test and a post mezosiklus test. According to the results of the pretest, the subjects were divided into two groups; a control group (n=11; ages: 15.18±0.60, weights: 53.00±4.89, heights: 163.81±6.41) and an experimental group (n=11; ages: 14.72±0.64, weights: 56.18±5.41, heights: 169.72±2.14).

While the control group was just given a volleyball training, the experimental group was given volleyball training and plyometrics training. In plyometric training, the box height was determined considering the breaking points of the players. In addition to the anthropometric features of the subjects, calf periphery (CP), thigh periphery (TP), and gluteal folding periphery (GFP) were measured with a tape measure. “Holtein” was used for the measurement of Calf skin-fold thicknesses and thigh skin-fold thicknesses. Heights were measured with wall meter method and weights were measured with an electronic weighing machine trademarked “Arzum”.

Jumping heights of the counter movement jumping (CMJ), squat jumping (SJ), drop jumping (DJ) and 15 second rebound jumping (RJ) were measured with Bosco Test Apparatus. Because of the differences on more than two measurement of the control groups and experimental groups and a lot of PI features were considered, a multivariate analyses of variance (MANOVA) was used for the analysis of results. Variance analysis (VA) was used for the double factor-repetitive measurements. Due to significant F value, the origin of the difference was determined by the Tukey Test.

At the end of the study it was observed that there was no statistically difference between groups (p>0.05).

It was observed that there was a statistically significant difference between the CMJ 1-2, 1-3, 15 second RJ 2-3, gluteal folding periphery 1-3, 2-3 and calf skin-fold thickness 1-3 measurements of the control group (p<0.05).

On the other hand, it was found that there was a statistically significant difference between CMJ 1-2, 1-3, 15 second RJ 1-2, 1-3, 2-3 gluteal folding periphery 1-2, 1-3 thigh skin fold thickness 1-2, 1-3, 2-3 and calf skin-fold thickness 1-2, 1-3, 2-3 measurements of the experimental group.

As a result, with the plyometric training, jumping strength could be improved however training programme have to be prepared by considering the developmental features of this age group.

FIT2DIVE- SPECIFIC PERFORMANCE TEST FOR DIVING

Dräger, T., Steegmanns, A., Röschmann, M., Hoffmann, U.
German Sport University Cologne, Germany

To guarantee the highest possible safety in scuba diving most divers today use redundant systems and alternative air sources. In contrast, the impact of a suitable level of physical fitness on the safety in scuba diving is often easily forgotten. Deficits in physical fitness could strongly increase divers’ workload within a dive such that automatisms for easy skills like clearing a facemask or for more advanced skills as rescue of a diver become much more difficult. In the worst case, a rather small problem can escalate and lead to a real emergency situation.

So far, available methods to investigate divers’ physical fitness need considerable time and costs of material to come to representative results. Hence, a collaboration of the German Sport University and the company aqua med developed a test which can be carried out in the field of leisure sport by every diver without a lot of expenditure. Thus, the aim of fit2dive is an easy practicable performance underwa- ter test for divers which can be apply in diving clubs and training organizations.

There are only a few materials necessary to realise the construction of the test, beside a rope which has marks in defined points and will be placed in shape of a hexagon on ground of a swimming pool, a stopwatch and a timedata is needed. Depth limitation are 5m, the subject must be a certified diver with a minimum age of 16.

In combination of the timetable and the stopwatch the diver is forced to swim a step-test and reach markers every 10m within a defaulted range.
A qualified fit2dive-coach evaluates the divers while testing and makes comments due to equipment configuration, finswimming technique and body position in terms of swimming drag. Directly after the test the diver has to classify the strenuousness in a Borg scale. Furthermore the diver has to complete a questionnaire to receive his full demographic data, diving and medical history. Besides the fact that the diver will receive feedback about his personal strength in the specific underwater environment, the test should sensitise the diver and should help the diver to be able to find his own borders. Moreover, a long-term purpose is to setup a European-wide database to evaluate the fitness state of divers. This database could help to find out more about the relation between physical fitness and diving safety, and therefore can be used for the advancement and adaptation of decompression models.

**QUANTIFYING THE DISTANCE TRAVELED AEROBICALLY AND ANAEROBICALLY TO MONITOR TRAINING LOADS IN INTERMITTENT SPORTS**

Rupf, R., Thomas, S., Yang, P.  
*University of Toronto, Canada*

Intermittent sports such as soccer demand athletes to be able to perform at multiple intensities upon demand. Considering an individual has a finite aerobic and anaerobic reserve, quantifying the energy expended in each energy system may be effective for focusing and optimizing an athlete’s training program. Therefore, the purpose of this study was to develop a model that could quantify the distance traveled using aerobic and anaerobic energy systems by individual athletes through common monitoring systems.

The model developed quantifies the distance traveled aerobically (AD) and anaerobically (AnD) from velocity data obtained from time motion analysis. Critical velocity testing was performed for each individual to determine two parameters: anaerobic capacity and critical velocity (CV). Two main assumptions were used in the development of this model. The first assumption used CV to determine whether a work rate was aerobic (below CV) or anaerobic (above CV). The second assumption modeled oxygen consumption to determine how the oxygen deficit of a given work rate below or above CV contributed to AnD. Oxygen consumption was also used to model recovery periods, assuming the excess oxygen consumption needed to regenerate the anaerobic capacity. Oxygen consumption was modeled using one parameter kinetics. A series of equations were then built on these assumptions to quantify the training load.

In order to test the construct validity of the model, two theoretical running conditions were tested. The first condition involved a continuous maximal run above the critical velocity. The second test condition involved a continuous intermittent run that involved 15 s of running at an intensity of 105% CV, and 15 s of running at an intensity of 80% CV. The AD and AnD were quantified for these two conditions after 5 minutes of continuous activity. AD values were 80% and 90% for the continuous and intermittent exercise respectively, while AnD were 20% and 10% for the continuous and intermittent exercise respectively. This agrees well with information available in the literature. Sensitivity analysis was also performed on the oxygen kinetic parameters, with tau values adjusted by +10% and -10%. Differences in AD and AnD were < 3%.

The model proves to be valid for both the continuous and intermittent exercise roles. Due to its ability to quantify the intensity of training by energy systems specific to each individual, it offers greater advantages over current monitoring systems for intermittent sports.

**SPORTS INJURIES IN BASKETBALL: EPIDEMIOLOGY AND PREVENTION STRATEGIES**

Henke, T., French, D., Herbeck, B., Moschny, A., Remmert, H., Schulz, D., Schwarz, M.  
(1) Ruhr-University Bochum, Germany, (2) British Performance Basketball, Great Britain, (3) Sportomed Reha, Germany, (4) ARAG Sports Insurance, Germany, (5) FIBA Europe, Germany

Purpose: Research related to sports injuries often has the aim to develop prevention measures for a respective kind of sport by means of specific analyses of accidents. Due to the fact that basketball injuries are ranking within the top ten of the sports injury statistics in nearly every European country, it seems to be necessary to develop sports specific prevention measures for basketball based on a detailed analysis of injury causing situations and mechanisms.

Methods: Athletes who report a sports injury receive a questionnaire containing questions about how the accident happened, about the injury itself and how it was treated. All athletes were actively participating in organized sports competition within Germany at the time of their reported injury. The response rate was 65%. To date, 170,000 accidents have been registered. Out of these, a sample of 5090 accidents resulting from basketball were statistically analysed and a free text analysis of the injury mechanisms and situations was carried out.

Results: Although basketball is a non-contact team sport by definition, approximately 80% of all accidents occur in competitive situations and during practice games. The accidents concern mainly four parts of the body. Injuries of the ankle joint are most prominent with about 45%. Knee, hand and head are each concerned in about 25 % of the cases. In case of the ankle injuries about 70% of the injuries occur either without ankle injury causing or because of landing on the opponent’s or teammate’s foot. Knee injuries mostly result from cutting or stopping maneuvers, collisions or happen when landing after a jump. Hand injuries are mainly contusions of the finger joints. Head injuries are mostly caused by the opponent’s elbow during actions under the basket e.g. rebound.

Conclusion: In order to reduce the risk of injuries, training should concentrate on the improvement of mobility (dynamic flexibility), stability and functional movement. Preventive training measures should focus on coordination and sensory motor training of the lower extremities as well as on low back and shoulders due to the overuse problem. Exercises are presented which focus on the specific mechanisms and situations in which knee and ankle injuries occur. Through very specific exercise prescription, it is possible to reduce the risk of injury by enhanced levels of physical conditioning. Guidelines are provided on how to integrate these exercises into a training session. In addition, an appropriate planning and dosage of the training as well as observance of sufficient regeneration periods after increased strains in practice and competitions help to prevent injuries.

**EFFECTS OF DIFFERENT WARM-UP STRETCHING PROTOCOLS ON 20 M SPRINT PERFORMANCE IN ASSOCIATION FOOTBALL**

Cousins, S., Johnstone, J., Ford, P., Goldstein, M., Gregg, M.  
*University of East London, United Kingdom*

The purpose of this study was to establish the effects of both static stretching (SS) and dynamic stretching (DS) on the sprint performance of University standard association football players. 31 participants (17 males, age 21 ± 0.7years, mass 82 ± 23kg, height 1.79 ± 0.12m, 14 females, age 20 ± 0.5years, 67 ± 11kg, 1.72 ± 0.09m, mean ± SD) from the University of East London Association Football squad were randomly assigned into two groups (SS n=16, DS n=15). All participants performed a generic standardised 10 min cardiovascular warm-
up, which was then followed by 3 x 20 m sprints that were timed (Speedtrap II, Braver Timing System, Draper, UT, USA). There was a 5 min active recovery between each trial. This protocol was repeated two days later, however immediately prior to the sprints each group performed respective stretching of the principle locomotive muscle groups. SS group held each muscle stretch for 20 s to the point of mild discomfort, whereas the DS performed dynamic moves while maintaining a slow whole body movement. All testing was completed outside, with all subjects wearing football kit. This study was approved by the institutions ethics committee. Data was analysed using a paired t-test, with significant accepted as p<0.01.

There was a significant increase in the mean sprint times of SS following their respective stretching intervention (+ 0.08 ± 0.02 seconds). In contrast, there was a significant decrease in the mean sprint times of DS following their respective stretching intervention (+ 0.05 ± 0.016 seconds). It appears that DS may elicit performance enhancing benefits in association football through improved sprint performance. However, the use of SS within a warm-up routine may have a negative impact upon the sprint performance, and thus association football performance. It is hypothesised that the performance improvements obtained following the DS intervention trials are as a result of post-activation potentiation elicitation or an increase in core and/or peripheral temperature. Whereas performance decrements incurred from the SS intervention may be associated with increased musculotendinous unit compliance or decreases in core and/or peripheral temperature. Yet, such mechanism warrant further investigation.

ANALYSIS OF UNUSUAL ALTERNATIVE PATTERNS OF BREASTSTROKES TECHNIQUE

Scurati, R., Michelon, G., Longo, S., Invernizzi, P.
Faculty of Exercise Sciences - University of Milan, Italy

Introduction.
Breaststroke is a continuously evolving technique. Several studies have been carried out about its biomechanics and its complex coordination structure, in particular analyzing continuity and frequency of propulsive actions [1, 2]. The aim of this study was to analyze the efficiency of some unusual alternative patterns of breaststroke's technique generally set by trainers during the training sessions, useful in elderly swimmers, people with disabilities, rehabilitation, leisure swimming.

Material and methods.
Nine swimmers (mean±SD, age 15.1±1.2 years, height 172.4±3.5 cm, body mass 61.5±3.4 kg) participated in the study. Firstly subjects experienced two alternative patterns of breaststroke's coordination: DA stroke, with a double arm stroke per stroke cycle (without breathing between the two arm strokes); DK stroke, with a double kick per stroke cycle. Then swimmers performed 25, 100 and 400 meters flat breaststroke (FB) and in the alternatives DA and DK patterns. Performances were collected and an index of efficiency (IE = velocity swim cycle length) was calculated from video recordings. We compared: the performances, the IE means for each swim distance and the IE in the three distances for each swim pattern.

Results.
No differences were found between FB and DA performances, whereas swimmers achieved better results in FB compared to DK pattern in all distances: 426.7±28.3 vs 442.9±32.5 s in the 400m (p=0.01); 94.4±8.9 to 100.9±8.7 s in the 100m (p=0.00); 20.4±1.8 to 23.2±1.9 in the 25m (p=0.01). Flat breaststroke showed also a higher IE in every distance both in FB-DA comparisons (25m p=0.005; 100m p=0.00; 400m p=0.00) and in FB-DK comparisons (25m p=0.003; 100m p=0.008; 400m p=0.00). With regard to the IE within each distance of swim, significant differences were found between: i) 400m and 25m both in FB (1.67±0.3 vs. 2.09±0.3, p=0.025) and in the DK pattern (3.04±0.6 vs. 4.09±1.0, p=0.014); ii) 400m and 100m in the DA pattern (3.61±0.6 vs. 3.92±0.5, p=0.01). Conclusion.
DA pattern is nearly as efficient as FB, whereas worse results were found in the DK pattern, perhaps due to a longer non propulsive phase per stroke (the two gliding after the two kicks). Therefore it seems that the DA pattern is more suitable when an alternative breaststroke is required, such as in elderly swimmers or people with leg disabilities. However, it should be noticed that as distance increases the lack of rhythm occurs more frequently and the maintenance of the DA pattern becomes more difficult.

STRUCTURE AND EVOLUTION TRENDS OF THE EXTERNAL LOAD IN UNEVEN BARS. ANALYSIS OF THE FLIGHT ELEMENTS IN COMPETITION ROUTINES

Ferreirinha, J., Silva, A., Marques, A.
University of Trás-os-Montes and Alto Douro1, Portugal, Research Centre for Sport, Health and Human Development (CIDESD)2, Portugal, Sports Faculty, University of Porto3, Portugal

Introduction.
Specific literature in Artistic Gymnastics is rich in considerations about evolution trends of flight elements in uneven bars routines. Based on the analyses of total participants in world championships and Olympic Games we can observe that gymnasts performed more flight elements in last Olympic cycle compared with preceding cycles. In this way, the purpose of the present study was to analyse the trends in number, difficulty and direct combinations of flight elements in uneven bars routines in elite gymnasts.

Methods.
Through the observational methodology, we constructed and validated an observation category comprising seven variables considered as indicators of the external load concerning flight elements in uneven bars. We observed 83 uneven bars routines from world championships and Olympic Games finals between 1989 and 2004. 12 competitions were framed in 4 Olympic cycles with 2 world championships and 1 Olympic Games each one. It was observed the total number of flight elements, direct combination of 2 and 3 flight elements, difficulty, number of preparation elements and body position in this kind of elements.

Data was analysed with descriptive statistics (mean and standard deviation) using Kruskal Wallis test used to compare general significant differences in all cycles and Mann-Whitney tests with Bonferroni correction to analyse differences between each cycle. The level of significance was established in 5% or 1.25% depending of the tests used.

Results.
EFFECT OF THE TEMPO OF ATTACK IN ATTACK PERFORMANCE IN COMPLEX II OF THE 2004 OLYMPIC GAMES

Nikolaidou, M., Barzouka, K., Bergelles, N.
National and Kapodistrian University of Athens, Greece

In a volleyball game, the action of every attacker is performed in cooperation with the setter and depending on the ball’s flight time, the attack can be performed in 3 tempos. It is generally believed that the shorter the ball’s flight time is the faster and the more efficient its performance will be. Previous studies have assessed the performance of attack actions in Complex I or II (Barzouka et al., 2005), however performance of the attackers as a function of the tempo of the attack has not yet been examined. The purpose of this study was to investigate performance of Olympic-level male athletes in attack in Complex II as a function of the attack’s tempo.

Volleyball games of male teams competing in the preliminary phase of the 2004 OG were videotaped. Assessment of players’ performance in attack in relation to 3 different tempos (1st-2nd-3rd) in Complex II in N = 2122 was based on the 5-point numerical rating scale (scores 0-4 with 0 indicating an error and 4 an excellent performance) as proposed by Eom & Schutz (1992). Average performance was defined as the performance calculated from mean values of the range of performance scores 0 to 4. Intra-rater reliability coefficients for the assessment of performance and the attack tempo were found to be r = 0.93 and r = 0.98, respectively. The calculation of percentages and frequencies among the 3 attack tempos in each performance rating score was made with the crosstabulation method with levels of 3x5. Possible differences in average attack performance among different attack tempos was examined with univariate ANOVA (p < .05).

From the total number of assessed attack actions in Complex II, results showed that 79% (37.6%) and 384 (18.1%) actions were assessed as errors, respectively. The remaining of the attack actions were assessed with excellent performance and 384 (18.1%) actions were assessed as errors, respectively. The remaining of the attack actions were assessed with performance scores from 1 to 3. The average attack performance of 3rd tempo attack actions (2.3±1.5) was significantly (p<.001) lower than the average performances of 1st (2±1.5) and 2nd (2±1.6) attack actions, respectively.

The results of this study indicate that in olympic-level male volleyball games for every 3 attack actions in the counter-attack process only one is efficient, whereas in every 6 attack actions an action resulting in a point won by the opponent takes place. Furthermore, it was found that the average attack performance during the counter-attack process is more efficient when attack actions are being performed with a fast (1st) or medium (2nd) tempo, while on the contrary, most erroneous actions occur when attack actions are performed with a slow (3rd) tempo. In conclusion, it can be speculated that when attack is performed in a fast tempo, it is efficient, in contrast with the higher incidence of erroneous actions that seem to result from an attack with a slower tempo.

HYDRODYNAMIC SKILLS IN YOUNG SWIMMERS: REPEATABILITY OF SOME GLIDING TESTS

Invernizzi, P., Scurati, R., Longo, S., Michielon, G.
Faculty of Exercise Sciences - University of Milan, Italy

INTRODUCTION
Analysis conducted in swimming competitions of distances up to 400m pointed out that the first 15m play an important role for the result of the entire performance (1). Hence the hydrodynamic ability to glide underwater in a streamline position (2) should not be neglected during training, especially in young competitors.

AIM
The purpose of this study was to identify some tests to evaluate gliding skills in young swimmers, which might be repeatable and correlated to their performances in 15m crawl and breaststroke.

MATERIAL AND METHODS
Fifteen males (M, mean±SD, age 16.5±1.9 years, height 180±8 cm, body mass 69.3±11.3 kg) and sixteen females (F, mean±SD, age 15.6±1.5 years, height 170±6 cm, body mass 57.4±6.3 kg) at national level were tested. After familiarisation, participants were positioned on a starting block and asked to dive and swim for 15m crawl (CR) and 15m breaststroke (BR) in two different trials. Later subjects underwent a series of hydrodynamic tests such as: diving and gliding underwater in a streamline position for 8m (DG), pushing off from the wall and gliding underwater in a streamline position for 8m (PG), pushing off from the wall, gliding and swimming crawl for 12.5m (PGB), pushing off from the wall, gliding and swimming breaststroke for 12.5m (PGB), sculling while floating on the back for 10m (SC). Time was recorded and all tests were repeated five times on the same day and again on a different day to assess their repeatability.

RESULTS
Repeatability was assessed through intraclass correlation coefficient (ICC). DG: r=0.90 vs 0.84, PG: r=0.89 vs 0.88, PGB: r=0.85 vs 0.81, PGB=0.88 vs 0.76, SC=0.84 vs 0.63, M and F respectively. M performed significantly better than F in all trials (mean±SD, CR=6.16±0.4 vs 6.88±0.2 s, BR=7.74±0.4 vs 8.58±0.5 s, DG=2.16±0.3 vs 2.61±0.2 s, PG=4.10±0.6 vs 4.62±0.6 s, PGB=5.27±0.2 vs 6.06±0.2 s, PGB=7.07±0.4 vs 8.08±0.5 s, SC=9.52±0.7 vs 10.60±0.6 s, p<0.02, M and F respectively).

Tests significantly correlated with both CR vs DG r=0.83, CR vs PG r=0.68, CR vs PGB r=0.93, CR vs PGB r=0.76, p<0.01) and BR (BR vs DG r=0.77, BR vs PGB r=0.67, BR vs PGB r=0.84, BR vs PGB r=0.83, p<0.01) performances.

CONCLUSIONS
The tests carried out on the groups were repeatable and the male group performed better than the female group. According to the literature, these gliding tests correlated well with the performance in 15m crawl and breaststroke, factors which highly influence the results in sprint competitions.

DIFFERENCES IN HEART RATE AND LACTATE BETWEEN CLASSIC STROKES AND WATER POLO SWIMMING TECHNIQUES AT CONSTANT PACE

Invernizzi, P., Scurati, R., Roveda, E., Longo, S., Michielen, G.

Faculty of Exercise Sciences - University of Milan, Italy

INTRODUCTION

Water polo is physiologically a highly demanding activity (1). During a match players often swim in different ways that do not reflect completely the classic four strokes. Hence the aim of this study was to compare heart rate and lactic acid production during classic swimming and water polo swimming techniques at constant speed in order to identify possible differences in cardiovascular energy requirement.

MATERIAL AND METHODS

Nine agonistic swimmers (mean±SD, age 15±1.58 years, height 163.8±4.6 cm, body mass 55.4±7.3 kg) volunteered for this study. Each participant performed 30m trials at a constant speed of 1m/s in four classic strokes: crawl (CR), backstroke (BA), breaststroke (BR), and butterfly (BU) and in their water polo variations (WPT): i) head above the water, ii) head above holding a ball, iii) arm stroke - dolphin kick, iv) backstroke lower hip, v) symmetric arm stroke - breast kick, vi) crawl arm stroke - breast kick, vii) breast arm stroke - butterfly arm stroke - breast kick, viii) six crawl arm stroke and six breaststroke arm stroke. Acoustic and visual aids were used to help swimmers keeping the pace. At the end of each trial heart rate (HR) and lactate concentration ([La-]) were measured through Polar X-Trainer PlusTM and Arkray-Lactate ProTM respectively.

RESULTS

Polar X-Trainer PlusTM and Arkray-Lactate ProTM respectively.

CONCLUSIONS

Concerning our subjects (agonistic swimmers but not waterpolo players), crawl is the most economic stroke as expected (2) and shows similar values of HR and [La-] if compared to WPT vii and ix respectively (where crawl arm stroke is involved in both).

The high HR we found in iv as a variation of backstroke is likely due to the low hydrodynamic body position which probably elicits more cardiovascular effort.

In general it seems that swimming crawl and backstroke at a constant speed of 1m/s is less demanding in term of cardiovascular effort than some of their WPT variations, whereas it is the opposite in breaststroke and the same in butterfly.

EFFECT OF PHYSICAL ACTIVITY ON STEREOSCOPIC VISION

Jendrusch, G., Vossebein, S., Platen, P.

Ruhr-University Bochum, Germany

Visual perception is of crucial importance for successfully coping with the tasks set in sport. Of particular relevance is the question how far physical stress influences perception and reaction. From a practical point of view it is of particular interest to consider to what extent potentially positive effects on visual ability could be used to optimise performance, e.g. through appropriate warming up.

PURPOSE: The aim of the study was to analyse the possible changes induced by physical activity on stereoscopic vision.

METHODS: Changes of stereoscopic vision at close range were examined using the TNO test for stereoscopic vision (Laméris Ootech B.V., Nieuwegein, NL). This standardised test consists of plates (to be viewed with the red-green-spectacles) which carry figures (random-dot stereograms) that can only be seen when both eyes cooperate. For the exact determination of stereoscopic sensitivity discs with a sector missing at one of four possible orientations as test figures were used. These figures were presented at six different depth levels (two at each level). The corresponding retinal disparities (bino cular parallax) ranged from 15 to 480 seconds of arc.

The plates were presented at a distance of approximately 40 cm.

28 subjects (14 females and 14 males; average age: 24.2 +/-2.4 years, range: 20-31 years) with normal eyesight (minimum visual acuity <= 20/20) were exposed to different types of strain. Firstly all subjects performed a maximal step-wise incremental test on a cycle ergometer (initial load = 50 W, 3 min step duration, 50 W increment until exhaustion). This test was followed by a 10-minute and a 20-minute constant-load cycle ergometric exercise with 80% of P4 and a control test without physical activity. These three tests were performed by each subject within three test days. The quality of stereoscopic vision was determined before, directly after as well as 15, 30 and 45 minutes after finishing the exercise.

RESULTS: Initially significant differences were found in the course of the stereoscopic vision measurement between the exercise tests and the control test (p<0.05) were observed. Significant changes of stereoscopic vision could be found for the maximal ergometric test (p<0.001), the 10-minute (p<0.001) and the 20-minute constant-load cycle ergometric exercise (p<0.001). No significant changes in performance occurred during the control test (p=0.800).

Stereoscopic vision significantly improved after ergometric bicycle strain in each test and remained on a raised level up to the end of the test, 45 minutes after finishing exercise. The best benefit in stereoscopic visual performance resulted following physical strain in the maximal ergometric test.

CONCLUSION: Improvement of stereoscopic vision following moderate or intensive heart-circulatory activating exercise can possibly be due to a more comfortable general metabolic situation (e.g. increase of the retinal blood supply and the cerebral oxygen supply) along with an increase in vigilance.
**MAXIMAL LACTATE STEADY STATE FOR AEROBIC EVALUATION OF SWIMMING MICE**

Gobatto, C., Carneiro, L., Manchado-Gobatto, F., Araujo, G., Reis, I.

Sao Paulo State University - UNESP, Brazil

The maximal lactate steady state (MLSS) has been considered the gold standard method for determination of aerobic/anaerobic metabolism transition during continuous exercise executed by human beings. An important tool for exercise physiology studies and correlated areas is the use of animals, including mice. However, studies aiming to determinations of the exercise intensity and evaluation protocols in these animals are scarce. The aim of the present study was to determine MLSS for aerobic evaluation in swimming mice. Adult male mice (25 animals, with 90 days and weighting 51±2.0g) which were adapted to aquatic ambient by two weeks, in a cylindrical water tank with smooth surface and water temperature kept at 31±1°C. Later, the mice were submitted to five continuous exercises using loads equivalent to 3,4,5,6 and 7% of body weight (bw) tied to the back. The continuous exercise were executed by 25 minutes and separate for interval of 48 hours. Blood samples (25 µl) were collected from a cut at the tail tip during swimming exercise (rest, 5, 10, 15, 20 and 25 minutes of exercise) for blood lactate analysis and MLSS determination. The individual MLSS was considered as the highest intensity in which the increase on the blood lactate concentration was equal to or below 1 mmol/L from the 10th to the 25th minutes of exercise. The blood lactate concentrations in several times of exercise were compared by one-way Anova and Newman-Keuls post-hoc test (P<0.05).

The results showed that the 36% of the swimming mice presented MLSS at 4%bw, 20% at 3%bw and 6%bw, 16% at 5%bw, and 8% at 7%bw. The blood lactate concentration at the maximal stabilization was 5.78±0.29 mmol/L (4.40-6.77mmol/L). It was observed a progressive increase in the blood lactate concentrations at higher intensities (upper MLSS) and some animals reached exhaustion between the 10th and 25th minute of exercise, in a similar form as what is verified in human beings and rats. In this way, these results indicate that the protocol of MLSS can be used for determination of the maximal aerobic intensity in swimming mice.

Supported by CNPq (proc n°301601/2006-2) and Fapesp and Capes.

**KINEMATIC CHARACTERISTICS OF THE SPRINT START IN HIGH LEVEL SPRINTERs**

Slawinski, J., Bonnefoy, A., Ontanon, G., Leveque, J.M., Riquet, A., Chatain, C., Vannicatte, Y., Miller, C.

Team Lagardère, France

**Introduction**

During the 100m final at the 1997 world championships the athletes reached 95% of their maximal speed before the 40 meters (Müller and Hommel 1997). The sprint start and subsequent acceleration are two extremely important phases which directly generate the results in a 60 m and 100 m sprint. However, few data have been published for high level sprinters. The purpose of this study was to describe the major kinematic parameters of a sprint start in high level sprinters. We compared the range of the knee joint angles, body centre of mass (CM) position and velocity, step length (SL), step rate (SR) to the available data from the literature.

**Methods**

Five high level sprinters took part in this study (their 100m best performances were comprised within 10.16 and 10.45s). Each subject performed 6 × 20m indoor block sprint start. The starting block phase and the three first steps were recorded with an opto-electronic Motion Analysis system (12 cameras). The body was modelled as 17 segments with 60 passive reflective markers (Wu, 2002, 2005). The 3D trajectories of the CM and horizontal velocities of the CM (VxCM) were computed (Dumas et al. 2007).

**Results**

20m sprint mean performance was 3.19 ± 0.05s. In the set position, the horizontal distance from the start line to the CM was 38.7 ±4.6cm. Front and rear knee angles were 99.9±7.3° and 123.0±8.1°. The horizontal velocities of the CM (VxCM) at the block clearance, the 1st, 2nd, and 3rd step were respectively, 3.40 ± 0.16, 4.84 ± 0.23, 5.60 ± 0.17 and 6.50 ± 0.22m.s-1. The first step was put at 53.8 ±9.8cm after the clearance of the block.

The correlations showed that to perform a good start, the sprinters must be able to create the greatest velocity during the three first steps (r = -0.39; p < 0.05 r = -0.36; p < 0.05; r = -0.71; p < 0.0001). SL of the 2nd, and 3rd step was 110.3 ± 8.8cm and 129.7 ± 13.2cm. Correlations were obtained between the VxCM at the push-off of the 1st, 2nd, and 3rd step and the 20m performance (r = -0.39; p < 0.05).

**Discussion**

In the set position, the horizontal distance from the start line to the CM was greater than that observed in other studies. This result did not confirm the hypothesis that positioning the CM as close as possible to the start line was important to a good start (Harland and Steele, 1997). Front and rear knee angles were in line with other studies. After the start signal, VxCM at the toe-off of the second step has been measured at 6.0 ± 0.2 m.s-1 for a sprinter (personal best time of 10.4s, oh et al.,2006). This is higher than the present results.

The correlations showed that to perform a good start, the sprinters must be able to create the greatest velocity during the three first steps after the clearance of the block.

**INFLUENCE OF BONE AGE ON ANTHROPOMETRIC VARIABLES OF YOUNG SOCCER PLAYERS**

Federal University of Parana, Brazil

Bone age or Skeletal age assessment is used to identify and estimate the level of maturity which a child has attained at a given point in time (Malina, 2006). It's related to chronological age, and it has been shown to be an effective method to identify the actual biological maturation level of children, in order to compare it to chronological age to detect same pass, in differences mainly in size, strength and power, among children of same chronological age group, but different maturity level. The aim of this study is to identify variations on anthropometric variables among young soccer players from the same age group, but presenting different bone ages.

The sample included 30 U-15 young elite soccer players (15.03 ± 0.56 years) were assessed. Bone age and anthropometric variables were assessed as following: Body Composition height (174.1 ±0.71 cm), weight (65.18 ± 8.49 kg) and Body Mass Index (BMI) (21.48 ± 2.31)
COMPARISON OF PERFORMANCE IN ONE REPETITION MAXIMUM TEST USING TWO DIFFERENT PROTOCOLS

Lima, F., Chagas, M., Avelar, A., Diniz, R., Costa, H., Marcossi, D., Almeida, R., Carvalho, F.
Federal University of Minas Gerais, Brazil

The control of the improvement of maximum strength by means of tests represents an important aspect of planning and regulation of the training. One of the most known tests for measure the maximum strength is one repetition maximum (IRM) test and the procedures of
this test arise some differences. In the study of Abdessemend et al (1), the volunteers carried out two repetitions per attempt, while the most common recommendation is one repetition per attempt(2). As the prescription of intensity in strength training is traditionally based on percentage values of the 1RM test(3), distinct performances due to the differences in the procedure could provide different information for the initial determination of the training load. The objective of this study was to compare the performance in the test of 1RM using two different protocols in the bench press exercise. 17 male volunteers trained in strength training (>6 months of regular practice and 1RM test ≥ body mass) have participated in this study. The protocol A consisted of the accomplishment of a maximum of six attempts, with recovery of five minutes between the attempts and the weight should be moved only once by the determined range of motion. The protocol B followed the same procedures of protocol A, but it was suggested to the volunteer to try on to realize two repetitions per attempt, being considered the best performance the weight that allowed the individual to perform only one complete repetition with concentric failure in the second one. The volunteers were familiarized with both testing procedures 48-72 hours before their respective test protocols. The end of the procedures of a protocol was separated from the beginning of the other by a period of 5 days. The sequence that the volunteer has carried out (A-B/B-A) was balanced and the individual allocation in each sequence was randomized. Statistical comparison was accomplished with a Student T paired test. The 1RM performance was significantly lower in protocol B than the protocol A (A=103,2kg ±12,7 and B=100,2kg ±11,6; p<0.05). The difference between the protocols indicates that the choice of the testing procedure affects the representative value for the measuring of the maximum dynamic strength. Thus, a determination of intensity based on percentage values of 1RM test will lead to different stimuli and prescriptions of the training load.

IS-BN08 The point on the electrophysiological methods to study neuromuscular adaptations

INTERPRETATION OF THE SURFACE ELECTROMYOGRAM
Enoka, R.
University of Colorado at Boulder, United States
The surface EMG comprises the sum of muscle fiber action potentials as detected by electrodes placed on the skin overlying the muscle. Although the muscle fiber action potentials are the consequence of action potentials discharged by spinal motor neurons, the surface EMG does not provide a simple measure of the neural activation of muscle. Rather, the summation of the muscle fiber potentials is influenced by factors that are unrelated to the quantity of the output from the spinal cord. The purpose of the presentation is to review the influence of these factors on selected measurements of the surface EMG during isometric contractions and to discuss some of the unresolved issues on the interpretation of the signal. Because muscle fiber action potentials comprise positive and negative phases, the sum of multiple action potentials involves some signal cancellation that reduces the amplitude of the surface EMG relative to the absolute motor output from the spinal cord. When normalized to the amplitude at maximal muscle activation, cancellation results in EMG amplitude overestimating the magnitude of the motor output at intermediate levels of muscle activation. Similarly, the amplitude of evoked potentials, such as M waves and motor evoked potentials, can be reduced by small changes in the timing of the constituent muscle fiber action potentials and by the location of the motor units that are activated by the stimulus. As the amount of cancellation varies with muscle fiber conduction velocity, so too are the spectral properties of the surface EMG. Despite the sensitivity of the surface EMG signal to factors unrelated to the neural drive to the muscle, the action potentials of 84% of the motor units in a population can be recorded with electrodes (9 x 9 array) placed on the skin overlying the muscle. Standard bipolar recordings of the surface EMG, however, are relatively insensitive to modest changes in motor unit activity. For example, different decreases in motor unit discharge rate during fatiguing contractions can be associated with a similar increase in the amplitude of the surface EMG. This effect, however, appears to differ across muscles and may be related to factors that influence how the muscle fiber action potentials sum in the different recordings. Furthermore, the depression of the maximal surface EMG at the end of a sustained low-force contraction is likely caused by changes in the muscle fiber action potentials during the fatiguing contraction, such as an increase in the amount of signal cancellation and a reduction in the amplitude of the intracellular action potential. Changes in EMG amplitude, therefore, must be referenced to an appropriate control value. Although the surface EMG provides useful information about muscle activation, its interpretation can challenge even the most accomplished experimentalist.

ASSESSING CORTICOSPINAL EXCITABILITY DURING EXERCISE
Taylor, J.
Prince of Wales Medical Research Institute and the University of New South Wales, Australia
Corticospinal neurones travel from the motor cortex (and associated areas) to terminate on interneurones or motoneurones in the spinal cord to provide the major pathway for the control of voluntary movement in humans. However, corticospinal excitability is commonly used to refer not simply to the excitability of corticospinal neurones but more globally to the motor pathway from primary motor cortex to muscle. Changes at multiple sites in this pathway can influence responses in the muscle. These sites include cortical interneurones, corticospinal neurones, spinal interneurones and motoneurones. One technique to test excitability of the whole motor pathway in awake humans is transcranial magnetic stimulation (TMS), which activates corticospinal neurones both directly, and synaptically through activation of intracortical neurones. When TMS is used in combination with cervicomedullary stimulation, which activates axons in the corticospinal tract at a subcortical level and so does not depend on cortical excitability, changes in excitability can be localised to a cortical or spinal level.
If TMS is given during voluntary contractions, the response evoked in the muscle (motor evoked potential, MEP) is larger than with the muscle at rest. If the corticospinal axons are stimulated, the muscle responses (corticomedullary motor evoked potentials, CMEPs) are also larger during contraction than rest. Comparison of the changes in the MEPs and CMEPs shows that there is increased responsiveness of the motoneurones to descending input, but also increased cortical excitability (1).

With increasing contraction strength, complex changes occur in MEP size. From rest to moderate contractions the MEP grows, but with even stronger contractions it becomes smaller again. Similar changes occur in the subcortically-evoked CMEP, which suggests that these changes are dominated by the behaviour of the motoneurones (2). The changes are consistent with a decreased response of rapidly firing motoneurones to synaptic input. The relationship between CMEP or MEP size and contraction strength can be understood in terms of the different effects of increasing voluntary drive on active motoneurones and on unrecruited motoneurones, and the proportion of each in the motoneurone pool at each contraction strength.

The interpretation of any changes in the MEP or CMEP evoked during muscle activity must take this relationship into account. For example, if muscles are recruited at moderate forces during exercise, CMEPs (or MEPs) may be on the ascending limb of the relationship where more excitation leads to bigger responses. With fatigue, recruitment of additional motor units to maintain force could move CMEPs (or MEPs) to the descending limb where more excitation leads to smaller responses. The interpretation of an increase in response size would be completely different at the two moments.

USE AND MISUSE OF THE H-REFLEX WHEN MEASURING NEURAL CONTROL
Cresswell, A.
The University of Queensland, Australia

The Hoffmann reflex (H-reflex) is often used to measure neural changes at the spinal level. These changes are generally occurring as a result of some form of intervention, treatment or change of condition, e.g., strength training, fatigue and/or change of posture. The size of the reflex, which is evoked in the muscle of interest by a brief electrical stimulus to its innervating nerve, is dependent upon the intensity of the stimulus and the pre- and post- synaptic properties of the activated motoneurone pool. Increased drive to the motoneurone pool from descending and peripheral sources combine to increase motoneurone excitability, which alone can give rise to an increase in the H-reflex for a given stimulus. However, pre-synaptic inhibition of the Ia-afferent terminal via PAD-interneurones can have a considerable effect on the size of the test H-reflex while the activation history and/or the amount of ongoing activity in the afferent nerve is also known to affect the H-reflex amplitude, albeit in a passive muscle. It has also been shown that the size of the test stimulus can affect the responsiveness of the H-reflex in situations where the level of voluntary activation is systematically increased. First and foremost however, is the need to deliver a constant test stimulus to the mixed nerve, which is mostly assessed by monitoring the size and shape of the muscle response (M-wave) elicited via direct activation of the motor efferents. Muscle length changes can also affect the size of the H-reflex due to alterations in the muscle-electrode configuration. Despite these difficulties and limitations, it will be shown how the H-reflex can be successfully used to assess neural alterations, such as those occurring in response to weak and strong static and dynamic contractions. Alterations in neural activity with time, such as those occurring during fatigue tasks, and those occurring as a result of small changes in postural configurations, such as during the different phases of postural sway, will also be presented, along with some novel approaches to recording the H-reflex.

OFFICE TOOLS FOR MEASURING BODY COMPOSITION IN OBESE ADULTS
Fields, D.
University of Oklahoma Health Sciences Center, United States

Identifying those who are obese is the single most important diagnosis a physician or health professional can make in the treatment of obesity. Shockingly, only one in five obese patients are given a diagnosis of obesity (i.e. body mass index of > 30 kg/m2) at the time of...
their primary care physician visit. The evaluation of obesity related comorbid conditions should be of major importance, more so than body composition per se, with the major concern being visceral fat. The single easiest measurement for the estimation of visceral fat is waist circumference. This is done easily and accurately in the office with a spring loaded tape measure. Site specific anthropometry (i.e. skin fold calipers) is useful to determine the accumulation of excess fat accumulation at specific depots (e.g. abdomen, triceps, high, and sub-scapular). Bio-electric impedance may have a role as an office tool in evaluating total body composition in obese individuals, though consideration should be given to gender and body weight. Additionally, air-displacement plethysmography provides a high level of sophistication, though cost may be prohibitive for many clinical settings. In determining the efficacy of a weight management programs an abdominal skin fold in combination with waist circumference can give an indication of fat loss location (i.e. visceral vs. subcutaneous).

**METHODS AND TECHNIQUES FOR ASSESSING BODY COMPOSITION IN CHILDREN**

Pietrobelli, A.
Verona University-Medical School, Policlinic GB Rossi, Verona, Italy

To promote obesity, both genetic and environmental factors must influence one or more components of energy balance. In this view, the traditional definition of nutritional status i.e., the introduction, absorption and utilization of nutrients has a new definition that underscores the relationship between nutritional status and health status. This view considers energy balance, body function, and specifically body composition as three interrelated entities. It is first important to note that children are not mature and that growth is the primary factor that influences pediatric body composition.

The measurement of body mass is extremely challenging. There are various indirect methods for measuring fat and fat free mass, all of which have assumptions and age-specific considerations. The value of understanding pediatric body composition methods and applications is manifold.

Body composition analysis provides a window into the complex changes that occur throughout childhood and a platform for evaluating their associations with metabolic and physiological measures. Currently overweight and obesity are defined on the basis of age-specific percentiles of Body Mass Index (BMI). However, measurement issues might be partially responsible for the results.

The central aim of our presentation is to discuss methods for body composition assessment that may provide new insights into the clinical practicality of pediatric obesity prevention/treatment. First we will analyze pro and contra of the different pediatric body composition measurements techniques that are used in the research setting. Second we will analyze simple and practical measurements that could be used in office or in clinical setting. Finally, we will discuss different measurements used in epidemiological studies.

Once refined body composition measurements are ascertained in large groups of healthy children, it will be possible to better understand the normal compartmental changes that occur during growth, as well as the effects of disease and medications on body composition.

We conclude that it is fundamental to search for more precise and sophisticated measures in order to identify potentially overweight/obese children as earlier possible.

**OBJECTIVE MEASUREMENTS OF PHYSICAL ACTIVITY WITH SPECIAL EMPHASIS ON CHILDREN AND YOUTH**

Froberg, K., Brage, S., Andersen, LB., Jørgensen, T.
University of Southern Denmark, Denmark

Despite much progress with physical activity assessment, the limitations concerning the accurate measurement of physical activity are often amplified in young people due to the biomechanical and physiological changes that occur during natural growth as well as a more intermittent nature of habitual physical activity in youth compared to adults. This presentation describes and compares commonly used objective methods to assess habitual physical activity in youth and then moves on to discuss the main issues regarding the use and interpretation of data collected with these techniques.

Accelerometry and heart rate monitoring are currently the most frequently used methods for the assessment of physical activity and physical activity energy expenditure (PAEE) in epidemiological physical activity research. Non-linear modeling techniques of energy expenditure, using accelerometry perhaps in combination with physiological parameters like heart rate or temperature have the greatest potential for increasing the accuracy of energy expenditure prediction of habitual physical activity. Although multi-sensor systems may be more accurate, this must be balanced against feasibility, a balance which shifts with technological and scientific advances and should be considered at the beginning of every new study. A move towards more informed, investigator-controlled data handling strategies and away from proprietary monitor-based processing should aid transparency and comparability in the field.

In order to better understand the role of physical activity in the health and well-being of youth, methods of physical activity assessment and postmeasurement estimation techniques need to be further refined, methodological inconsistencies reduced and data reduction procedures clearly articulated.

**TESTING OF THE PHYSICAL CONDITION IN A POPULATION - HOW GOOD ARE THE METHODS**

Jørgensen, T., Andersen, LB., Froberg, K., Mäder, U., Martin, BW., Smith, LVH., Aadahl, M.
Research Centre for Prevention and Health, Denmark

A sedentary lifestyle has become prevalent in modern society and a poor physical condition, expressed as physical inactivity and poor physical fitness- is associated with development of chronic diseases and premature death.

The aim of this presentation is to evaluate the currently available methods for measuring physical activity and physical fitness in the general population.

Physical activity should be determined by duration, frequency and intensity and it derives from many different domains. Physical activity can be measured by objective and subjective methods. Of the objective methods accelerometry seems to be the most attractive technology, and is well enough developed for general use in large populations. The advantage of the method is that it is not dependent on memory of the individual, but the disadvantage is the fact that accelerometry seems to grossly underestimate energy expenditure, due to
the lack of registration of certain activities. This may be solved to a certain extent by combining it with heart rate measurement, an emerging technology. Of the subjective methods self-report questionnaires are feasible and easy to administer. Many questionnaires have been developed, and we are in need of further development of internationally standardised questionnaires, as e.g. IPAQ. Many questionnaires correlates well with biological markers and development of chronic diseases, but will always face a certain degree of misclassification. Remembering the duration, frequency and intensity of physical performed in the past can be difficult, especially if the recall timeframe is extensive. Furthermore, unstructured physical activity like e.g. housework may be subject to recall bias. So far no measurement seem superior to the other, and covering different aspects of physical activity it could be tempting to recommend the use of both objective and subjective methods. Advantages and limitations of subjective and objective measurements will be discussed at the seminar.

Physical fitness comprises several components with cardiorespiratory endurance as the most important, because of its strong relation to development of chronic diseases. But also muscle strengths and endurance will be discussed. As regard cardiorespiratory fitness, both maximal and submaximal exercise tests have been tested in the general population. Whereas the maximal tests do provide the most accurate results, they are also more costly or time consuming, and submaximal procedures, like cycle ergometer-test and a simple 2-km walking test, are still acceptable compared with the criterion measure: the direct measurement of oxygen consumption. As regard muscle strengths only test-retest reliability is available. The hand held dynamometers greatly facilitate field testing for maximal isometric strengths only test-retest reliability is available. The hand held dynamometers greatly facilitate field testing for maximal isometric muscle strength assessment, whereas force plate measurements can be used for the lower extremities. For endurance simple tests like push-ups and sit-ups seems reliable.

ASSESSMENT PHYSICAL FITNESS: EUROPEAN COLLEGE POSITION STATEMENT

Andersen, LB., Froberg, K.
University of Southern Denmark, Denmark

Physical fitness comprises several components including cardiorespiratory endurance muscle strength, muscle endurance, muscular flexibility, and body composition (Council of Europe 1993). This report will focus on simple methods for assessing cardiorespiratory endurance in larger populations. Direct measurement of maximal oxygen uptake is considered the golden standard, but only few studies have studied representative population samples using this method.

Tests can in principle be maximal or submaximal and protocols may use different ergometers, walking or running. Many equations estimate aerobic fitness from a number of associated variables and even equation without any exercise test have been published. These equations may quite accurately predict aerobic fitness in populations with great variability in age, gender, BMI and self-reported activity, but as variables such as age and sex cannot be changed it is important to find equations where to test result explain the variance in fitness. Submaximal tests have low reproducibility and are weaker associated to aerobic power than maximal tests no matter the type of exercise. Submaximal should mainly be used in older populations and groups of patients where maximal testing is perceived unsafe. Maximal cykel ergometer protocols have been validated and found reliable, and a number of running tests such as the Legër shuttle run test and the Cooper test are also good alternatives depending on the target group (Léger and Lambert 1982). A new intermittent running test, the Andersen test, will be presented. This test does not require any equipment. Ten to fifteen subjects can be tested in 10 min and participating children and young adults have reported they felt less exhausted than in the other maximal tests they tried even if maximal heart rate was achieved. Reproducibility was high and a correlation of 0.9 was found to maximal oxygen uptake.

OP-BN04 Biomechanics 4 - Injury

THE EFFECT OF ‘CONTROLLED’ SLIP ON MUSCULAR ACTIVITY AND GRF DURING CHANGE IN DIRECTION TASKS

Kersfing, U., Bulsink, V.
Aalborg University, Denmark

Introduction: Ankle sprains are the most common injuries during sport games. They occur during fast cutting movements either with or without interference of an object or opponent. Often considered to be a minor injury an unrecognized high proportion of complications and associated costs were stressed by Larsen et al. (1999). Many studies assessed the effect of interventions, such as bracing or training, as well as risk factors, such as foot shape, surface and others. Across these studies many contradictory results were presented. Bahr and Krosshaug (2005) explained this by the fact that the underlying injury mechanisms are not understood. Therefore, better controlled epidemiological studies and systematic laboratory experiments are needed.

A robotic platform was developed allowing for fast and controlled perturbations around 4 degrees of freedom (DOF) (van Doornik & Sinkjaer, 2007) to a force platform. This device is fast enough to simulate varied amplitudes and velocities of ‘slip’ as found in sports on different surfaces.

The aim of this study was to assess the effect of small, fast slip episodes during ground contact in a change of direction task.

Methods: Nine subjects were asked to carry out 180 degree cutting moves while making contact with the robotic plate. The plate was covered with 2 mm thick rubber to generate maximum friction between shoe and surface. Randomly, five conditions where applied just after first contact. Amplitudes ranged from 0 - 6 cm over times of 30 - 60 ms. Ground reaction forces (GRF), electromyographic (EMG) data from eight lower extremity muscles (2000 Hz) and 3-dimensional kinematics (250 Hz) were recorded.

Results: Maximum horizontal GRF showed only slight differences between conditions. Vertical GRF decreased with increasing amplitudes of slip. Power generation was highly individual and did not systematically vary with slip. Pre-activation levels of the muscles of interest were consistent across slip conditions. Some muscles showed significant increases in activation at slower slip velocities.

Discussion: Results demonstrate that restricted amounts of slip are not necessarily performance limiting. Interestingly, vertical GRF and EMG showed significant changes which may have implications for joint loading and stability. It is obvious that this experimental approach will allow for further insights in how musculoskeletal loading is affected by slips. This will be highly relevant for assessing footwear, surface and ankle stabilizing interventions.
Peripheral sensory feedback is believed to play an important role in sensorimotor control processes that usually maintain balance and stability during locomotion. Especially plantar cutaneous feedback has been shown to be an important factor in dynamic balance control [1]. For example, the clear increased rates of falls in patients with sensory loss caused by peripheral neuropathy are well documented and occur mainly during disturbances while walking [2]. However, stability control can be modified resulting to feedforward (predictive) as well as feedback adaptive improvements on postural behaviour while perturbations. The purpose of this study was, therefore, to examine the effects of predictive and feedback adaptive locomotor improvements on dynamic stability while disturbed walking by reduced plantar cutaneous sensation.

Twenty-two healthy young subjects (20-29yr), including ten experimental group (EG) and twelve control group (CG), participated in the experiment. In the EG sensation from the weight-bearing surface of both foot soles was directly reduced through multiple intradermal injections of an anaesthetic solution [1]. Sensory perception threshold of the plantar foot was quantified for pressure touch and vibration. A Motion Capturing system was used to determine the whole body 3-D kinematics and ground reaction forces, respectively. The gangway consisted of one exchangeable element not visible for the subjects to vary the surface stiffness (hard/soft). The gait-protocol comprised 23 trials with soft and hard surface, arranged to detect predictive as well as feedback strategies over the repetition trials. Components of dynamic stability were calculated according to Hof et al. [3].

Plantar cutaneous sensation was in the EG reduced (p<0.05) at the level of sensory neuropathy. Both groups increased (p<0.05) within the gait repetitions similar the margin of stability at touchdown (TD) on the disturbed leg compared to baseline walking (EG: -2.8±5.1cm to 0.4±4.2cm, CG: -1.9±3.3cm to 0.9±3.8cm). This increase in margin of stability was realized by increasing the base of support at the step before the perturbation. In the step after the perturbation the margin of stability at TD decreased (p<0.05) in both groups (EG: -3.3±4.2cm to -4.2±6.7cm, CG: -3.0±2.4cm to -9.1±5.2cm) but stabilised after 2 to 4 repetitions to the baseline values. The EG showed a higher (p<0.05) increase of base of support in the first unexpected perturbation resulting to a lower decrease in the margin of stability compared to the CG. Summarizing, the reduced plantar cutaneous sensation does not affect the predictive as well as feedback adaptive improvements during disturbed walking. The higher increase of the base of support in the EG after the first perturbation suggest a modification of the descending corticospinal pathways.

FUNCTIONAL EVALUATION OF ANKLE BRACING USING INJURY SIMULATION, BALANCE TESTING AND STABILITY PERCEPTION

Alt, W., Brand, S., Haar, B.
University of Stuttgart, Germany

Introduction
Athletes use external ankle support (i.e. tape or braces) to either prevent ankles from being sprained or to reduce the risk of re-injury. The effects of external ankle support has been investigated by means of different trapdoor or tilt platform mechanisms using electromyometers for mechanical and surface electromyography (sEMG) for neuromuscular evaluation. The aim of the present study was to compare Injury Simulation, Balance Testing and Stability Perception with two different ankle braces and without brace.

Methods
Dynamic injury simulation (DIS) (Alt and Brand, 2007) has been used in this study. Subjects wore dummy or inversion soles under shoes, with no or 24 degrees of inversion to investigate stabilizing effects of two different ankle braces (Aircast® Brace AB and Active Ankle® AA) during landing tasks. sEMG of three ankle muscles has been used to evaluate neuromuscular effects of bracing during these different tasks. Single leg balance stability (sLBS) has been measured by means of stabilometry (GK1000®) and subjective stability perception (sSP) has been tested by questionnaire. A scale from 0 (no stability) to 10 (absolutely stable) has been used. In this study N=15 subjects with no history of acute ankle sprain within the last 12 months participated (mean age 23.7 ± 1.3, mean body mass index 22.0 ± 2.2).

Results
Both maximum inversion angle and inversion velocity during DIS has been reduced significantly by braces. However, only one brace (AB) reduced plantarflexion significantly. Inversion velocity mean ± s.d. was calculated: without brace 1083 ± 505 °/s; with AB 424 ± 248 °/s; with AA 680 ± 355 °/s respectively. There were no differences in neuromuscular effects between the two tested braces. Compared to 40 seconds single leg stance without brace both braces reduced body sway with significant differences between braces, too.

SSP was calculated to 7.3 ± 1.4 (AB) and 6.6 ± 2.0 (AA) during DIS and to 7.0 ± 1.9 (AB) and 6.5 ± 2.3 (AA) during balance test sLBS. No significant differences have been found.

Discussion
Functional testing with DIS revealed a clear reduction of inversion movements by bracing which is in line with results of Ubell (Ubell et al., 2003). Compared to previous studies reflex activity of ankle muscles during static injury simulation showed a lower level. From a functional point of view task-specific reflexes could be concluded. Balance performance was improved by bracing, but it is still unclear if this is a result of neuromuscular improvement or just a mechanical effect. Subjects’ perception of stabilizing effects by bracing was in line with objective measurements.

EVIDENCE OF MECHANICAL LOAD REDISTRIBUTION AT THE KNEE JOINT WHEN PERFORMING RAMP AND STAIRCASE LOCOMOTION IN THE ELDERLY

Karamanidis, K., Arampatzis, A.
German Sport University of Cologne, Germany

It is well established that the aging process is associated with an increased rate of progression of osteoarthritis (OA) particular in weight-bearing joints such as the knee[1]. Recent studies give evidence that the magnitude of adduction moment at the knee joint during daily activities develop joint pain and OA in the elderly[2]. It is also reported that the older adults due to their reduced musculoskeletal capacities decrease their external dorsiflexion and knee flexion moment when performing locomotion activities[3, 4]. However, altering the mechanics of a joint at one plane can affect the kinetics of the other planes[5]. Assuming a new distribution at the knee joint (i.e. a conversion of the reduced knee flexion moment to a knee adduction moment), the resulting higher adduction moment could be a potential mechanism for the development of knee pain and OA in the elderly population. Therefore, in this study we examined the external joint moments at the lower extremity in all three directions in a group of older and younger adults when performing incline walking as well as stair climbing.

Twenty-eight healthy older (aged 60-69 years) and sixteen younger adults (aged 23-32 years) ascended a purpose-built 2-step staircase as well as a 3-step ramp. Motion capturing system and three force plates were used to determine subject’s 3-D kinematics and ground reaction forces, respectively. Calculation of the leg kinematics and kinetics was done by means of a three-segment 3-D rigid body’s leg model.

Older adults had lower external dorsiflexion and knee flexion joint moments but higher hip flexion moments than the younger ones (P<0.05). Concerning the other two planes older adults showed higher (P<0.05) external adduction moments at the knee and hip joint and higher knee internal rotation joint moments. Furthermore, the older adults exhibited higher (P<0.05) internal rotation values of the tibia in relation to the femur during the two examined conditions. The findings show that older adults redistribute their muscular outcome at the lower extremity increasing the contribution of the muscles surrounding the hip joint affecting the mechanical load at the knee joint. The higher adduction and internal rotation moments at the knee joint combined with the kinematic changes in the transverse plane may result to a redistribution of the mechanical load within the load bearing regions of the knee and may increase the risk of knee OA in the elderly population.

WALKING SPEED MODULATION IN YOUNG AND ELDERLY PEOPLE

Cherubini, D., Soto Hermoso, V., Cappozzo, A.
1Rome University Institute for Motor Sciences, Italy/2Granada University, Spain, Italy

Human locomotion is certainly the most analyzed motor task and subject of a great deal of literature. However, conclusions drawn are not always consistent and this is often caused by the variability of mean speed of progression SoP, stride length (SL) and cadence (SF), which are not taken in due consideration. In addition, laboratory/experimental constraints impose values to these parameters that make walking non-spontaneous, possibly affecting the analysis. Moreover, second-by-motor tasks influenced gait parameters1 and differences were observed when subjects walked at maximum speed compared to a comfortable pace2. These aspects led us to hypothesize that, during walking, an increase in SoP, supported by an increase in gait parameters, could represent a pattern that becomes apparent until effort is perceived comfortable, hence, correlated to the subjects capability.

To check for this hypothesis, we tried to rule out any possible conditioning in the subject’s natural gait while walking continuously along a circuit, in the centre of which a GAITRite system was placed. Two groups of healthy elderly (EG, n=17, 67±4 years) and young (YG, n=28, 22±3 years) people volunteered for the study. They walked starting at their most comfortable speed, slightly increase SoP each 1’30, until they perceived the effort from hard to very hard. Then, they ran only one way test at the maximum speed. For each subject, the incremental test data was clustered in terms of the 33rd, 66th and 100th percentile of the Z-score speed values. This procedure allowed us to compare the data collected for the same exerted effort, even if the exerted speed could differ. The Pearson’s correlation coefficient was computed between the gait variables, for each speed condition, and for each subject. A linear hierarchical regression was conducted to highlight possible differences in the relationship between them, during the different walking efforts.

Both EG and YG supported the increase in SoP using SF more than SL, and the EG maintained the capability of exerting SF at a similar level as the YG. The SF and SL of both groups showed high correlation values with SoP only at the most comfortable speed. As SoP increased, these values tended to clearly decrease, differently progressing in the two sample groups. Above all, the linear hierarchical regression showed high significant differences of the regression models analyzed at each speed, in both EG and YG. Moreover, both EG and YG showed highly significant differences among the variances between- and within-subjects, for each parameter.

Our results confirm the hypothesis that during walking the increase in SoP is consistently determined by a linear increase of SL and SF, but only until the effort is perceived as comfortable. Beyond this limit, and irrespective of age, consistency among individuals becomes less robust.

Wheels of the routes’ origin and destination points were accurate and reproducible. GPS tracings of actual commuting routes taken (n=19) tested for normality using a 2-sided goodness-of-fit Lilliefors test (p<0.05). After that, a one-sided paired t-test was performed to verify if the mean distances covered in the first half of the game were greater than in the second half. The total distance covered by the players ranged from 3522.3 to 5690.2 m (4563.3 ± 822.8 m). Because the duration of first (31.6 min) and second (35.7 min) halves were not the same, the mean velocity value was compared. The mean velocity of player movement in the first half was 1.21 ± 0.20 m/s. The mean velocity of player movement in the second half was 1.06 ± 0.20 m/s. The results of the Lilliefors test (p<0.05) revealed that the data were normally distributed. The mean velocity in the 1st half of the game was significantly greater (p<0.001) than in the 2nd half, with a decrease of 13%. Conclusion: These results show the feasibility of this methodology to analyze wheelchair rugby. In addition, the results provide important information regarding player movement patterns during the game that can be used by coaches to plan adequate training strategies.

OP-HF08 Health and Fitness 8 - Testing Protocols

A CRITERION METHOD FOR MEASURING ROUTE DISTANCE IN PHYSICALLY ACTIVE COMMUTING

Schantz, P., Stigell, E.
The Åstrand Laboratory, Sweden

Introduction

Distance is a variable of pivotal importance for analysis of many different issues of physically active transportation. Thus, there is a need for accurate and reliable methods for determining route distances. The aim of this study was therefore to scrutinize if distances of commuting routes drawn by physically active commuters and measured with a digital curvimetric distance measurement device could serve such a purpose.

Methods

Participants were recruited when they walked or bicycled in the inner urban area of Stockholm, Sweden. Questionnaires and individually adjusted maps were sent twice to the participants (n=133). Commuting routes from home to work were drawn on the maps. These were measured using a digital curvimetric distance measurer which was carefully checked for validity and reproducibility. Marked origin and destination points were checked for validity using stated addresses and geocoded site search systems. 19 subjects were followed with GPS for validity checks of drawn routes. An analysis of the effect of any deviations between GPS route tracings and drawn routes on distance measurements was undertaken.

Results

The test-retest correlation coefficient was 0.998 (p ≤ 0.01) and the equation for the linear regression was y = -0.026 + 1.002.x. Thus the test-retest values accumulated along the line of identity. The typical percentage error for the method was 2.4 per cent. The map markings of the routes’ origin and destination points were accurate and reproducible. GPS tracings of actual commuting routes taken (n=19) displayed in six cases slight deviations from the routes indicated by the commuters on the maps. However, these deviations played an insignificant role (0.4 per cent) for distances measured.

Conclusion

Routes drawn on maps by physically active commuters represent a valid and reproducible basis for distance measurements in physically active commuting.

DETERMINATION OF PHYSICAL ACTIVITY LEVEL WITH DIFFERENT RESTING HEART RATE PROTOCOLS

Sahin, Z., Hazir, T., Acikada, C.
Hacettepe University, Turkey

Purpose: The aim of this study was to investigate the effects of different resting heart rate (HRrest) protocols on definition of physical activity level (PAL) of adolescents assessed by heart rate reserve (HRR).

Method: Minute by minute heart rate (HR) were continuously monitored over one week in 51 healthy adolescents aged 14-16-yrs. Different percentages of HRrest (maximal resting) were calculated and evaluated as low (below 50% HRR), moderate (between 50-70% HRR), and vigorous (above 70% HRR) PAL. Maximal heart rate (HRmax) was measured with the shuttle run test and HRrest was determined with five commonly used protocols (minimal mean HR of 7 nights HRnight), all daily HR within lowest 3 beats (HRmin<3), means of the lowest 5
beats (HRmin5), lowest 10 beats (HRmin10), lowest 50 beats (HRmin50), and, thus, 5 different HRR obtained. Furthermore, moderate to vigorous physical activity (MVPA) sustained over 5-, 10-, 20-, and 30- minutes were also calculated as frequency and duration. The differences between variables were analysed with Repeated Measures ANOVA with Bonferroni. Regression analysis was used to determine the accuracy of HRmin+3, HRmin5, HRmin10, and HRmin50 with HRnight which was taken into account as a reference protocol. In addition, Bland-Altman plots were used for agreement between the protocols with HRnight.

**RESULTS**

The differences between protocols were found significant. HRmin5 values were found significantly lower than the other protocols except for HRmin+3 (p<0.05). Furthermore, HRmin10 were found significantly lower than HRnight (p<0.05). However, HRmin50 values were found significantly higher than other protocols except for the HRnight (p<0.05). HRnight protocol considered as a reference protocol and the regressions between HRrest by HRnight and other protocols did not significantly deviate from the line of identity. Bland-Altman analysis revealed no significant bias between HRrest measured by HRnight and other protocols. However agreement limits of HRrest were high for other protocols (+6/-9 bpm). PAL frequency which calculated from HRmin5 protocol of 10-19 minutes sustained MVPA were significantly higher than HRmin50 protocol (p<0.05). PAL durations which calculated from HRmin50 protocol of 10-19 minutes sustained MVPA were significantly lower than HRmin5 and HRmin10 protocols (p<0.05).

**Conclusion:** This study pointed out that, although, HRrest from different protocols overlapped with reference protocols, these protocols on estimation of physical activity levels of adolescents, which assessed by HRR, showed differences according to chosen protocol and cannot be used instead of each other.

**COMPARISON OF TWO ACCELEROMETERS FOR THE MEASUREMENT OF ENERGY EXPENDITURE IN FEMALES DURING WALKING**

Harrington, D., Donnelly, A. University of Limerick, Ireland

Objective and valid measures of Physical Activity (PA) are important for quantifying free living PA levels in different populations (Rowlands & Eston, 2007). One non-invasive method of estimating PA is collection of data from recording accelerometers, which allow several days of continuous measurement. Data from accelerometers can be used to estimate energy expenditure in activities such as walking.

The aim of the study was to compare the effectiveness of two accelerometers, the ActiVital Professional physical activity logger (PAL Technologies Ltd, Glasgow, Scotland) and the Actigraph accelerometer (LLC, Pensacola, Florida) in predicting Energy Expenditure (EE) during walking.

The study was approved by the University of Limerick Research Ethics Committee, and volunteers completed informed consent documents prior to participation. Seventeen females aged 23 (SD 2) yrs walked for 7 minutes at each of 5 speeds (3.2, 4.8, 5.6, 6.4 and 7 km per hour) on a treadmill whilst simultaneously wearing the ActiVital and the Actigraph accelerometers. Oxygen consumption and other variables were recorded for the last 2 minutes at each walking speed by expired gas analysis. Step counts were recorded every 15 seconds by the accelerometers and also by analysis of video recordings. Additionally, accelerometer counts were sampled by both accelerometers for each 15 second epoch.

Step count agreement r-value between ActiVital and Actigraph was 0.954. Correlations between ActiVital steps and Actigraph steps with manual steps count were 0.988 and 0.953 respectively. When comparing energy expenditure (kilojoules per minute) with the two accelerometer step counts, the agreement was 0.594 and 0.552 for the ActiVital and Actigraph respectively. Adjusting the energy expenditure for body weight increased the agreement to 0.632 and 0.581 for the ActiVital and Actigraph respectively. On comparing metabolic equivalent to step count of the two accelerometers, correlations of 0.543 and 0.528 for the ActiVital and Actigraph respectively were seen. Comparison heart rate at each speed to step count revealed correlations of 0.727 and 0.685 for the ActiVital and the Actigraph respectively. However, accelerometry counts correlated more closely with EE.

Both accelerometers accurately measured step count, though the Actigraph tended to underestimate counts at low speeds. Relatively low correlations between accelerometry and measured EE indicate that accelerometry can at best only approximate EE with the ActiVital outperforming the Actigraph in all analyses. However, raw acceleration data may provide a better predictor of EE since it is more sensitive to small changes in intensity.

**ESTIMATION OF LOAD INTENSITY WITH HEART RATE VARIABLES IN A SPECIFIC CIRCUIT WEIGHT TRAINING**

Benito, P.J., Alvarez, M., Díaz, V., Peinado, A.B., Calderon, F.J. Universidad Politécnica de Madrid, Spain

**INTRODUCTION**

The estimation of exercise intensity through heart rate (HRR) has been studied several times (1, 2). However, the way to control the intensity in strength training has been traditionally the weight lifted, instead of using physiological variables. The aim of this study was to develop an equation to predict training intensity based on easily measurable physiological variables as HR, body weight or work load.

**MATERIAL AND METHODS**

Twelve subjects participated in this study, six men (23.7±1.6 years; 71.5±1.8 Kg.; 174.6±10.5 cm.) and six women (23.3±1.0 years; 56.4±2.8 Kg; 160.9±4.2 cm.) with the following characteristics: healthy students of Physical Education and physically active. The protocol consisted of evaluate a circuit training with seven exercise at six different intensities (40% to 85% of 15 repetition maximum (15RM)) with rhythm fixed at 1:2 (concentric-excencentric). The 15RM were calculated individually for each exercise. All cardiopulmonary variables were measured with a portable metabolic system (Jaeger Oxycom Mobile®).

A step by step regression analysis was used to predict load intensity in the test. Significant level was set at p<0.05.

**RESULTS**

The following variables were used to predict the intensity: HR relative to maximal HR (HRR%), mean HR measured during the circuit (HR), maximal HR measured during the circuit (HRmax), HR after two minutes of recovery, mean load moved during the circuit (Loadavg), intensity relative to the HR reserve and body weight. There were obtained three models, but these were the chosen equations that they predicted better.

For men:

\[ \text{I (\%)} = 57.265 + 0.512 \text{ HR} - 0.696 \text{ HRmax} + 1.035 \text{ Loadavg} + 0.188 \text{ Body Weight} \] (R²=0.92; SEE=4.9%);

For women:

\[ \text{I (\%)} = 4.036 + 0.412 \text{ HR}\% + 1.667 \text{ Loadavg} \] (R²=0.79; SEE=7.7%).

**DISCUSSION**
It is obvious that estimating the proportion of work load during circuit training is sometimes difficult. The relationship between HR and VO2 is different depending on the activity (3) and the implied body limbs (2). Using HR in EE estimation is not new in exercise (3, 4), although few studies have applied these techniques in circuit training (3). Rotstein et al. indicate a better prediction of intensity for running than for arm exercises. However, as Collins et al. pointed out, the relation HR/VO2 is linear for intensities between 40 and 70% of 1RM. But it is possible to emphasize that until the moment none have proposed estimation equations based on gender differences.

BASE - A NEW CONCEPT FOR HEALTH PREVENTION FOR LOGISTICS WORKERS

Wollesen, B., Mattes, K.
University of Hamburg, Germany

The demographic change in Germany increases the working life of employees. Therefore health prevention programs in companies become more relevant. There are many well designed programs to reduce lower back pain but only a few of them integrate participating elements. To prevent muscle-skeletal disorders in employees with manual boxlifting activities the concept BASE was created (BASE is an acronym in German for: B= “Bedarfsbestimmung” for requirements, A= “Arbeitsorganisation” for organisation of work, S= “Schulung des belastungsverträglichen Alltagshandelns” for coaching preventive behaviour at work, E= “Eigenverantwortung u. Selbstwirksamkeit” for self responsibility and self efficiency). This concept integrates a problem- and practical-orientated view of prevention. Currently the outcomes of BASE for (1) practicality, (2) outcome effects in box handling techniques and (3) lasting effectiveness are examined.

Methods: 38 workers (mean age 34.7± 9.9) of a Logistics company were tested. 18 workers started with a 10 week BASE-Intervention (45 min 1x a week during work time). Health related data was collected using the SF12 and the Nordic questionnaire. The mental representation of the boxlifting technique is measured by the SPLIT 0.56 software and calculated by the SDM-A method of Schack (2004). The PILE-test (Meyer et al. 1988) combined with video was used to collect data of the boxlifting process under resistance load. The PILE-test ended when the worker lifted the box in an dysfunctional way. 2D kinematics was used to collect information of the boxlifting technique.

Results: 22 workers had lower back pain (LBP) in the last 12 months. Workers with LBP showed a reduced physical wellbeing (p= 0.032, F=0.8319). The mental representation of the boxlifting process is not unique however the process is mostly unknown. The PILE-test ended at a weight of (14.8 ± 7.7 kg).

Discussion: The results showed the importance of a “technique-orientated” education of the boxlifting process to reduce lower back pain and to prevent muscle-skeletal disorders. Under stress conditions during the PILE-test it was shown that low technical expertise results in dysfunctional behaviour. The BASE concept integrates coordination, perception and technique factors. Workers learn to be aware of their body positions during the working process to be able to correct dysfunctional body positions. It is expected that increases in the PILE-test with optimised body positions after 10 weeks of the BASE-intervention will be recorded. Furthermore, we think that the mental representation will be more detailed.

PHYSICAL ACTIVITY AND FITNESS OF CHILDREN AGED 9-10 YEARS: A-CLASS PROJECT

Ridgers, N., Graves, L., Stratton, G.
Liverpool John Moores University, United Kingdom

Physical activity is an integral component of a healthy lifestyle, with positive relationships documented between physical activity levels, fitness and indices of health. The aim of this study was to investigate the baseline physical activity levels and fitness of children participating in the Active City of Liverpool, Active Schools and SportsLinx (A-CLASS) Project.

One hundred and fifty-four children (41% boys, 59% overweight) from 8 schools participated in the study. Children’s fitness was assessed using a discontinuous, incremental exercise test to volitional exhaustion, which involved walking (4 and 6 km.h-1) and running (8, 10, 12, and 14 km.h-1 or until volitional exhaustion). Participants exercised at each speed for 3 minutes with 30-s passive recovery between stages. Following volitional exhaustion participants actively recovered for 5 minutes at 3.5 km.h-1. Respiratory variables were averaged using uni-axial accelerometry over seven consecutive days. The main outcome variable was total physical activity (counts per minute (CPM)). Children were divided in to tertile groups based on VO2peak scores. Analyses of variance were used to determine differences in tertile groups and boys and girls’ total weekday, weekend and whole week physical activity.

Boys VO2peak (51.7 ± 6.7 ml kg-1 min-1) was significantly higher than girls (43.7 ± 6.5 ml kg-1 min-1; p > 0.01). Results revealed no significant differences between boys and girls weekday (boys = 589 ± 140 CPM; girls = 575 ± 313 CPM), weekend (boys = 667 ± 247 CPM; girls = 564 ± 211 CPM) and whole week total physical activity (boys = 611 ± 155 CPM; girls = 572 ± 253 CPM). A tertile group main effect was found for weekend physical activity, with the lowest tertile (532 CPM) being less active than the highest tertile group (1644 CPM; p = 0.04).

No other main effects were found for tertile group. No tertile group x sex interactions were significant (p > 0.05).

The results do not support previous studies where boys are reported to be more significantly active than girls both during weekdays and weekend days. In addition, this study suggests that weekend activity is greater than weekday physical activity, though differences are small (32 CPM). The finding that the least fit tertile were less active than the most fit tertile during the weekend in this study suggests that the weekend may be an important period in childhood for children to accumulate physical activity that may benefit fitness and health.
MIRROR NEURONES ON A BALANCE TASK: SELF-OBSERVATION AND IMITATION
Catela, D., Branco, M., Grilo, V., Fernandes, S.
Escola Superior Desporto Rio Maior, Portugal

Mirror neurones fire both when the monkey observes an agent acting with the hand upon an object and when the monkey grasps the object itself (Rizzolatti et al., 1988). Those neurones may mediate the internal representation of actions evoked by the observation of the actions of others, playing a role in both imitation and recognition of action (Rizzolatti et al., 1996). During a seated balance task on a fitness ball, we have exposed 20 adults (20.8±1.60, 10 women) to 4 conditions: (i) doing the task without demonstration or self-observation, (ii) looking at oneself in a mirror, (iii) first looking to the instructor doing the task and then doing it, (iv) looking to the instructor and then to oneself in the mirror. Time of standing on the ball without falling was recorded. Order of conditions, were random-ized across subjects (4 groups). Mirror neurones activation is supported if condition (iv) promotes better performance than the other three conditions. Additionally, conditions (ii) and (iii) should promote better performance than condition (i). Data was treated on SPSS v. 15.0.

Only condition (iv) revealed normal distribution of data (Shapiro-Wilk, p>0.05). Friedman test revealed significant differences among experimental conditions (Greenhouse-Geisser adjustment) (Wilcoxon signed ranks test revealed that on condition (iv) subjects performed significantly more time (14.90±9.08s) than on conditions (i) (10.64±9.95s, Z=2.837, p<0.011) and (ii) (12.12±8.97s, Z=2.539, p<0.03), but not compared with condition (iii) (12.67±8.78s, Z=1.867, p>0.05). Friedman test revealed significant differences among conditions (i) and (ii) (Z=2.359, p<0.05) and (iii) and (iv) (Z=2.651, p<0.01). There were no significant differences among conditions (ii) and (iii) (Z=0.784, p>0.05). Results completely support mirror neurones' role: observation of the actions of another person may have played a role on a better performance (condition (iii), which combined with self-observation (condition (iv)) seemed to upgrade the effect of imitation 4.

Observing others and self execution favours motor learning and may have a neuroethical support on mirror neurones. Because no instructions were involved, perception-action perspective (Reed, 1982) is strongly supported, namely because condition (iii) and (iv) had similar effect on performance.

MULTISENSORY INFORMATION: DOES AUDIOVISUAL INFORMATION ENHANCE MOTOR LEARNING?
University of Hanover, University of Bremen, University of Hamburg, Germany

A growing number of studies has been realized about efficiency of multisensory information in motor learning in basic research (1), but only a few studies related to applied research. Here we focus on motor learning of rowing and compared learning based on two different conditions: For the visual group (VG) instruction as well as feedback was given as video and for the audiovisual group (AVG) there was audiovisual instruction/feedback in terms of video + motion attendant sounds (MAS), the sound of the rowing-ergometer blower-wheel and sliding seat. To quantify differences of subjects’ technique compared to the models’ technique a dynamic-time-warping algorithm was adapted.

Method: 32 male subjects (all novices) tried to learn the rowing technique on the ergometer. Instructive technique was demonstrated as a video of a junior world champion, performing on an identical ergometer with low power. The performance of VG (video instruction) and AVG (audio and video) were compared. Subjects had been parallelized for initial performance index and age. Technical performance was measured with four sensors (grip force, footrest force, grip pull-out, sliding seat position) on a pre-test, for three weeks of training (2 trainings a week á 5 blocks) and two blocks on three week retention. For all sessions differences of subjects’ technique to the models’ technique were computed using a dynamic-time-warping algorithm. MAS were captured with a directional microphone (Behringer ECM 8000) and monitored via headphones (sennheiser dynamic DT 100).

Results: Learning effects became evident over the whole training as well as over a single training session (ANOVA, rep. measurements, main effects on ‘training’ was 18.2; p<0.01; ‘block’ was 10.7; p<0.01). Also learning effects remained stable, no differences between last training
and retention became evident (t-test, VG: T = 23, p = .82, AVG: T = 80, p = .43). Between both groups no differences became evident (treatment between groups: F = .06, p = .82, ANOVA, rep. measurement).

Discussion: Though we got evidence that the experimental setting was well suitable to initiate motor learning of a closed skill, no benefits of additional acoustic information became measurable. Results are surprising, because the ergometer generates a broad spectrum of MAS for a long period of each rowing cycle. The instruction model video contains corresponding MAS, though a comparative orientation between subjects’ own and models’ sound pattern should have been feasible. Maybe the duration of MAS IID each 50 cycle-training block was too short or visual information is sufficient for initially acquiring the technique of ergometer rowing.

**EFFECTS OF FREQUENCY OF KNOWLEDGE OF RESULTS ON MOTOR LEARNING IN PERSONS WITH DEVELOPMENTAL DELAY**

Mendes, R., Rita, N., Chiviacoswsky, S.
Escola Superior de Educação - Instituto Politécnico de Coimbra, Portugal

Knowledge of results (KR) is one of the most important learning factors. The purpose of this study was to investigate the effect of relative frequency of KR on motor learning. High (100%) and low (50%) frequency knowledge of results were applied in a group of 24 individuals with developmental delay (age from 22 to 57 years) and in gender and age-matched average individuals learning a motor skill; over-hand throw a tennis ball to the target circle on the carpet. Participants were randomly assigned to either a 100% KR or a 50% KR group. KR was provided during the 40 trials of acquisition phase according to group assignment as participants learned the motor skill, whereas no KR was provided during the retention phase (10 trials) performed 15 minutes later. The results indicated both populations who received 50% KR in the acquisition phase showed better performance in the retention phase than those who received 100% KR. These results were consistent with Rice and Hernandez (2006) results with a motor learning a laptop computer task. As has been found in the average population, reducing the KR frequency provides for individuals with developmental disabilities the opportunity to develop intrinsic error detection and correction capabilities on the no-KR trials.

**MOTOR TASK DOES NOT ALTER SYNCHRONOUS CHANGES IN EXCITABILITY OF HAND MUSCLE REPRESENTATIONS IN HUMAN MOTOR CORTEX DURING MOTOR PREPARATION**

Lavender, A., Harrison, J., Hunter, D., Ngo, M., Scott, O., Nordstrom, M.
The University of Adelaide, Australia

Muscle evoked potentials (MEP) following transcranial magnetic stimulation (TMS) vary in size from trial-to-trial. These fluctuations are positively correlated for muscles of the same upper limb [1], partly due to synchronous fluctuations in corticospinal neuron excitability. The mechanism and function of this coupling is unclear, but widespread corticomotor (CM) synchrony may assist in dynamic linking of neurons for particular tasks (binding). To assess functional organization of CM synchrony we compared the correlation of MEP size fluctuations for 2 hand muscles during preparation prior to a movement requiring their synergistic or independent activation. We hypothesized that CM synchrony would be stronger when the movement plan calls for synchronous activation of hand muscles compared with the independent activation of one muscle of the pair.

Surface electrodes recorded electromyographic (EMG) activity from left first dorsal interosseous (FDI) and abductor digit minimi (ADM) in ten healthy right-handed subjects (6M, 4F; 24±2 yrs), with focal TMS to right motor cortex. A choice reaction protocol was employed. Subjects were given a visual cue (0200 ms) indicating one of four movement tasks (randomised order), followed by an auditory cue to execute the movement starting at 550, 600, 650, 700 or 750 ms. TMS (1.3 x resting motor threshold) was delivered at 380 or 440 ms. Tasks were 1) relax both FDI and ADM, 2) activate ADM (relax FDI), 3) activate both FDI and ADM, and 4) activate FDI (relax ADM). Trials were repeated every 5s in 5 blocks of 40 (50 trials/task). Subjects relaxed the muscles prior to the audio cue, whereupon they abducted the instructed digit or digits as quickly as possible. They were tested after training required for satisfactory task performance. MEP peak-to-peak amplitude was quantified for FDI and ADM in each trial. Linear regression coefficient (r) revealed a significant positive relationship between FDI and ADM MEP size for the 50 trials/task in 37/40 (93%) comparisons. Mean (±SE) regression coefficients (r=1) were: task 1, 0.49±0.06; task 2, 0.49±0.04; task 3, 0.50±0.06; and task 4, 0.43±0.04, with no significant difference between tasks (F3,9 = 0.56, P>0.05). Mean MEP amplitude did not differ between tasks (F3,9 = 2.31, P>0.05).

These results suggest that CM synchrony does not change in the early period of motor preparation when synchronous, rather than independent, activation of muscles is required for the movement. During this period overall CM excitability remained unchanged. Differences in CM synchrony may emerge if TMS were applied closer to movement onset, when CM excitability is enhanced for muscles engaged in the movement [2]. The present findings, however, do not support the hypothesis that CM synchrony reflects functionally relevant binding of sub-populations of corticospinal neurons controlling hand muscles.

**COMPARISON OF POSTURAL SWAY BETWEEN GYMNASTS AND NON-GYMNASTS**

Hastings, K., Goss-Sampson, M.
University of East London, United Kingdom

Maintaining upright stance normally requires minimal conscious control and relies on the continuous regulation and integration of somatosensory inputs from the central nervous system. Two mechanisms have been proposed for the control of quiet stance, firstly that the body acts as a spring damped inverted pendulum pivoting at the ankle and secondly that postural adjustments are achieved using feed-forward and feedback neural control. The objective of this study was to investigate postural sway parameters in gymnasts and non-gymnasts using three postural conditions.

14 female gymnasts and 10 female non-gymnasts were recruited. Three conditions were studied: Normal stance, feet placed a pelvic width apart (NoS); narrow stance, with feet in tandem (NaS); and beam stance (BS) which was the same as the NaS but on a gymnastic beam set 80 cm above the floor. Retroreflective markers (19 mm) were placed bilaterally on the ankle, knee, pelvis, shoulder and head. Participants performed 5 trials in each position, the order of which was randomised. For each trial 30 seconds of kinematic data were collected (100 Hz) using 8 MPU 240 cameras (Qualisys SE). The stochastic nature of sway led to non-normally distributed data, therefore,
statistical significance between groups was analysed using non-parametric tests. Significance for all statistical analyses was accepted at P < 0.05. All subsequent data are presented as mean ± sd. No significant differences were found in segmental sway areas between the non-gymnasts and gymnasts in the normal stance condition. All subjects exhibited an inverse conical sway volume when segmental absolute sway areas were viewed from the ankle to the head, irrespective of stance condition. The absolute sway areas (mm²) for each segment were as follows: knee (52 ± 1.1), pelvis (20.3 ± 3.4), shoulder (30.3 ± 4.3) and head (45.1 ± 6.4) each being significantly different to the one above. In both the narrow and beam stance conditions both groups significantly increased their sway areas at all segmental levels compared to normal stance. When comparing the transition from narrow to beam stance, non-gymnasts significantly further increased their sway areas at all segments except the pelvis. In contrast, gymnasts showed no further increase in any of the segmental sway areas. This appears to be the first study showing segmental postural differences between non-gymnasts and gymnasts. Compared to normal stance, the reduced base of support in narrow stance provides a greater postural challenge as evidence by both groups increasing their postural sway at all segmental levels. However, when this same position is performed on the beam non-gymnasts show a further increase in sway instability. These findings do not appear to be explained by the inverted pendulum mechanism but suggest that feed-forward mechanisms may dominate in such conditions.

OP-PE04 Physical Education 4 - Physical Activities

PHYSICAL ACTIVITY GUIDELINES: COMPLIANCE IN A SAMPLE OF CHILDREN AND YOUTH WITH 60 MINUTES OF MODERATE TO VIGOROUS PHYSICAL ACTIVITIES (MVPA)

Ribeiro, J., Sousa, M., Sá, C., Santos, P., Silva, P., Aires, L., Mota, J.
Sports Faculty, University of Porto, Portugal

Physical inactivity is a well documented risk factor for coronary heart disease and is associated with increased risk for other chronic diseases, including obesity, Type II diabetes mellitus, hypertension, colon cancer, depression, and osteoporosis. Despite evidence on the social, health, and personal benefits of physical activity, many people still choose not to exercise. Accordingly, promoting physical activity has become a public health priority worldwide. Because of the growing awareness of the health benefits of regular physical activity, public health guidelines for physical activity have been established. Several of these guidelines focus on youth. PURPOSE: The aim of this study was to compare the compliance between boys and girls of 60 minutes of MVPA during almost every day of the week (60MVPA).

METHODS: A random sample of 210 (12-18 years) boys In, 80, age, 15.11 ± 1.63, weight, 62.4 ± 14.3, height, 168.6 ±11.1, BMI, 21.7 ± 3.6) and girls In, 130; age, 14.8 ± 1.8, weight, 53.7 ± 9.5; height, 159.1 ±6.6; BMI, 21.2 ± 3.3) was evaluated from Porto region. Body Mass Index (BMI) was calculated from the children’s height and weight [weight (Kg)/height² (m)]. The following measurements were carried out: percentage of fat mass, and PA levels (GT1M, MTI Acligraphs). The activity monitor was used as instrument to objectively measure daily PA. The study was conducted during 7 consecutive days. RESULTS: Our results reveal that there’s a difference in the compliance of 60MVPA between boys and girls, during all days of the week and weekend (p<0.05). When comparing results in the different days of the week, we can observe that in girls the percentage, meeting the guidelines for a day, fluctuate between 19.4% (Saturday) and 70.6% (Sunday). When comparing boys we can examine values between 47.7% (Sunday) and 84.6% (Friday). Unfortunately when we analyze all children that accomplish the recommendations of 60MVPA during all days of the week (7 days) only 15% of boys and 7% of girls meet the criteria. CONCLUSIONS: The prevalence of children and youth meeting the guidelines of 60MVPA for every day of a week is very small, although when comparing individually the days of the week we can find percentages between 19.4% (girls) and 84.6% (boys) in specific days of the week. There is uncertainty concerning the true prevalence of compliance with physical activity guidelines in Portuguese children and youth, a national representative sample is needed in order to establish several public health strategies aiming at increasing the compliance with physical activities guidelines.

EXPERIMENTAL RESEARCH IN MOTOR AND SPORT ACTIVITIES FIELD IN PRIMARY SCHOOL IN ITALY: AN INTEGRATED MODEL OF ACTION RESEARCH AND DESCRIPTIVE RESEARCH

Sibilio, M., Raiola, G., D’Elia, F., Goldieri, M., Carlonmagno, N.
University of Salerno, Italy

Experimental Research in Motor and Sport Activities Field in Primary School in Italy: an Integrated Model of Action Research and Descriptive Research

Every activity that becomes part in Italian school, including research, must model itself on the complex educational system that is regulated by didactical, organizational and managerial constraints. It is necessary for all areas of research to be carried out in school during childhood, to use a methodology fit for an integration with the program, mostly impacting on didactic and on the quality of teaching. Therefore research in motor-sports activities in the educational contexts requires the use of methods and techniques compatible with the culture and the rules of school, with its logistics, its organizational models, its educational needs and its professional characteristics. Action research and observational research meet these requirements. Kurt Lewin (Lewin, Weiss Lewin, 1948) coined the terms “action research” to describe a particular qualitative research whose characteristics permit to intervene in the observed phenomenon. Many researchers have developed this model of research directed primarily to solve educational problems (McKinnon & Whitehead, 2006). The observational research in this educational practice involves techniques for observation of behaviors, recording quantitative and qualitative aspects.

Educational research in the motor-sports field is subject to constraints that are not present in other fields and that require researchers’ specific skills. As a matter of fact every activity of movement involves apparatus and body systems, produce neurophysiological reactions and is regulated by biomechanical principles. In particular the effect of motor both at cognitive and at functional level binds to a number of factors related to the sex, the age, the characteristics of the subject.

The organization and supervision of the research is linked also to the need to guarantee security conditions of the child during execution - individual and group - phases in advance.
Then the activity must combine different models of research in an integrated frame whose specific characteristics allow to implement a “practice aimed to the improving of teaching and learning” (Kemmis S. & R. McTaggart, 1988), within a more complex research protocol which integrates the positive aspects of action research, the ties of experimental research and the methodologies of observational research in sport-motor field (Thomas Nelson & Silverman, 2005).

PICTURES OF ACTIVE AND INACTIVE GIRLS IN SWEDEN; PHYSICAL ACTIVITY, LEARNING PROCESSES IN SCHOOL PE AND SIGNIFICANT OTHERS

Meckbach, J., Lundvall, S.

GIH, Swedish School of Sport and Health Sciences; Sweden

Several studies show that girls have lower physical activity levels in relation to boys and that the dropping out rate from organized sport occurs earlier for girls than boys. In Sweden there is also a higher percentage of non-participation in school PE among female students. Although data shows that inactive teenage girls would like to become more physically active, but they don’t know how.

Objective: The aim of this study has been to describe and analyse female students and their self-reported physical activity level in relation to attitudes to school physical education, learning processes, significant others.

Method: Data from a follow up study 2002 within a multi disciplinary project called School-Sport and Health (SIH) has been used. The SIH-base study contained 48 randomly chosen schools, in total 1975 students. The follow up study was undertaken 1 1/2 years after the base study, where a strategic sample of the five most physical active schools together with six of the less active was undertaken. The categorization was made by a self-reported physical activity index. Results from questionnaires to students aged 14 103 girls and 117 boys and their parents 186 will be presented. The results have been analysed by SPSS. Included in the analysis is also a neighbourhood environmental index for physical activities, which was measured for each participating school.

Results: The girls and their parents have a corresponding opinion of the girls’ view of their self as an active or non-active person. Inactive girls had, surprisingly, more negative attitudes towards the subject PE and the learning process in terms of experienced learning competence, attitudes towards learning and expressed feelings about the subject. They also had lower grades and fewer friends that were physically active. The mother’s influence (as a significant other) is only significant for the active girls. Socio-economical background in terms of the mother’s educational level, the parent’s own physical activity or view of the school PE had no relation with the activity level of the girls. A majority of the parents valued the school PE as equally important as other subjects in school. When it came to the neighbourhood environmental index, schools rating low on the environmental index scale showed a significant higher incidence for inactive female students.

Discussion: The presented data will be discussed from a critical pedagogical perspective in the context of existing research with focus on girls, gender order and the school subject PE and physical activity.

CHANGES IN THE ABILITY TO CONCENTRATE BY THE INTRODUCTION OF DAILY PHYSICAL ACTIVITY DURING LESSONS IN SECONDARY SCHOOL AGES

Seidel, I., Rummer, K., Sedlak, A.

Universität Karlsruhe, Germany

Problem
Current empirical results inferring that physical activity influences on the ability to concentrate are inconsistent (Memmert & Weickgenannt, 2006). Some studies have proven statistical connections between physical activity and learning (Etnier et al., 1997). Unfortunately, few studies have been made in secondary schools. Furthermore, almost no substantiated data indicating the influence of physical activity on the learning ability are available. Therefore, we examined the effects of daily physical activity on the development of the concentration in a secondary school with pupils aged 13 to 17.

Method
Over a period of ten weeks 103 pupils from grades 8-11 received daily activity breaks of five minutes duration in the fourth and sixth blocks of the school day (TG). The 101 pupils of the parallel classes served as control group (CG). The development of the ability to concentrate was measured using the d2 Test of Attention (Brickenkamp, Zillmer, 1998). This test shows good reliability and validity and is suited as an compatible procedure for the analysis of the ability group being researched. The test was conducted prior to the intervention, after 4 weeks and at the end of the complete 10 weeks of intervention. To determine the differences in the development of performance, variance analyses of the KL-parameter were carried out.

Results
Over the period of 10 weeks both TG (n=82) and CG (n=84) improved their ability to concentrate [F=322.54; df=157; p=.000; part. eta²=.80]. The additional influence of the intervention couldn’t be statistical verified [F=2.80; df=157; p=.06; part. eta²=.03]. However, the analyses show an interaction over time between TG/CG and the grade level [F=2.55; df=316; p=.02; part. eta²=.05]. Particularly the pupils in the 9th grade belonging to the TG, performed significantly better after the intervention. Moreover, the analysis shows that the TG achieved higher rates of increased performance than the CG [F=6.66; df=157; p=.002; part. eta²=.08].

Discussion
The results show, that the pupils, who take place in a regular daily physical activity program during school lessons, can reach a higher level in their ability to concentrate after a period of ten weeks, than the other pupils do. The next question is, if this improvement of the ability to concentrate as one part of the learning conditions can improve the learning results.

RELATIONS OF MOTOR FITNESS OF PRESCHOOLERS AND SOME ANTHROPOMETRIC MEASURES

Serbetar, I.

Faculdade de Motricidade Humana, Portugal

This paper identifies and analyzes meaningful research carried in Portugal about preactive decisions of PE teachers, in the last 15 years, published by authors in books, reviews, and master and doctoral thesis. Previous syntheses are upgrading (Carreiro da Costa, 2006; Sanches & Jacinto, 2004).

Methods.

Initial sample was consisted from 68 children (38 boys) in a mean age of 6.17 yrs ± .67. EUROFIT test battery (Adam et al. 1988) was performed in order to assess motor fitness of preschool children. Flexed arm hang was not performed, instead children were measured with additional test of coordination so called Indian skip. Five anthropometric measures were also taken (height, weight, subscapular, triceps and abdominal skinfold), and body mass index was calculated. Multiple linear regression analysis was used to determine the association between motor variables set as dependent variables while anthropometric measures (BMI and skinfold measures) were used as independent variables. Since ANOVA revealed difference between boys and girls only in grip strength and in standing long jump, at first regression analysis was done for whole sample. Additionally three separate regression analysis were performed on three subsamples classified on the basis of summarized T-scores (Baumgartner and Jackson, 1999) for motor variables.

Results.

After adjustment for outliers regression analysis on whole sample showed that tapping (R² = .61 F(4,40)=5.78 p<.009) and shuttle run (R² = .58 F(4,40)=5.07 p<.002) were significantly predicted by independent variables although only triceps skinfold BETA was significant. Grip strength was significantly related to body mass index and abdominal skinfold (R² = .55 F(4,40)=4.24 p<.006). On the basis of sum of T-scores of motor variables participants was divided in high level fitness group, middle level and low level group. Regression analysis performed on those limited samples groups showed that in low and middle level groups group significant relations were obtained between Indian skin and independent variables (R² = .77 F(4,15)=5.63 p<.006). BETA coefficient of BMI, triceps and subscapular skinfolds were significant.

THEORETICAL AND METHODOLOGICAL ISSUES OF TEACHER’S PLANNING CONCERNING PREACTIVE DECISIONS IN PE

Januario, C.

Facultade de Motricidade Humana, Portugal

This paper identifies and analyzes meaningful research carried in Portugal about preactive decisions of PE teachers, in the last 15 years, published by authors in books, reviews, and master and doctoral thesis. Previous syntheses are upgrading (Carreiro da Costa, 2006; Sanches & Jacinto, 2004).

We search to answer the following five questions: What research questions are stated? What kind of process, techniques and samples has been used to data gathering? What are the major methodological problems we can identify? What are the main results and findings? Finally, how can we overview future goals and ways to know better teacher planning practices and constraints?

OP-PM11 Physiology 11 - Sports

PHYSICAL DEMANDS IN MODERN FEMALE ELITE TEAM HANDBALL

Michalsik, L.

Institute of Sports Science and Clinical Biomechanics, Denmark

The purpose of this study was to determine the physical demands in a handball match for Danish female elite players as well as to clarify any possible differences arising from different playing positions. Twenty four Danish female elite handball field-players ([25.7±3.3 years, 174.9±5.7 cm and 70.3±7.4 kg]) were examined over a four-year period from 2002 to 2006. Video analyses of tournament matches were carried out. For each player, both a locomotive and a technical analysis of the game were undertaken. The players were divided into three categories for both attack and defence, namely wing players (WP), circle runners (CR) and backs (B). In addition, the heart rate was continuously monitored. A treadmill test was carried out in order to find the individual correlation between heart rate frequency and oxygen uptake. Furthermore, a Yo-Yo intermittent recovery test was performed on a separate day. The average maximal aerobic power for female elite handball players was 47.5 ml O2/min/kg. The average physical load during match play was found to be 79 % of VO2-max. A mean total distance of 4.0 km was covered per match and up to 700 changes of action were...
observed on the basis of eight categories of the locomotive analysis. The high, intense work of quick runs (0.7 %) and sprints (0.1 %) constituted a total of approximately 1 % of effective playing time. Each player had an average of 27 high intense play actions per match. There were a number of marked differences in both the locomotive and the technical analysis and in the practical, physical test between the various playing positions. Both WP (4063 m) and CR (4050 m) covered a greater total distance per match than B (3866 m, P< 0.05). WP also did more high intense work (3.56 % of total distance covered) than CR (2.32 %, p<0.05) and B (1.35 %, p<0.01). In attack, WP received less tackles (1.8 per match) than both CR (2.54, p<0.01) and B (15.9, p<0.01), but did more quick runs (4.4 per match) than both CR (2.47, p<0.05) and B (1.35, p<0.01). In defence, WP gave less tackles (1.8 per match) than CR (2.7, p<0.01) and B (24.6, p<0.01). WP covered a greater distance in the Yo-Yo intermittent recovery test (1516 m) than both CR (1360 m, p<0.05) and B (1352 m, p<0.05). WP was slower in both height (169.3 cm) and weight (63.5 kg) than CR (177.7 cm, 72.5 kg, p<0.01) and B (177.0 cm, 70.6 kg, p<0.01).

In conclusion, this study shows that modern female elite team handball places high demands both on the player’s aerobic and on the anaerobic energy production. A mean total distance of 4.0 km was covered per match with an average physical load during match play corresponding to 79 % of VO2-max. A game consists of up to 700 activity changes with an average of 27 high intense play actions per match. There are distinct differences in the physical demands in the various playing positions, where wing players do more high intense work, cover a greater running distance, and do less tackles compared to backs.

**PHYSIOLOGICAL AND METABOLICAL IMPACTS OF RUGBY TOURNAMENT FOR YOUNG PREPUBERTAL BOYS**

Boussaidi, L., Piscione, J., Rand, J.J., Guézennec, Y.C.

*Cellule recherche FFR, conseil général de l’Essonne, France*

**Hypothesis:** We presume that the physiological and biological impacts of the Rugby competitions currently organized in France for the children aged respectively less 9 (-9years) and less 13 years (-13years) are unsuited to their capacities.

**Method:** Twelve players -9years (36.9±/−5.3kg, 136.9±/−4.7cm, 147.5±/−3.9cm) and 12 players -13years (46.5±/−6.7kg, 147.5±/−3.9cm) had taken part in an official tournament (3 matches) organized by the French federation of Rugby. The total duration of matches was 24min for the -9years and 30min for -13years. Each one of them was equipped with a cardiofrequencemeters to record heart rate (HR), with an accelerometer (Armiband) to evaluate the distances covered and was filmed during matches. Before and after the tournament a blood microcapillary sample was carried out in order to analyze by infra-red spectrometry the evolution of 19 plasmatic parameters.

**Result: discussion:** We did not record any significant difference (physiology and biology) between the groups. During matches on average, children were stopped 59% ± 2 or walked 24% ± 1. More than 84 % of their HR ranged between 40 and 85 % of their HRmax. Their metabolic profile showed a sensitive rise in their glycemia accompanied by a modest lactetemia (6±1,45mMol/L) nevertheless a lipid mobilization suggested by a significant increase of the glycerol and a moderate increase of free fatty acids (FFA) which can be the witness of probable hydrolysis of triglycerides with orientation of FFA towards the muscles. All these results testify to a moderate intensity aerobic physiological request (approximately 60 ±70% of VO2max).

**Conclusion:** Favoring in a modest way the aerobic pathway, the children Rugby tournament proves to be insufficient either to develop their physiological and motion capacities or to prepare them to a more intense future practice.

**SOCCER TRAINING AND COMPETITION EFFECT ON Crossover CONCEPT IN YOUNG ELITE PLAYERS DURING A SEASON**

González-Haro, C., González-de-Suso, J., Egaña, I., Jiménez, R., Escanero, J.

*School of Medicine, University of Zaragoza, Sports Medicine and Physical Department, Real Sociedad de Fútbol SAD, Donostia-San Sebastián, Spain*

**Purpose:** To evaluate the effect of a training and competition season to the response of the adaptation to the Crossover concept in elite young soccer players.

**Methods:** 19 young elite soccer players (age: 17.9 ± 0.7 yrs) from the sports academy of a professional Spanish soccer team where evaluated during a treadmill test 3 times throughout the season (T1: 8 weeks after the beginning of the season, T2: 12 weeks after T1, and T3: 16 weeks after T2). During this test (inclination: 1%, initial speed: 8 km/h-1, step duration: 3 min, passive pause: 30 sec, and increments: 1 km h-1 until exhaustion) Fat (FAOx) and carbohydrate (CHOox) oxidation rates were estimated and averaged for the last 2 minutes of each step throughout stichometric equations. Maximum Fat (FATmax) and CHO (CHOmax) oxidation rates were calculated as well as Crossover Point (COP), and Minimum Fat oxidation rate (FATmin) in relation to % O2max. CHOoxr and FAToxr were calculated for the following three intensity zones: Z1: FATmax-COP, Z2: COP-FATmin, and Z3: FATmin-CHOmax for each of the laboratory tests. Team average training load was quantified in seconds during the season (T1, T2, and T3) and for each of the 3 intensity zones (Z1, Z2, and Z3). A repeated measures ANOVA was used to compare the level of the studied variables. The statistical level of significancy was P<0.05.

**Results.** The relative intensities for each oxidative variable studied throughout the season were FATmax: (72.1 ± 6.9, 73.0 ± 7.5, and 72.6 ± 6.5 %HRmax), COP: (85.6 ± 4.7, 85.7 ± 5.9, and 82.8 ± 5.5 %HRmax), CHOmax: (100 ± 0 %HRmax), and CHOmin: (79.7 ± 3.1, 87.6 ± 4.7, and 93.0 ± 5.6 %HRmax), and COP: (85.6 ± 4.7 vs. 82.8 ± 5.5 %HRmax), p< 0.05, and T3 (85.7 ± 5.9 vs. 82.8 ± 5.5 %HRmax), p< 0.01). The average FAOx decreased significantly in Z2 between T1 and T3 (0.11 ± 0.03 vs. 0.09 ± 0.02 g·min-1, p<0.05). CHOOxr decreased in Z3 between T1 and T3 (5.03 ± 0.87 vs. 5.17 ± 1.06 g·min-1, p<0.05). Finally, the average training load decreased significantly throughout the season in Z1 (1523 ± 244, T2: 1279 ± 224, and T3: 1178 ± 241 sec, P<0.001), and in Z2 (1009 ± 215, P2: 759 ± 240, and P3: 764 ± 232 sec, P<0.001). No significant differences were found in Z3 (T1: 92 ± 130, T2: 67 ± 99, and T3: 65 ± 98 sec).

**Conclusion:** The players from the evaluated soccer team showed a disadaptation to aerobic metabolism during the last third of the season, specifically in the relative intensities in the COP, FAToxr and CHOoxr in Z2 and Z3 respectively. This could be due to a decrease in the training load observed at sub-maximal intensities starting from T1. Therefore, it is suggested to increase the training load at sub-maximal intensities during the second third of the season to maintain the level of aerobic adaptation.
INFLUENCE OF ACTIVE OR PASSIVE RECOVERY AFTER EXERCISE ON SPRINT PERFORMANCE

Maassen, N., Schmidt, O.

Medical School Hannover, Germany

It is known that during active recovery lactate concentration decreases faster than during passive recovery. This is often interpreted as an indirect sign for a faster recovery, but this was seldom proven directly. In this study we therefore tested the hypothesis that active recovery performance in sprint tests is better than after passive recovery. Ten male subjects (age: 25.2 ± 5.5 years) took part in the study. In a pre-test the maximum power (Wmax) subjects was determined in an incremental cycling test. From this test the power for warming up (50% of Wmax) and the active recovery (40% of Wmax) was deduced. To test the hypothesis we administered three randomly ordered trials of 3 min all-out sprint tests. The trials were separated by 60 min of passive recovery. The main test consisted of two Wingate-tests (WT) separated by 60 min of active recovery (ACT) and followed by 18 min of passive recovery (PAS). The study was performed in a crossover design. Five subjects started with PAS and five with ACT. The test started with a resting period (3min) sitting on a cycle ergometer (Lode Excelsior Sport) followed by the warming up consisting of 2min with 10 Watt and 10 min at 50% of Wmax at a cadence of 80 to 90 rpm. After a break of 1 min the first WT (30sec) was started. After this test the subjects remained sitting on the bike and 1 min after termination of WT started cycling with 40% Wmax for 18 min. Afterwards power was increased again to 50% for 10 min. After a break of 1 min the second WT was started. The following recovery period lasted 10 min (ACT and PAS, resting in a deck-chair). In the PAS trial exercise was replaced by 15 min rest on the deck chair. During the whole test heart rate and spirometric data (Metalyzer IIIb, Cortex) were continuously measured. Blood for lactate determination was taken from a hyperaemized earlobe.

Wmax in the incremental test was: 4.06 ± 0.7 Watt/kg. Lactate concentration reached 12.3 mmol/l 3 min after WT. Thereafter lactate further increased to 12.8 mmol/l during PAS, but decreased to significantly lower values during ACT and remained lower during the second warming up, during the second Wingate tests and the recovery period (P<0.001). Maximum WACT: 1231.4 ± 179.2 Watt and WPASS: 1250.2 ± 1707 Watt and mean power (739.9 ± 64.3 and 742.5 ± 62.4 Watt, respectively) during WT1 were not significantly different between both conditions. Maximum power in WT2 was not different from WT1 and not different between ACT and PAS. However, mean power in WT2 was significantly lower after ACT than after PAS (ACT: 727.7 ± 801.5 PAS: 741.4 ± 75.5 Watt; P<0.05).

In spite of the lower lactate concentration maximum power was not influenced by active recovery. That shows that the decrease in lactate is not necessarily a measure for recovery. Mean power was higher after PAS than after ACT in spite of higher lactate values showing that lactate seems not to be limiting under these strenuous exercise conditions. The reason for the lower performance might be a larger glycogen breakdown or an enhanced electrolyte shift during the active recovery.

EFFECTS OF INTENSIVE ENDURANCE TRAINING ON MAXIMAL OXYGEN UPTAKE AND ENDURANCE PERFORMANCE IN HIGHLY TRAINED JUNIOR CROSS-COUNTRY SKIERS

Sandbakk, O., Welde, B.

North-Troendelag University College, Norway

The aims of this study were (1) to predict performance in 1.5 km and 12 km free technique roller skiing, and (2) to investigate the effects of three different endurance-training regimens upon maximal oxygen uptake and performance in 1.5 km and 12 km free technique roller skiing. Twenty-four highly trained male and female junior cross-country skiers (17 ± 0.5 yr) were tested for maximal aerobic capacity and performance before and after an eight week training period. The men and the women had a baseline maximal oxygen uptake of 71 ± 4 ml/min/kg and 61 ± 6 ml/min/kg, respectively. The major finding in this study was that highly trained junior cross-country skiers responded more positively to a training program with increased training at lactate threshold compared to increased training at intensities well above or well below the lactate threshold. The group of skiers who emphasized training at lactate threshold significantly improved their 1.5 km free technique roller ski performance compared to the other groups (P<0.05) and, moreover, it was also the only group to significantly improve the 1.5 km free technique roller ski performance (P<0.05) and the 6.7 km hill run (P<0.05) from pre- to post-test. Another main finding in this study was that the variance in the 12 km free technique roller ski performance was significantly (P<0.05) predicted by maximal aerobic capacity, 2 km double poling on roller skis, and 12 km free technique on roller skis. As well, 82% of the variance in the 12 km free technique roller ski performance was significantly (P<0.05) predicted by a 2 km double poling on roller skis and a 6.7 km hill run. It is concluded that increased training at the lactate threshold can improve performance in highly trained XC-skiers.

INFLUENCE OF PRIOR SPRINT EXERCISE ON THE PARAMETERS OF THE ‘ALL-OUT CRITICAL POWER TEST’

Vanhatalo, A., Jones, A.

University of Exeter, United Kingdom

The power-duration relationship for severe intensity exercise is defined by two parameters: the critical power (CP) and the W’ which represents a fixed work capacity above CP. These parameters can be established in a 3-min all-out cycling test against fixed resistance, where the end-test power (EP) represents the CP and the work done above EP (WEP) indicates the W’. Prior intense exercise could enhance the aerobic energy provision during a subsequent exercise bout, but insufficient recovery following prior exercise might compromise the repletion of high-energy phosphate stores and thus result in reduced performance. The aim of this study was therefore to establish how prior sprint exercise and subsequent recovery duration may influence the all-out test EP (predominantly aerobic) and WEP (predominantly anaerobic) parameters during the 3-min all-out cycling test.

Following ethical approval, seven male subjects completed a ramp incremental test, a 3-min all-out familiarization trial, a 3-min all-out test (control), a 3-min test preceded by a 30-s sprint and a 2-min recovery, and a 3-min test preceded by a 30-s sprint and a 15-min recovery (Lode Excalsior Sport cycle ergometer, Groningen, The Netherlands). The last three trials were administered in a random order. The EP was calculated as the mean power output over the final 30 s of the 3-min test and the WEP as the power-time integral above EP. Parameter estimates from different trials were compared using one-way repeated measures ANOVA.

The EP measured in the 2-min recovery’ test (16.5 ± 3.3 kJ) was significantly lower than in the 5′-min trial (21.2 ± 4.5 kJ) and the control trial (20.8 ± 3.9 kJ), F2,6 = 17.9, P < 0.001. The total work done in the 3-min test was also lower in the 2-min trial (56.4 ± 7.2 kJ) than in the 15-min trial (63.0 ± 6.0 kJ) and control trial (63.5 ± 6.6 kJ). The EP was similar in all trials (Control 235 ± 44 W; 2-min trial 223 ± 46 W; 15-min trial 232 ± 50 W; F2,6 = 2.45, P = 0.13). The highest VO2 attained during the all-out tests were not different from the ramp test determined VO2peak (Ramp test 4.07 ± 0.49 L·min⁻¹, control VO2 4.05 ± 0.32 L·min⁻¹, 2-min VO2 4.07 ± 0.34 L·min⁻¹, 15-min VO2 4.07 ± 0.23 L·min⁻¹, F3,6 =
The reduced WEP when the recovery time following the initial sprint was limited to 2 min supports the notion that the work capacity above CP is dependent upon the availability of the immediate intramuscular energy stores. The overall performance in the 3-min test, as indicated by total work done, was not improved by prior sprint exercise and 15 min recovery (i.e. priming exercise did not enhance exercise tolerance), and performance was markedly reduced when only 2 min recovery was permitted.

**ORAL PRESENTATIONS (OP)**

**OP-PM12 Physiology 12 - Thermoregulation**

**THERMOREGULATORY DEMANDS OF ELITE PROFESSIONAL AMERICA’S CUP YACHT RACING**

Neville, V., Barlow, M., Findlay, M., Greshy, K., Cooke, C.

Loughborough University, United Kingdom

America’s Cup yacht racing is predominantly performed in hot and humid conditions, with athletes exposed to the environment for prolonged periods, yet there is little data in the published literature on thermoregulatory demands and fluid balance during sailing. Core and skin temperature, fluid balance and sweat composition were measured in thirty-two elite, professional, male America’s Cup yacht racing athletes during a 1.5 h 40 min moderate intensity race simulation between two similar America’s Cup racing yachts. Environmental conditions were regarded as moderate for sailing, due to the light wind strength (33C, 56% relative humidity, 5 m/s wind speed (8.5 m/s upwind, 1.0 m/s downwind). Core (Tc) and 4-site skin temperatures (Ts) were measured using ingestible temperature sensors and wireless dural thermostats, respectively. Sweat loss was calculated as the change in body mass corrected for fluid intake and urine excretion. Sweat electrolyte content was assessed from absorbent patches applied to four skin sites. The racing intensity of both boats was similar with an overall subjective rating of 3 out of 5. When comparing the different crew positions, the bowmen recorded the greatest elevation in Tc (peak 39.1°C, range 39.0 to 39.4°C; n=4) followed by the grinders (peak 38.3°C, range 37.9 to 38.6°C; n=6). No significant difference was found in Tc between the upwind and downwind legs. There was no significant difference in mean Ts between positions, however, within positions, bowmen had significantly lower regional skin temperatures at the lower leg compared with the chest (P<0.05), while grinders had significantly greater forearm skin temperatures compared with the chest (P<0.05). A modest correlation was found between Tc and percentage dehydration (r=0.45, P<0.05). For the whole group sweat loss during racing was 2.24 ± 0.89 L (range 0.74 to 3.95 L) with bowmen experiencing the greatest loss of sweat (3.7 ± 0.9% of body weight). Mean fluid intake was highly correlated to sweat loss (P<0.001) with 72 ± 41% of sweat losses replaced. Sweat sodium and chloride concentrations were strongly related to sweat rate (P<0.001), although no relationship was found for magnesium or potassium. The mean sodium concentration of sweat was 27.2 ± 9.2 mmol/L (range: 12.0 to 43.5 mmol/L) and the rate of sodium loss was 0.6 ± 0.4 g/h (range: 0.1 to 1.7 g/h). The total NaCl loss during racing was 3.8 ± 2.4 g (range 0.7 to 10.0 g).

This is the first study to quantify the thermoregulatory demands of racing in elite professional sailors. The apparent lack of a significant difference in Tc between upwind and downwind legs may be attributed to the relatively short duration of each leg. Even though the race intensity was moderate, bowmen appeared to be at risk of hyperthermia and dehydration during racing. These findings have important implications in the management of hydration and prevention of heat injury in America’s Cup athletes.

**EFFECTS OF THE MENSTRUAL CYCLE ON TEMPERATURE RESPONSES TO EXERCISE AND PROLONGED EXERCISE PERFORMANCE, BOTH IN TEMPERATE AND IN HOT, HUMID CONDITIONS**

Janse de Jonge, X., Thompson, M.

University of Newcastle, Australia

Eumenorrheic women have a biphasic rhythm in basal body temperature throughout the menstrual cycle. After ovulation, temperature is elevated during the luteal phase, compared with the follicular phase. The most widely accepted explanation is that the thermoregulatory set point is increased during the luteal phase, which would imply that body temperature remains elevated during exercise and/or heat stress. This increased temperature during the luteal phase may exert a negative effect on prolonged exercise performance, particularly in hot, humid conditions. The present study investigated effects of the menstrual cycle on temperature responses to exercise and prolonged exercise performance, both in temperate and in hot, humid conditions. Twelve recreationally active young women volunteered to take part in this study. Testing was conducted during the follicular (low progesterone) and the luteal (high progesterone) phase, in both temperate (20 degrees C, 45% relative humidity) and hot, humid (32 degrees C, 60% relative humidity) conditions. Prolonged exercise performance was measured as time to exhaustion in an incremental performance test immediately following 60 minutes of sub-maximal exercise at 60% of maximal oxygen consumption. Rectal temperature (Tre) and skin temperature (Tsk) were measured. Mean Tsk was calculated according to Ramathan (1964).

Resting serum progesterone measures revealed that seven out of twelve subjects had ovulated during both environmental conditions (progesterone concentration > 16 nmol/L). The mean (range) for age, height and weight was 24.4 (19-29) years, 166 (160-176) cm and 68.2 (51.8-82.9) kg respectively. Repeated measures ANOVA showed that Tre was significantly higher during the luteal than the follicular phase, both at rest and during sub-maximal exercise. The rate of increase in Tre during submaximal exercise and Tre at exhaustion did not show a significant difference over the menstrual cycle. Tsk at rest, during sub-maximal exercise and at exhaustion demonstrated no significant difference over the menstrual cycle. Time to exhaustion was shorter during the luteal than the follicular phase, and also during hot, humid conditions as compared to temperate conditions. No interaction was found between menstrual cycle phase and environmental conditions.

The fact that the increased resting Tre during the luteal phase remained significantly elevated throughout sub-maximal exercise supports the thermoregulatory set point theory. The results further suggest a negative effect of increased luteal phase body temperature on prolonged exercise performance, independent of environmental conditions. Practical recommendations may therefore include advising regularly menstruating athletes to attempt to compete in endurance events during the follicular phase.

ARE SOME PEOPLE PREDISPOSED TO EXERTIONAL HEAT STROKE?

Thompson, M., Heap, T., Ruell, P., Best, S., Chapman, P.

The University of Sydney, Australia

Exertional heat stroke (EHS) is a potentially life-threatening condition that occurs in some individuals when they perform prolonged intense physical activity in warm environments. Ethically, controlled studies are not able to induce EHS, which leaves case reports as the primary source for identifying the causes of EHS.

A fit VO2max 72.0mL/kg/min 29 year old male collapsed 700m from the finish of an ironman distance triathlon. During the 9.5 hour event the ambient temperature ranged from 15.2°C to 31.3°C and the relative humidity ranged from 19% to 60%.

The patient was found to be unresponsive to pain and his heart rate was 120bpm. On route to the hospital he projectile vomited several times and he became cyanotic at the entrance to the hospital. His blood pressure was 100/60mmHg and he was hypothermic (T 40.4°C).

The patient was suffering significant rhabdomyolysis; his initial CPK was elevated at 2,865U/L and increased over the first 24 hours post collapse to reach a peak of 30,798U/L. His AST and ALT levels were both raised considerably reaching peak values of 1490U/L and 909U/L respectively. He was given 4 litres of normal saline and his rectal temperature decreased to 37.9°C before he was transferred from emergency to the intensive care unit. The patient was hospitalised for 3 days and was given intravenous bicarbonate fluids. His liver function and CPK were monitored 12 hourly. He had regular coagulation profiles to rule out disseminated intravascular coagulation.

Four weeks later the patient undertook a thermal tolerance test. The ambient temperature was set to 35°C, 40%rh. The patient cycled at 300 Watts (70%VO2max) on a cycle ergometer. He was stopped after his rectal temperature had reached 39.8°C. He had a resting mean arterial pressure (MAP) of 95mmHg and maintained his MAP throughout the test. His heart rate increased gradually throughout the test to offset a decline in stroke volume. Cardiac output remained steady at 26.2L/min after the first 20 minutes of exercise. VO2 remained constant at 3.9-4.0L/min. Rectal temperature increased at a rate of 0.06°C/min, while skin temperature fluctuated between 37.05°C and 37.41°C.

There are a number of studies showing that heat shock proteins play an important protective role for cell survival. Moran et al showed that a drop in HSP72 during the first hour of recovery after an exercise heat exposure was indicative of heat intolerance due to impairments in heat shock protein gene transcription (Moran et al, 2006). The patient’s HSP72 returned to resting levels in the first hour after the thermal tolerance test indicating an intolerance to heat that may have predisposed him to EHS. More research is needed to determine why some people are susceptible to EHS and to determine the relationships between EHS and abnormal HSP72 response.

CHANGING WORK INTENSITY IN COLD IS BENEFICIAL FOR MUSCLE FUNCTION

Oksa, J., Ollila, T., Paasovaro, S.

Finnish Institute of Occupational Health, Oulu, Finland

Repetitive work in cold induces higher level of strain and fatigue for the working muscles as compared to similar work in thermally neutral condition (Oksa et al. 2002). There are implications that intermittently increasing the intensity of repetitive work from 10 %MVC to 30 %MVC induces lower level of strain and fatigue than work at 10 %MVC level only (Oksa et al. 2006). Therefore, the purpose of this study was to evaluate whether intermittently increasing the workload from 10 %MVC to 50 %MVC level is also able to induce beneficial effects on muscle function during repetitive work in cold.

Eight healthy female subjects participated in the study and were exposed once to 21°C (TN) and twice to 4°C for 120 minutes. During the exposure to 21°C and first exposure to 4°C (C10) subjects performed wrist flexion - extension work bouts at 10 %MVC level. On the second exposure to 4°C the workload was increased every fourth minute to 50 %MVC (C50). Maximal wrist flexion force (MVC) was measured before and after the experiment. During work EMG activity was measured from two wrist flexor and extensor muscles. From EMG data work loading parameter which defines the percentage amount of activity coming from each muscle (4 muscles = 100 %) was analyzed. The activity from flexors and extenders is presented as mean of two muscles.

The cumulative work at C50 was 5508±467 kg and differed significantly from C50 and TN (4950±420 kg, p<0.05). After exposure MVC was 9 % (NS) lower at C10 (155±12 N) in relation to TN (170±12 N) and C50 (169±11 N). The percentage EMG activity in forearm flexors and extensors was similar during TN (78.5±0.5 and 21.5±0.4) and C50 (78.2±0.7 and 21.6±0.5). However, significantly lower percentage activity from flexors (71.5±1.1) and higher from extensors (28.5±1.1) was observed during C10 exposure indicating increased co contraction.

In all exposures maximal wrist flexion force decreased indicating muscle fatigue. However, the most pronounced change was observed after C10. Likewise, the relation between the activity of agonist - antagonist muscles in the forearm was similar between C50 and TN whereas, the level of co contraction during C10 was the highest. Therefore, it can be concluded that intermittently increasing the workload in cold condition induces similar changes during repetitive work as in thermoneutral condition, less pronounced fatigue and level of co contraction. Thus, altering work load during low intensity repetitive work in cold can be regarded as beneficial in terms of muscle function in relation to the use of low intensity work only.

ACUTE RECOVERY OF VOLUNTARY AND EVOKED MUSCLE PERFORMANCE FOLLOWING INTERMITTENT-SPRINT EXERCISE IN THE HEAT

Duffield, R., King, M., Rouse, M.

Charles Sturt University, Australia

Despite the volume of research outlining the reduction of exercise performance in the heat, there is a paucity of research describing the effects of warm conditions on acute post-exercise recovery. Therefore, the aim of this study was to determine the effects of warm condi-
tions on the acute recovery of voluntary and evoked muscle performance following intermittent-sprint exercise. Nine male and six female team-sport athletes performed two testing sessions separated by 7 days. Sessions consisted of both a 30-min exercise protocol and a 60-min passive recovery in either 21°C or 33°C. The exercise protocol involved a 20 s maximal sprint every 5-min, separated by constant-intensity exercise at 100 W on a cycle ergometer (LODE Excalibur Sport). Pre- and immediately, 15-, 30- and 60-min post-exercise, maximal voluntary contraction (MVC) and a resting and superimposed twitch (IP) of the right knee extensors were assessed, while a capillary blood sample was obtained to measure lactate, pH and HCO3. During and following exercise, core temperature from a telemetry ingestible capsule (MiniMitter), heart rate (Polar) and Rating of Perceived Exertion (RPE) were also measured. A repeated measures ANOVA and Cohen's d effect size analysis were used to determine differences between conditions. Results indicated no difference (P<0.05) in peak power during repeated 20 s sprints between hot and mild conditions. Post-exercise MVC was reduced (P<0.05) in both conditions and a moderate effect size (d=0.50) indicated a small suppression in recovery of MVC in the hot environment (60-min post: 82 ± 76% recovered). There were no differences (P>0.05) in IP at any time point pre- or post-exercise. Both heart rate and core temperature were significantly higher (P<0.05) post-exercise and during the recovery in the hot condition. Blood lactate, pH and HCO3 did not differ between conditions at any time point during exercise or recovery. Finally, RPE was higher immediately and 60-min post-exercise in the heat. The current data suggests that passive recovery in warm temperatures not only delays cardiovascular and thermal recovery, but may also slow the recovery of MVC. This slower recovery of MVC seems likely to be from a central or motivational origin, as evoked twitch force was not different between conditions and no contractile properties were evident. Additionally, RPE was significantly higher in the heat and may indicate the increased perceptual strain or a reduction in motivation to perform. It must be noted that peak core temperatures were not exceptionally high (<38.5°C) and a greater induced thermal strain may result in a more pronounced suppression of performance or slower recovery. In summary, these data indicate the possible delayed recovery of not only the cardiovascular and thermal systems, but also muscle performance during passive recovery in the heat and hence highlights the possible usefulness of post-exercise recovery strategies.

COMPARISON OF PHYSIOLOGICAL RESPONSES DURING SNOW REMOVAL IN SEDENTARY MEN AND WOMEN

Bhambhani, Y., Van Os, D.
University of Alberta, Canada

Manual snow removal is a necessary winter task that is performed by men and women. It is positively correlated with an increased risk of injury and cardiac events such as myocardial infarction or sudden cardiac death (1). While safety guidelines have been developed for performing this task in healthy men (2), guidelines are currently lacking for women. The purpose of this study was to compare the physiological responses during self paced snow removal in sedentary men and women. It was hypothesized that there would be no significant gender differences in these physiological responses, and therefore, gender based safety guidelines would not be necessary. Consent was obtained from six sedentary healthy males and six females who completed: (a) an incremental arm cranking test to determine peak oxygen uptake (peak VO2; mean = 17.6 ± 4.5 ml/kg/min and 18.6 ± 2.0 ml/kg/min in men and women respectively) and (b) two self paced snow removal trials on an outdoor grass covered surface with a snow depth of 50 cms. Subjects scooped the snow with a 2 kg shovel (72 cm handle) and threw it sideways to clear a vertical path. Each trial lasted 10 mins interspersed with a 10 min indoor rest period. Mean outdoor temperature, wind and relative humidity during the 10-day snow removal period were: -7.5 ± 4.9°C, 13.6 ± 3.8 km/h and 85.1 ± 7.9% respectively. Physiological responses were recorded with a wireless metabolic system and heart rate monitor. Data were averaged over 20 sec intervals and the peak values of oxygen uptake (VO2) and heart rate (HR) were used for analysis. Blood pressure (BP) was measured during the first minute of recovery and blood lactate (La) was measured from a fingertip two minutes post exercise. Two-way analysis of variance with repeated measures on trials indicated no significant differences (p > .05) between genders and trials for VO2, HR, systolic and diastolic BP, and La. The respective means for the men and women were: VO2 = 19.1 ± 6.3 and 18.8 ± 2.7 ml/kg/min; HR = 159.6 ± 19.8 and 152.1 ± 12.1 bpm; systolic BP = 141.4 ± 19.1 and 141.0 ± 15.8 mmHg, diastolic BP = 88.9 ± 8.6 and 82.5 ± 6.4 mmHg; La = 3.95 ± 1.1 and 3.50 ± 0.7 mmol/L. The VO2 during snow removal corresponded to 109.7±29.3% and 101.0 ± 10.3% of peak VO2 measured during arm cranking in men and women respectively. The corresponding values for HR were 91.0 ± 13.0% and 98.7 ± 6.0% respectively. These relative intensities were also not significantly different (p > .05) between genders. Self paced snow removal by sedentary men and women induces an energy expenditure that equals or exceeds that observed during maximal arm cranking in healthy men (2), guidelines are currently lacking for women. The purpose of this study was to compare the physio-

FIGHTING SPORT PROJECT 2000: CREATING A SOFTWARE FOR TRAINING PROGRAMMING IN COMBAT SPORTS

Gasperini, D., Scaringella, S., Distaso, M., Villani, R.
Cassino University; IUSM Rome, Italy

Introduction

In modern combat sports and martial arts competitions, the training and the high level of specialization of the athletes, play a key role. Therefore is very important to program and plan training in a functional and scientific way. Filling in a questionnaire, the 95.65% of Italian Karate technicians said to know the advantages of training programming, but only the 86.96% of them actually plan their work. Moreover, only the 22.61% of them stated to know software for training programming, but only the 64.35% of them would be interested in over, only the 22.61% of them stated to know software for training programming, but only the 64.35% of them would be interested in
method and questionnaires (those functions are included in the software). Such trainings might be organized following the classical model of periodization (Matwejew, Tschiene) or the blocks one (Verchosanskij), or also mixed models. With FSP 2000 you can decide what to do during your training session: Karate’s agonistic training or technical teaching (low level belt and young activity). The performance of each exercise is shown by a descriptive and a multimedia section (through video and images). You can also choose the parameters of the exercise: execution time, recovery time, repetitions, series, volume, density, intensity, loading percentage. The software is able to display the trend of the training’s loading, both for a single session and a longer one, through the intensity/volume chart and the time sharing for each objective.

Conclusions
FSP 2000 is ever growing in order to meet every problem and variable the modern theory and methodology of training and the several needs of sport technicians present. Now we are modifying some program’s functions to optimize the programming process and we are trying to adapt it to the needs of others combat disciplines (judo, wrestling, boxing, TKD, kick boxing...).

FACTORS TO PREDICT FREESTYLE PERFORMANCE TIMES IN MASTER SWIMMERS
Zampagni, M., Casino, D., Schena, F., De Vita, G.
University College Dublin, Ireland and IUSM Roma, Italy

Many studies have been conducted to identify models based on anthropometric and strength measures capable of describing the performance time in swimmers. Some studies have focused on investigating the implication of hand [2, 4] and forearm strength swimming performance using different methodologies and devices being generally in agreement with the important role of upper extremity in the total thrust in the crawl stroke [2, 4, 1]. Few studies are dedicated in Master swimmers athletes despite they are an invaluable model to trying to adapt it to the needs of others combat disciplines (judo, wrestling, boxing, TKD, kick boxing...).

The assessment of fatigue thresholds in order to evaluate swimming performance potential and to promote an efficient training control and advice seems to be possible only in mixed or dominantly aerobic efforts. In this field the anaerobic threshold it’s very well none. The study of fatigue thresholds in efforts of the anaerobic domain is apparently unusual. This is probably due to some lack of knowledge associated to anaerobic performance, once tests who most directly evaluate it (e.g. muscular biopsy or Nuclear Magnetic Resonance) are expensive, invasive and not applicable in sports practice. The most widely accepted anaerobic test is the cycloergometer Wingate test. Although, Wingate is very unspecific for swimmers, and other tests must be found to evaluate this capacity. The aim of the present study was to find and compare fatigue thresholds 30s time-curves obtained with swimmers. 90 swimmers, 30 pre-pubertal, 30 pubertal and 30 post-pubertal, being 15 males and 15 females in each group, participate in the study. Pubertal stages were defined using stages described by Tanner (1962). Experimental procedures included five 30s tests: (i) free swimming with the swimmers connected to a cable velocimetric system, (ii) fully tethered swimming (Globus strain-gage), (iii) simulated swimming on a biokinetic swim bench, (iv) crank ergometer Wingate test and (v) cycloergometer Wingate test. Two especially developed Matlab programs allowed to assess fatigue thresholds on the continuous 30s efforts of the three first tests (Soares et al., 2006) and on the two Wingate tests. It was possible to observe the existence of velocity, force and power time-curves with one and two fatigue thresholds. In curves with one threshold, fatigue appears around 13s from the beginning of the effort. In curves with two fatigue thresholds first appears around 8s of exercise, and the second around 18s from the beginning of the effort. We could conclude that fatigue thresholds appearance seems to be independent of the kind of effort performed by swimmers.

EVOLUTION OF PERFORMANCE DURING CYCLING–RUNNING SUCCESSION ALONG ONE SEASON IN YOUNG TRIATHLETES

Zapico, A., Díaz, V., Peinado, A., Alvarez, M., Benito, P., Calderon, F., Sillero, M.
Universidad Politécnica de Madrid, Spain

INTRODUCTION

The cycling-running succession has an important physiological component: it is difficult to adapt to running after cycling. Hence, triathletes who show the best overall performance are therefore those in whom the cycling component least affects their running (1). The aim of this study was to compare the changes along two seasons of the cardiorespiratory response and performance during a cycling-running succession in elite young triathletes.

MATERIAL AND METHODS

Nine elite young triathletes selected by the Spanish Triathlon Federation as the best in their category (under 16) participated in the study. Experimental protocol was repeated in the same moment of two different seasons (2006 and 2007) and consisted of two trials performed in random order. In trial 1 (C-R) subjects completed 30 min cycling at 3.5 W/kg on a cyclergometer. Immediately after, subjects run 3000 m as fast as possible on a 400 m track (7.5 laps). Trial 2 (R) consisted of running 3000 m as fast as possible. All cardiorespiratory variables were measured with a portable metabolic system (Jaeger Oxycon Mobile) and oxygen cost of running (O2C) was calculated each 400 m using the formula of Di Prampero (2).

RESULTS

The C-R trial was associated with: 1) an acute cardiorespiratory response compared with R and, 2) an impairment of 3.5% in performance during running (647.0 ± 22.9 vs. 624.9 ± 15.0 seconds for C-R and R respectively).

When seasons were compared, cardiorespiratory response and O2C were similar, but performance improves significantly in both conditions. Thus, time to complete the running sector decreased a 6.4% during C-R (667.3 ± 24.7 s) from 2006 to 2007 season.

DISCUSSION

Our study confirms the specific cardiorespiratory response and the loss of performance showed by others during cycling-running trial (1, 3, 4), but in our knowledge, this is the first work that evaluate the changes along a season. Millet and coworkers indicated that performance in the running sector might be more important than the VO2max in the detection of talented competitors, and suggested this performance be monitored over time (5). Thus, we conclude that monitoring and comparing this performance with professional could be be helpful in the detection of talented triathletes.

EFFECTS OF RUNNING VERSUS SPECIFIC AEROBIC TRAINING IN YOUNG HANDBALL PLAYERS

Buchheit, M., Laursen, P., Kuhnle, J., Renaud, C., Ruch, D., Ahmaidi, S.
Faculty of Sport Sciences, University of Picardie, Jules Verne, 80025, Amiens, France

The aim of the present study was to compare the effect of high-intensity running exercises versus specific handball aerobic training on athletic performance in young handball players. Thirty two highly-trained adolescents (15.5 ± 0.9 y, 16 girls, 16 boys) were randomly assigned to either running (HIT; n = 17; girls = 8) or specific (HB; n = 15; girls = 8) training groups. During 10 weeks, HIT consisted in 15-s runs at 95% of the speed reached at the end of the 30-15 Intermittent Fitness Test (VIFT) interspersed with 15 s of passive recovery (15/15); HB training consisted in small-sided handball games (4-a-side) of similar duration than HIT series. Groups performed either HIT or HB twice per week and maintained similar external training programs. Before and after training, performance was assessed by the VIFT, using the formula of di Prampero (2).

To assess the differences between C-R and R, and between seasons, paired t-tests were performed and the significant level was fixed at p<0.05.

RESULTS

The C-R trial was associated with: 1) an acute cardiorespiratory response compared with R and, 2) an impairment of 3.5% in performance during running (647.0 ± 22.9 vs. 624.9 ± 15.0 seconds for C-R and R respectively).

When seasons were compared, cardiorespiratory response and O2C were similar, but performance improves significantly in both conditions. Thus, time to complete the running sector decreased a 6.4% during C-R (667.3 ± 24.7 s) from 2006 to 2007 season.

DISCUSSION

Our study confirms the specific cardiorespiratory response and the loss of performance showed by others during cycling-running trial (1, 3, 4), but in our knowledge, this is the first work that evaluate the changes along a season. Millet and coworkers indicated that performance in the running sector might be more important than the VO2max in the detection of talented competitors, and suggested this performance be monitored over time (5). Thus, we conclude that monitoring and comparing this performance with professional could be be helpful in the detection of talented triathletes.

COORDINATIVE AND TACTICAL PARAMETERS IN THE HANDBALL THROW AND THEIR INFLUENCE TO THE LEVEL OF PERFORMANCE

Wagner, H., Kainrath, S., Müller, E.
University of Salzburg, Austria

For testing the performance level of handball players physical fitness tests to measure physical characteristics, strength, jump height, throwing velocity, power-load, sprint running time or running endurance (cf. Gorostiaga et al., 2005) or 3D-kinematics of throwing movements to measure throwing velocity and precision, angles, angular velocities and joint velocities (cf. Wagner et al., 2006) were used generally. But the performance level of handball players and their teams are also strongly influenced by technical and tactical parameters. Therefore the aim of this study was to analyse these parameters and their influence to quality parameters and performance level.

Fifteen games of the last World championships (performance level 10 and 9), the qualification for the European championship (level 8 and 7) and the qualification tournament for the second Austrian handball league (level 3 and 2) were analysed for this study. Every throw of both teams during the game were assigned and separated in different categories like quality parameters (goal, blocked throw, saved or missed), throwing technique (jump, cross over step, standing or dive throw), last passing direction (goal keeper, rebound, from left or right side, cross, pivot pass or intercepted), fast break, throwing position (wing, backcourt, pivot, left, right side or middle), throwing execution (with high ball velocity, lifting or turning throw), throwing arm (over or under shoulder) and trunk position (bend left, right or no bend). To calculate the correlation between performance level, quality parameters and all assigned technical and tactical parameters pearson’s product-moment correlation were used. To identify performance determining parameters linear regression analysis were calculated as well.

Significant correlation were found between performance level and backcourt right, middle position (+ corr), rebound, left wing position, fast break (- corr), between goal and pivot pass, backcourt left position (+), cross over step throw with throwing arm under shoulder (+), between blocked throw and cross over step throw, backcourt middle position (+), fast break, left wing, pivot middle position (-), between throws saved from goalkeeper and pivot pass, backcourt left position (-) and between goal missed and backcourt left, pivot right position (+), cross over step throw with throwing arm over shoulder and backcourt middle position (-). The linear regression analysis with the criterion variable performance level calculated a model with the predictors fast break and backcourt right position.

Interpreting the results of this study it could be summarized that the jump throw is the most applied throwing technique (>70%) in handball and that throwing more often from the right backcourt position and preventing the fast break of the rival team should increase the performance level.

TRAINING AND GENE EXPRESSION IN CELL CULTURE AND HUMAN MODELS

Steinacker, J.M., Wang, L., Prokopchuk, O., Liu, Y.
University of Ulm, Germany

Skeletal muscles have a great capacity for adaptation to training requirements and stress. Exercises with high metabolic, catabolic effects in high-intensity training lead to predominance of a slow muscle type, since slow muscle fibers are more resistant to stress than rapid fibers. Muscular adaptation proceeds via various mechanisms. Changes in protein isoforms, new fiber formations or splitting, hypertrophy of fibers and fiber degeneration. At the protein level, the isoforms of the myosin heavy chain (MHC) largely determine the contractile properties of a fiber and characterize the muscle. The new formation of muscle fibers proceeds from the pool of satellite cells, which differentiate under the influence of myogenic differentiation factors Pax7, MyoD and Myf5. The isoform MHC I alpha which has newly been discovered in skeletal muscle normally finds cardiac expression and could indicate satellite cell activation. Muscle hypertrophy and fiber regeneration are controlled essentially by the hormones insulin, thyroxin and insulin-like growth factor.

Mechanisms are induced via the external cytoskeleton and via special channel proteins as signal pathways for genetic transcription. The muscle produces secretes its own mechanically-induced growth factor, the mechano growth factor and dependant on intensity also cytokines like interleukin-6 or stress proteins. Elimination of unneeded proteins and fibers is necessary for fiber adaptation, and controlled cell death (apoptosis) probably plays an important role here.

There is a limit of current training models in athletes in respect of the detection of underlying biochemical and molecular mechanisms because of limitations in samples and in respect of the possible interventions by training (intensity, duration). Athletes are primarily interested in sports success and in new training ideas, however, control groups are often difficult to organize. Pharmacological or transgenic interventions are clearly limited by biological and ethical limits. Therefore cell culture models are a interesting option.

Electrical stimulation (ES) is frequently used to investigate muscle response to cellular stress, and ES can bring about a series of functional and structural responses in the skeletal muscle, which varies with characteristics of ES. We use ES in C2/C12 mouse myoblasts as a model to study mechanisms underlying skeletal muscle adaptation to cellular stress.

Electric stimulation to C2/C12 cells led to distinct Hsp70 response at both mRNA and protein level, which associated with characteristics of ES. Not only the duration of ES, but also the frequency of ES could significantly affect the Hsp70 response. There was a discrepancy in Hsp70 response in the ES-stimulated cells between mRNA and protein level, suggesting possible different regulation at transcriptional and translational level in the Hsp70 response. The control of apoptosis and cell cycle is balanced.
Muscle plasticity was presented and discussed. By comparing a number of proteomic studies, performed by our group, in animal models and in humans, a list containing proteins, both analysis of the changes observed in various conditions such as training, detraining, bed rest, hypoxia, microgravity, and in pathological alteration or decrement, the muscle plasticity was evaluated by a proteomic approach. This approach implies the qualitative and quantitative analysis of a large number of proteins at the same time. Skeletal muscle wasting also occurs in human muscles as a result of denervation, aging, starvation, and a number of disease states. The atrophy observed under these different conditions imply the activation of different types of molecular triggers and signalling pathways producing muscle wasting. As a result, these activated signals can influence the protein turnover by differentially modulating the protein synthesis and degradation. To define this phenomenon at the molecular level and particularly the proteins involved in muscle mass increment or decrement, the muscle plasticity was evaluated by a proteomic approach. This approach implies the qualitative and quantitative analysis of a large number of proteins at the same time. By comparing a number of proteomic studies, performed by our group, in animal models and in humans, a list containing proteins, both contractile and metabolic, involved in muscle plasticity related to physiological, parapathophysiological, pathological conditions was built. The analysis of the changes observed in various conditions such as training, detraining, bed rest, hypoxia, microgravity and in pathological conditions in specific contractile (myosins, heavy chains, myosin light chains, troponysins, troponins, actins), regulatory, transport and metabolic proteins will be presented and discussed.

APPLICATION OF PCR AND LC-MS METHODS AND GENOMIC DATABASES IN SPORTS SCIENCES

Dékány, M., Györe, I., Gógl, Á., Berkes, I., Pucsok, J.

The series of the human gene map for performance and health-related fitness phenotypes began in 2000 with the goal of making available all the advances on the genetic basis of a large family of exercise-related traits in an easily accessible format. The genes with evidence of association or linkage with a performance or fitness phenotype in sedentary or active people, in adaptation to acute exercise, or for training-induced changes are positioned on the genetic map of all autosomes and the X chromosome. By 2004 the human gene map for physical performance and health-related phenotypes includes 140 autosomal gene entries and quantitative trait loci, plus four on the X chromosome. Moreover, there are 16 mitochondrial genes in which sequence variants have been shown to influence relevant fitness and performance phenotypes. In 2000 this map contained only 29 autosomal markers. Thus, the map is growing in complexity and progress is being made.

The genetic basis for variation in human athletic performance is a new direction in exercise physiology. Due to its consequences the importance of genetic databases has increased. The first part of this presentation has been shown the foundation of hungarian sport-genomic database and its importance.

The second part of this paper has been presented the mass spectrometry based proteomics, which has established itself as an indispensable technology to interpret the information encoded in genomes. Protein analysis by mass spectrometry has been most successful when applied to small sets of proteins isolated in specific functional contexts. The systematic analysis of the much larger number of proteins expressed in a cell, an explicit goal of proteomics, is now also rapidly advancing, due mainly to the development of new experimental approaches.

The coupling of electrospray ionization with Fourier Transform Mass Spectrometry has created a new capability for analysis of proteins and other large biomolecules. Mass spectrometry nowadays has a central role for studying the primary structure of proteins, protein expression levels, and protein-protein interactions.

Invited symposia (IS)

IS-PM12 Muscle lipids and insulin resistance

MUSCLE TRIACYLGLYCEROL AND INSULIN RESISTANCE

Hesselinke, M.

A sedentary life style and consuming energy dense diets contributes to the development of insulin resistance (IR), a hallmark in the pathogenesis of type 2 diabetes. IR and storage of excess of calories as triacylglycerol (TG) in non-adipose tissue (ectopic TG storage) relates positively to peripheral insulin resistance in untrained, but not in fat oxidation prone trained subjects. This suggests that not TG per se impede insulin signaling, but rather intermediates in synthesis and degradation of TGs. Although this notion is already around for years, information on the origin and type of insulin desensitizing lipid moieties is still fragmentary. Neither is it known how lipid moieties are modulated upon insulin (de)sensitizing interventions.

Storage of TG as lipid droplets in humans is most abundant in type 1 muscle fibers. Upon increased fatty acid availability, lipid droplets increase in size and number. Thus, acute infusion of an emulsion with long chain fatty acids massively increases TG storage, this in contrast to lipid emulsions containing also 50% of the more readily oxidizable medium chain fatty acids. In both conditions, however,
similar effects on IR were observed. In addition, we observed that acute infusion of lipid in humans induced IR along with downregulation of genes encoding for mitochondrial biogenesis (PGC1α and PPAR). We also showed these genes to be downregulated in muscle biopsies from type 2 diabetic patients. Jointly, these findings suggest that an increase in muscular TG content in diabetogenic models requires mitochondrial defects to impede insulin signaling. Interestingly, administration of Rosiglitazone for 8 weeks to type 2 diabetic patients improved skeletal muscle glucose uptake along with restoration of PGC1α and PPAR, to control values. Improved insulin sensitivity occurred in the absence of changes in whole muscle TG content but with declined muscular protein content of ADP and OXPAT, lipid droplet coating proteins with a putative role in lipid droplet dynamics. Thus, under conditions of a low fat oxidative capacity, decreased mitochondrial biogenesis and increased lipid load, the muscle is prone to insulin resistance. Improvements in insulin sensitivity, however, can occur without changes in muscular TG content. This has led us to pursue studies towards the dynamics in lipogenesis and lipolysis of ectopically stored TG.

Enhancing TG storage capacity by overexpressing of the TG synthesizing enzyme DGAT1 may provide a 'sink' for fatty acids, either dietary or derived from non-muscle lipolysis, leaving the level of insulin signaling desensitizing lipid moieties low. In contrast, inhibiting muscle lipolysis by knocking down its major TG lipase ATGL impedes insulin signaling. This indicates an indirect and complex interaction between TG storage and IR, with multiple proteins involved in the dynamics of ectopic lipid storage, some of which will be discussed during the conference.

CERAMIDES AND INSULIN RESISTANCE

Helge Jørn, W.
University of Copenhagen, Denmark

The appearance of insulin resistance is considered one of the early signs of metabolic dysfunction, which left untreated, will lead to major metabolic derangement and overt diabetes and/or the metabolic syndrome. It is generally thought that excess intramyocellular lipid storage mediates an attenuating effect on insulin sensitivity through an increased fatty acid precursor supply which leads to accumulation in skeletal muscle of one or more of the lipid intermediates diacylglycerol, long chain fatty acyl-CoA and ceramide. In muscle ceramides are generated primarily through de novo synthesis from palmitate and serine or through breakdown of sphingomyelin in the membranes. In rat muscle and in cell lines there is evidence that increased content of ceramide attenuates insulin signalling through serine/threonine phosphorylation of Akt/protein kinase B, which subsequently leads to impaired translocation of GLUT4 to the plasma membrane and attenuated activation of glycogen synthase.

In human muscle a higher ceramide content have been found in obese insulin resistant compared to lean insulin sensitive subjects and 8 weeks of endurance training was found to reduce muscle ceramide content and improve glucose tolerance in obese young insulin resistant subjects. However, other studies have demonstrated similar muscle ceramide concentration in lean and overweight male subjects and similar muscle ceramide content in trained compared to untrained normal young and middle aged men. Furthermore, in middle aged men muscle ceramide content was similar across a very wide range of insulin sensitivities. Obviously it is at present not possible to point to a very clear cut role of muscle ceramide for insulin resistance in man.

To further unravel the influence of muscle ceramide in man interventions that modify plasma fatty acid availability such as lipid infusion, acute prolonged exercise induced a 25% increase in muscle ceramide content concurrent with a decreased insulin sensitivity after the lipid infusion. In rats lipid infusion of saturated fatty acids induced insulin resistance through muscle ceramide accumulation, whereas infusion of unsaturated fatty acids induced insulin resistance through increased muscle diacylglycerol content. More consistent evidence is available for insulin infusion as there was no influence on ceramide content in human skeletal muscle. In contrast acute prolonged exercise induced a 25% increase in muscle ceramide content in both trained and untrained male subjects.

Although not unequivocal the data in rats implies that the type of fatty acid availability may play a role for accumulation of muscle ceramide and a subsequent increased insulin resistance.

MITOCHONDRIAL RESPIRATION AND INSULIN RESISTANCE

Mogensen, M.
University of Southern Denmark, Denmark

It is well known that a part of the pathophysiology behind insulin resistance in skeletal muscles, revolves an imbalance between lipid availability and lipid removal. The mitochondrion is the site of lipid oxidation and therefore an essential part of the lipid removal. During the last decade numerous studies have investigated the mitochondrion and its relation to insulin resistance, and for a good reason, studies have shown a correlation between insulin resistance lipid oxidation, diseases such as Friedreich's ataxia and mitochondrial diabetes, which are characterized by mutations in the mitochondrial genome or mutations in genes coding for mitochondrial proteins in the nucleus, have symptoms which are very similar to type 2 diabetes patients, and finally, studies investigating patients with insulin resistance have revealed a decreased gene expression of several mitochondrial proteins involved in the electron transport chain and an increased phosphorylation (inactivation) of the ATP-synthase-subunit. These results have led to the hypothesis that insulin resistance is caused by a mitochondrial dysfunction. The proposed mechanism is that a low mitochondrial capacity leads to a decreased lipid oxidation, which increases the concentration of intramuscular lipid metabolites such as ceramides, diacylglycerides and long chain acyl-CoA's, that are known to inhibit the insulin signalling.

A decreased mitochondrial function may be caused by numerous factors such as increased oxidative stress, physical inactivity, lipid oversupply, insulin resistance and inheritance. These factors are highly related. However, it has been suggested that increased intramuscular lipid concentration, have the potential to induce mitochondrial dysfunction.

Few studies have investigated the mitochondrion and its relation to insulin resistance and even fewer studies have distinguished between mitochondrial quality and mitochondrial quantity. At present time the results from these studies are ambiguous, but indicating that there may be a decreased mitochondrial function in subjects with insulin resistance.
Psychosomatic principles have suggested for a long time that what we think and feel will have an impact on our physical functioning. When the body’s activity affects how we think and feel this should be classed as ‘somatopsychic’ (Harris, 1973). In exercise psychology we explore somatopsychic processes, to seek answers to why physical activity might help people feel better. Here we examine the role of exercise as a somatopsychic process during treatment and recovery from breast cancer. Using a randomised controlled trial design we aimed to determine the functional and psychological benefits of a 12 week supervised group exercise programme during treatment for early stage breast cancer with a 6 month follow-up. The participants were 203 women and 177 completed the 6 month follow up. We excluded those with concurrent unstable cardiac, hypertensive or respiratory disease; cognitive dysfunction; and those who were regular exercisers. The control group received usual care. The intervention was a supervised group exercise programme twice weekly for 12 weeks in addition to usual care. The main outcome measures were: Functional Assessment of Cancer Therapy questionnaire, Beck Depression Inventory, Positive and Negative Affect Scale, body mass index, 7 day recall of physical activity, 12 minute walk test and assessment of shoulder mobility. The results showed both functional and psychological benefits: a 60% increase in minutes of moderate intensity activity reported in a week (+67 [52 to 84]), minutes of moderate intensity activity reported in a week (+182 [75 to 289]), shoulder mobility (+2.6 [1.6 to 3.7]), breast cancer-specific quality of life (+2.5 [1.0 to 3.9]), positive mood (+4.0 [1.8 to 6.3]). In general, these effects were maintained at the 6 month follow-up (Mutrie et al., 2007). Qualitative data provided evidence that the participants viewed the exercise as something that helped them feel better at a time of health challenge (Emslie et al., 2007) and for some even provided post-traumatic growth. The findings suggest that there is indeed a somatopsychic effect from exercise and that clinicians should promote exercise to help patients feel better. These somatopsychic effects may be available to many clinical populations and to the general population.

**THE PHYSICAL SELF AND ITS IMPACT ON MENTAL HEALTH**

Fox, K.

University of Bristol, United Kingdom

Physical activity participation is clearly associated with reduced risk of some mental illness and disorders, most notably depression, cognitive impairment and dementia, and has also shown effectiveness as a treatment for depression. Furthermore, physical activity improves a range of aspects of the physical self, such as improved perceptions of competence and autonomy, and reductions in negative states and disorders such as depression and anxiety. Contemporary theories of motivation, however, place emphasis on the reasons for engaging an activity as important predictors of the quality of that engagement and whether or not participation results in mental health benefits. In particular, Basic Needs Theory, a mini-theory within the larger Self Determination framework (Deci & Ryan, 2000) suggests that positive changes of feelings of self determination (and the underpinning satisfaction of basic needs for competence, autonomy, and connection with others) may be mechanisms explaining the physical activity and mental health relationship. Studies will be highlighted which support the application of this theoretical perspective to the exercise domain (see Edmunds, Nitoumanis, Duda, J.

University of Birmingham, United Kingdom

The benefits of regular physical activity for mental health and emotional well-being are well documented in the literature. Pulling from this body of work, it is often assumed that participation in physical activity will translate into positive psychological and emotional outcomes and reductions in negative states and disorders such as depression and anxiety. Contemporary theories of motivation, however, place emphasis on the reasons for engaging an activity as important predictors of the quality of that engagement and whether or not participation results in mental health benefits. In particular, Basic Needs Theory, a mini-theory within the larger Self Determination framework (Deci & Ryan, 2000) suggests that positive changes of feelings of self determination (and the underpinning satisfaction of basic needs for competence, autonomy, and connection with others) may be mechanisms explaining the physical activity and mental health relationship. Studies will be highlighted which support the application of this theoretical perspective to the exercise domain (See Edmunds, Nitoumanis, Duda, J.)
Determination of Muscle Characteristics in Isometric Plantar Flexions

Kurz, G.
Institute of Sport and Sports Science, Germany

Introduction: Maximal muscle force and muscle power can be determined using maximal voluntary contraction tests, both in time discrete and time dependent conditions. One of the key factors of these abilities is the distribution of muscle fibre types within the relevant muscles. Up to now the fibre compositions of a muscle have only been determined using complex, invasive and ethically questionable procedures, such as muscle biopsies. The deduction of fibre type composition from non-invasive methods has not been discussed sufficiently in the literature. Therefore, the purpose of this study was to develop a non-invasive method for the identification of the mechanical muscle properties of the plantar flexors.

Methods: 50 male subjects (25.4±2.3 yrs, 181±5 cm, 77.8±7.0 kg) performed maximal voluntary contractions of the plantar flexors on a specifically designed measuring device. The ground reaction forces acting on the foot were measured using a self-made 1D force plate. The seat position and the angle of the ankle were adjusted individually based on the anthropometric conditions of the subjects. The forces during isometric contractions over time were measured at 13 different ankle angle values (75°-135°, 5° increment). Results and discussion: Fmax and Fex decrease systematically and significantly with an increase of the ankle angle (and consequently the reduction of the muscle-tendon complex length) in isometric plantar flexions (Fmax 1453±265 N at 75° to 465±253 N at 135°, Fex 6830±1780 N/s at 75° to 1740±1450 N/s at 135°). This is due to the decreased overlapping of the actin-myosin-filaments in shortening the muscle-tendon complex. The results are highly specific according to individual muscle-mechanical properties of the subjects.

Conclusion: The measuring device and in combination with the protocol provides an adequate method to determine the muscle mechanical characteristics of the plantar flexors. Based on the individual anthropometric data and specification of the initial conditions (ankle angles), the test routine provides information regarding the following aspects: (1) subject specific plantar flexor characteristics (Fmax, Fex) as a function of muscle-tendon length and (2) inter-subjective comparison of plantar flexor characteristics. This is important information that can be used to control and optimize training regimes.

Influence of Body Weight on Joint Loading in Stair Climbing

Strutzenberger, G., Schneider, M., Schwameder, H.
University of Karlsruhe, Germany

In Germany 15% of the children between 3-17 years are overweight and 6.3% are recorded as obese (Kurth & Schaffenrath Rosario, 2007). Excessive weight leads to numerous health problems not only for the metabolic system but also for the locomotor system (Wabitsch et al., 2005). Obesity is a known risk factor for osteoarthritis but the specific mechanisms are still not well understood. Research on joint loading of overweight children has been performed in level walking and standing, but little research has been done in other daily living activities (e.g. Morrison et al. 2007, Nantel et al, 2006). Therefore, the purpose of this study was to examine whether or not obese children exhibit altered patterns of joint loading in the lower extremities during stair climbing, compared with children of normal weight. 5 normal weight children (11.4 ± 0.9 yrs, 41.6 ± 7.2 kg) and 4 obese children (12.1 ±0.8 yrs, 71.6 ± 14.7 kg) participated at this study. A staircase with 6 steps (117 cm x 28 cm per step) was built. To record the dynamic data of 2 consecutive steps, 2 force plates (AMTI, 1200 Hz) were embedded in the 3rd and 4th step. The kinematic data was collected by 10 infrared cameras (Vicon, 300 Hz). The children performed 3 valid trials walking upstairs and downstairs at 3 different speed levels: 90, 110,130 steps/min. The most representative out of 3 valid trials was taken for further analysis. Dynamic data was normalized to bodyweight and both kinematic and dynamic data was time-normalized to the stance phase. Inverse dynamics was calculated and peak values of the ankle, knee and hip joint moments were identified. Independent t-tests were used to examine differences between the two groups within each speed-condition. In all speed conditions obese children show more pronounced hip flexor moments, especially in the downstairs condition. Analogous to level walking (Nantel et al., 2006) the change between extensor and flexor moment occurs earlier in the gait cycle in obese children than in their normal-weight counterparts. Obese children reveal a significantly higher maximal varus-moment in the knee when walking downstairs. The obese children pronounce a tendency to higher plantarflexor moments and higher pronation moments in walking upstairs. In obese children a clear trend to higher lower extremity joint loading in stair climbing can be observed. In combination with misalignments of the joints this might cause local overloading within the joints. Furthermore, this might be related to a greater occurrence of lower extremity joint problems and osteoarthritis. Latter has to be proven in long-term studies.

Introduction
Electromyostimulation (EMS) training is based on electrical induced rhythmic muscle contraction. In human, it has been shown that a fibre type transition phenomenon from type I to type II fibres results from this kind of training in the vastus lateralis muscle (1). In animal, a fiber type transition has been associated with changes in muscle stiffness (2). Thus, the aim of the present study was to analyze whether EMS training leads to changes in musculotendinous (MT) stiffness of the human triceps surae (TS) as observed after changes in functional demand (3).

Methods
Experiments were done on 11 college students. The subjects had to perform a training protocol (4 weeks, 4-5 sessions of 1 hour per week) based on a 75Hz frequency electromyostimulation program. Laboratory tests were performed using an ankle ergometer (4). Subjects had to develop a maximal effort in plantar flexion (MVC). Three trials were carried out and the best was considered as true MVC of the day. Then, MT stiffness was established by means of a quick-release technique, when the subject maintained a voluntary isometric torque (40%, 60% and 80% MVC). The ratio between variation in dynamic torque and displacement was related to the isometric torque initially exerted by the subject. The slope of the linear relationship so obtained was defined as stiffness index (SIMT). Then, sinusoidal perturbations (3° peak-to-peak, 4-16 Hz) were imposed at different voluntary isometric torque levels (0%, 20%, 40% and 60% MVC). For each level of torque, a second order model was adjusted to a Bode diagram to calculate inertia, viscosity and elasticity of the musculoarticular (MA) system. These parameters allowed the calculation of $V'_{max}$ defined as the maximal shortening velocity at a torque value corresponding to zero by using an adaptation of Hill's equation to sinusoidal perturbations (5).

Results
Mean MVC changed significantly from $113.6\pm10.5$ to $135.2\pm12.6$ Nm, which correspond to a significant increase of 19.8%. SIMT decreased significantly from $2.1\pm0.16$ to $1.7\pm0.17$ rad$^{-1}$ (-17.8%). Finally, mean $V'_{max}$ was significantly increased by 21.3% (from $7.7\pm0.71$ to $9.1\pm0.71$ rad s$^{-1}$).

Discussion/Conclusion
The present results are the first ones showing the SIMT evolution due to EMS training. It is well known that SIMT is composed of an active fraction (muscle fibres) and a passive fraction (tendon). There is no reason to believe that tendon decreases its stiffness as a result of training. Then, the decrease in SIMT can be interpreted in terms of fibre type transition phenomenon as it is known that an increase in type II fibers lead to a decrease in muscle stiffness (2). This is also comforted by the increase in $V'_{max}$, since this parameter depends mainly on the fiber type distribution.

IN VITRO ASYMMETRIC STRAIN DISTRIBUTION IN THE HUMAN ACHILLES TENDON AT DIFFERENT LOADING LEVELS - INTERACTION BETWEEN M. TRICEPS SURAE FORCES AND CALCANEAL ALIGNMENT

Lersch, C., Potthast, W., Segesser, B., Koeckije, J., Brueggemann, G.P.

German Sport University Cologne1, Germany, Rennbahnklinik Multitenz2, Switzerland, University of Cologne3, Germany

Nonhomogenous strain between different fibers of a tendon represents a possible underlying mechanism for tendon injury. The following factors may cause asymmetrical loading of the Achilles tendon (AT): a) the joining of three different muscles with different force potentials and activation patterns into the musculotendinous junction, Mm. gastrocnemius medialis (GMI) and lateralis (GIL) and m. soleus (SOL) b) Distal AT fiber insertions at the calcaneus (CAL) have been described as separate for different portions of the M. triceps surae (TS) (1,2). However, the interaction between TS forces and CAL alignment regarding a possible asymmetric strain distribution in different parts of the tendon is only studied with forces up to 400N (2). Therefore the purpose of the this study was to determine the strain distribution within the human AT while changing TS force application at different levels and changing the positioning of the CAL.

Three human cadavric ATs were mounted in a specially designed loading simulator. Length changes on the ventral and dorsal side of the tendon were controlled with high-resolution video cameras. Different loads (400-1200N in total) were applied to the three parts of the TS while calcaneus position was changed systematically (neutral position, eversion (EV), inversion (INV) each 7.5°/15°). Moments around the CAL were calculated from reaction forces gained by force dynamometers implemented in the testing device.

Different TS loading simulations induced different tendon strain distribution patterns, whereas GL and GM seemed to be more sensitive to induce asymmetric strain than the SOL. Strain in the proximal part (up to 2%) was lower than it was in the distal part (up to 4%) of the tendon. All different muscle loading conditions induced different CAL INV moments with the neutral positioning of the CAL. These findings could be explained by the morphology (twist) of the CAL. EV of the CAL provoked higher strain on the medial side (ventral and dorsal) in the proximal as well as in the distal part of the tendon. Strain increased from 4-6% with increment of the EV angle from 7.5° to 15°. The laterally reversed pattern could be found for the CAL INV angles with strain values up to 5.5%. A CAL INV moment could be found for the neutral CAL position as well as for the EV conditions. A comparably lower EV moment was only found for the INV conditions. Again these findings could be explained by the morphological configuration of AT fiber distribution/twist. This study showed that asymmetric strain within the AT can be caused by TS muscle force variations as well as by different CAL angles in the frontal plane. The latter can induce a greater effect on strain magnitude. Except for the INV conditions greater strain in the medial part of the tendon could be found. The findings of these study could lead to a better understanding of AT pathologies.

Changes in architecture of aponeurosis of tibialis anterior upon contraction measured by 3D-ultrasonography

Ikegawa, S., Kurihara, T., Sakaguchi, M., Kanehisa, H., Fukunaga, T., Kawakami, Y.
Tokyo Metropolitan University, Japan

Introduction.
Architectural feature of the aponeurosis is important for the modeling of the muscle-tendon unit, especially for pennate muscles. The width of the central aponeurosis of the tibialis anterior increases as the contraction level is increased (Maganaris et al 2001, Muramatsu et al 2001). Not much is known, however, about the changes in shape and position of the aponeurosis during contraction. The aim of the present study is to clarify the position and surface area changes of the aponeurosis of human tibialis anterior muscle upon contraction by using 3D-ultrasonography.

Methods.
A healthy male participated as a subject in the experiment. The ankle joint was fixed at 30 deg plantar flexion with the knee joint positioned at 0 deg (full extension). In the present study, we employed 3D-ultrasonogram (USE-1200, Nihon-Kohden, Japan) with an electromagnetic position sensor attached to the ultrasonic transducer. During the scanning, the probe was moved by the tester along the longitudinal axis of the muscle belly from the distal end of the tibia toward the proximal end. Transverse serial images of the tibialis anterior muscle were retrieved as composite video signals from the ultrasonic machine and three-dimensional ultrasound images were reconstructed using a software (Tomtec3D, Tomtec, Germany). During the ultrasonic data acquisition, the subjects were asked to relax then maintain isometric dorsiflexion at three force levels (20, 40, and 60% of the maximal voluntary force level [MVC]).

Using the software, the serial cross-sectional images (10mm interval) of the tibialis anterior muscle were detected. The x,y coordinates of the surface of the central aponeurosis in each image were measured. The distances between the central aponeurosis and superficial and deep muscle fascia were measured.

Results and Discussion.
The surface area of the aponeurosis increased from 287 mm² at rest to 390 mm² at 60% MVC. The distance between the aponeurosis and deep muscle fascia did not change. The results indicate that the central aponeurosis has transverse elasticity, and that we need to reconsider the model of contraction of pennate muscles with a constant muscle thickness.

Conclusions.

Muscle and Tendon Properties during Isometric Ramp Contractions of the Ankle Plantar Flexors in Children

Kannas, T., Kellis, E., Arabatzi, F., De Soez, E.
Aristotle University of Thessaloniki, Greece

AIMS: Architectural arrangement of muscle fibers is a very important factor for muscle force production (1). Most studies examined isometric force and muscle architecture properties (2) in adults. In contrast, there is a lack of data in children. Recent studies have shown that children present different values at muscle pennation angle as well as fascicle length (3) compared with adults. The aim of this study was to examine the relationship between fascicle length and tendon aponeurosis displacement and isometric force production in children.

METHODS: Twenty boys (age= 11.2 ± 0.26 years, mass= 48.78 ± 9.15 kg, height= 156.7 ± 7.28 cm) participated in this study. All tests were performed on a Kin Com (Kin-Com, Chattanooga Group Inc, USA) dynamometer. In vivo muscle architecture was assessed using B-mode ultrasonography (SSD-3500, 7.5MHz, Aloka, Japan). Isometric torque of the plantar flexors was assessed at angles of -15° (dorsal flexion), 0° (neutral position), 15° and 30° (plantar flexion). The subjects performed three efforts at 100%, 40%, 60% and 80% of MVC. The total duration of each effort was 5 seconds. Subsequently muscle thickness, fascicle length and aponeurosis strain were evaluated.

RESULTS: The changes of muscle thickness were very small with increasing level of muscle effort. Particularly the muscle thickness of MG ranged from 2.5cm to 2.4 cm at 30°, from 2.18 cm to 2.14cm at 15°, from 2.26cm to 2.13cm at 0° and from 2.3cm to 2.15cm at -15° ankle angle. Higher fascicle length values were found at an angle of -15° while the smaller one was observed at 30°. Fascicle length ranged from 4.5cm to 3.5 cm, from 4.1 cm to 3.2cm, from 3.7cm to 3 cm and from 4.6 cm to 3.7cm for 30°, 15°, 0° and -15° ankle angles, respectively. Aponeurosis elongation increased as the angle decreased. The maximum value (9.22%) was obtained at -15° and the minimum (1.98%) at 30°.

CONCLUSIONS: To our knowledge, this is the first study which examined the relationship between isometric force production and muscle tendon interaction in children. The results of this study are consistent with previous studies on the plantar flexor architectural properties. Even though children demonstrated lower fascicle length, thickness and tendon elongation values than adults, the relationship between level of force and each architectural parameter was similar as previous published results in adults.

References.
Within the present study, should provide more scientific evidence of psychosocial processes in obese adolescents seeking weight loss.

Methods
Subjects were 49 obese adolescents (BMI M=30.7 SD=4.5 kg/m², age M=13.6 SD=1.5 y, 25 girls) being followed in a tertiary health unit, who are participating in a long-term program that comprises medical, nutritional, physical activity and psychological interventions. The program comprises up to 3 sessions of exercise per week in addition to lifestyle physical activity recommendations. Self-esteem (Rosenberg, 1969), Emotions (PANAS, Watson et al., 1988), Weight Efficacy Lifestyle Questionnaire (WELO, Clark et al., 1991), Exercise motivation (IBREG-2, Markland & Tobin, 2004), Body Size Dissatisfaction (BIA, Williamson et al., 1989), weight and height were measured at baseline and 2 months later during the program. Paired t-tests were used for the analysis of differences between baseline and 2 months’ values. Pearson correlations measured the association between psychosocial changes with weight and BMI changes, while independent t-test evaluated change differences between gender.

Results
Although no differences were found in weight or BMI, improvements were observed in positive emotions (p<.035), intrinsic motivation (p<.026), and in the WELO’s sub-scales: negative emotions (p<.043), availability (p<.026) and social pressure (p<.013). There were also marginally significant improvements in identified motivation (p<.094) and total self-efficacy (p<.070). These improvements were similar between gender and were not associated with weight and BMI changes.

Conclusion
Despite the short-term time frame of the analysis, the positive changes observed in psychosocial variables suggested the same conclusions registered in studies with longer periods (Blaine et al., 2007). The improvements in the more self-determinate type of motivation, which should influence exercise and program adherence (Teixeira et al, 2006), represent a particularly strong sign that the program might be successful among the adolescents that increased their exercise’s intrinsic motivation. Further data with longer time periods, within the present study, should provide more scientific evidence of psychosocial processes in obese adolescents seeking weight loss.

METABOLIC SYNDROME AND PHYSICAL ACTIVITY IN ADOLESCENTS

Tammelin, T., Pirkola, J., Laitinen, J., Nåyhä, S., Ekelund, U., Remes, J., Ruokonen, A., Järvelin, MR.
Finnish Institute of Occupational Health, Finland

Purpose: Metabolic syndrome (MS) is defined by the clustering of central obesity, impaired glucose metabolism, dyslipidemia and hypertension and indicates increased risk of cardiovascular disease and diabetes. In adults, higher levels of moderate to vigorous intensity physical activity have been associated with a reduced risk of having MS, but there is little information regarding adolescents. This study aimed to evaluate the association between the level of physical activity and prevalence of MS in adolescents.

Methods: The study population consisted of 2565 males and 2638 females aged 16 years, members of population based Northern Finland Birth Cohort 1986 (NBBC 1986), who responded to a mailed questionnaire and were clinically examined in 2001-2002. Metabolic syndrome was defined using the International Diabetes Federation paediatric definition (Zimmet et al. 2007). Physical activity was assessed by self-report taking into account both intensity level and time duration, and was summarised as metabolic equivalent hours (MET hours). Prevalence of MS and 95% confidence intervals (CI) were estimated in the quintiles of physical activity described by MET hours.

Results: The overall prevalence of MS was 2.4%, and was higher in males (3.5%) than in females (1.1%). In males, the prevalence of MS was inversely associated with the level of physical activity, and was 2.0% (CI 1.0 to 3.7) in the physically most active quintile and 4.7% (CI 3.1 to 7.4) in the least active quintile. In females, the prevalence of MS showed no significant variation by physical activity.

Conclusion: In males aged 16 years, the level of physical activity was inversely associated with the prevalence of MS while no such association was seen in females.

THE ASSOCIATION BETWEEN SKELETAL MATURITY, SOCIO-ECONOMIC STATUS AND BODY MASS INDEX IN MADEIRAN CHILDREN AND ADOLESCENTS

Faculty of Kinesiology and Rehabilitation Sciences, K. U. Leuven, Belgium

The association between skeletal maturity, socio-economic status and body mass index was investigated in a mixed longitudinal sample of Portuguese children and adolescents (251 girls and 256 boys), 7 through 18 years of age. Skeletal age was estimated from a radiograph of the left hand and wrist using the Tanner-Whitehouse method II. Socio-economic status was based on Census 91 developed by the Portuguese Institute of Statistics. Stature and body weight were measured and body mass index was used as an adiposity indicator. Early maturing boys and girls showed higher body mass index values than their average and late maturing peers. The significant differences among maturity groups were not present in boys 14 to 15 years of age. Youngsters from families with a high socio-economic status...
showed a higher body mass index than those from families with an average or low socio-economic status. However, no significant differences were found between socio-economic categories for boys 10-11 years and for girls 12-14 and 15-18 years. Body mass index is associated with skeletal maturity and socio-economic status in children and adolescents from Autonomous Region of Madeira, Portugal.

ENVIRONMENTAL CORRELATES, PHYSICAL ACTIVITY AND BODY MASS INDEX OF CHILDREN

Al-Nakeeb, Y., Duncan, M., Woodfield, L., Lyons, M., Dowdall, S.
Newman University College Birmingham, United Kingdom

Introduction.
Research findings suggest that sedentary behaviour of children is influenced by a number of social and built environment factors. Also, strong evidence indicates that physical inactivity and obesity are major risk factors for Coronary Heart Disease (CHD). Therefore, exploring environmental factors and assessing young people’s physical activity (PAI) and body fatness has become a key component of understanding disease prevention and intervention strategies. The aims of this study were: (1) to examine physical activity patterns of British children and to determine the variation across weekdays and weekends according to body mass index (BMI) and gender; (2) to explore the environmental causes of sedentary behaviours amongst this age group.

Methods.
Three hundred and thirty five children (157 boys and 178 girls) aged 8-14 years from Central England volunteered to participate following informed consent from children and parents along with institutional ethical approval. BMI was determined as kg/m2 and weight status was classified according to International Obesity Task Force (IOTF) cut-off points. The children wore a sealed pedometer for 4 consecutive days (2 weekend days and 2 weekdays) to determine their daily step counts. They were asked to complete a brief survey to verify the length of time they wore the pedometers. Questionnaires and semi-structured interviews were used to explore the impact of social and built environment on PA.

Results.
A 2 X 2 X 2 repeated measures analysis of variance (ANOVA) with 2 levels of steps per day, 2 levels of gender and 2 levels of weight status was used to assess children’s pedometer determined PA and to examine any variation due to BMI, gender or day. Results indicated that 28.8% of participants were classified as overweight/obese and 71.2% were classified as normal weight according to IOTF criteria. 34.4% of boys and 43.1% of girls met or exceeded the BMI referenced cut-offs for health respectively. A significantly higher number of steps/day was recorded during weekdays than weekends (F(1,333) = 47.8, p = 0.001) with normal weight children achieving significantly greater steps/day than their overweight/obese peers (F(1,333) = 13.36, p = 0.01). Additionally, neighbourhoods’ social and built environment appeared to have a major impact on opportunities for PA.

Discussion.
The results suggest that the majority of children are not achieving sufficient PA to gain health benefits. A significant number of them were overweight or obese and did less PA than their normal weight peers. Intervention strategies are needed to increase opportunities for PA. Active commuting to school and interventions through modifying the social and built environment of children are important to overcome the PA deficit and change children’s sedentary behaviour. The findings highlighted the need for multi-level interventions that encompass psycho-social and environmental factors.

INCREASE IN LEISURE-TIME PHYSICAL ACTIVITY OVER 9 YEARS DECREASES THE RISK OF METABOLIC SYNDROME IN YOUNG ADULTS

Yang, X., Telama, R., Hirvensalo, M., Raitakari, O.
IJKES-Research Center for Sport and Health Sciences, Jyväskylä, Finland

Background and Aim: Regular physical activity may prevent or delay the onset of the metabolic syndrome in adulthood. It is unclear, however, what are the longitudinal effects of physical activity on metabolic syndrome risk in young adults. This study aims to examine the association between physical activity and the metabolic syndrome over a period of 9 years in a population-based cohort of young adults.

Methods: Data were obtained from the Cardiovascular Risk in Young Finns Study in which 2214 young subjects participated in the study in 1992 and 2001. The participants were 15-, 18-, 21-, 24-, 27- and 30-year-olds in 1992, and 24-, 27-, 30-, 33-, 36- and 39-year-olds in 2001. Leisure-time physical activity (LTPA) was assessed using a self-report questionnaire at two consecutive measurements and summed as physical activity indices (PAI). Change in LTPA was first calculated as a continuous variable by subtracting follow-up PAI from baseline PAI and then, as a categorical variable (LTPA tertiles) in order to study the effects of change in LTPA on the metabolic syndrome risk. Metabolic risk variables consisted of fasting insulin, waist circumference, serum triglycerides, inverted HDL cholesterol, systolic blood pressure, diastolic blood pressure, and plasma glucose. The original values of metabolic variables were transformed to z-scores for each individual, and then summed to create a continuously distributed the metabolic risk variable.

Results: Multivariate analysis of variance revealed that both men and women who increased their physical activity from the lowest tertile to the highest tertile at follow-up had a lower risk of metabolic syndrome. Similar results were found among both sexes in those who moved from the moderate tertile at baseline to the highest tertile at follow-up. Both men and women who maintained their high level of physical activity had lower metabolic risk than those who in low-low tertiles over time. Linear regression analysis showed that the increasing LTPA was significantly and inversely associated with the metabolic risk score for both sexes (p < 0.001), independently of baseline PAI values, age, smoking and education. A graded decrease was found in the metabolic risk across tertiles of change in LTPA for both sexes after adjusting for the confounders.

Conclusions: We conclude that both increased and persistent physical activities are significantly associated with a lower risk of metabolic syndrome in young men and women. This benefit is also influenced by the increasing physical activity during 9 years. The continuity of physical activity in adulthood is important in preventing clustering of metabolic syndrome risk factors.
FROM CHILDHOOD TO PUBERTY: LONGITUDINAL RELATIONSHIP BETWEEN BMI, PERCENTAGE BODY FAT, AND PHYSICAL FITNESS

Rodrigues, L., Bezerra, P., Saraiva, L., Leitão, R.
Polytechnic Institute of Viana do Castelo, Portugal

The main goal of this study was to search for the relationships between somatic characteristics and physical fitness along childhood and puberty. Two hundred seventy four children were longitudinally followed from 6 to 15 years of age (at 6, 7, 8, 9 and 15 years), and their somatic (BMI, %BF) and physical fitness (60 sec sit-ups, flexed arm hang, standing long jump, 50 meters dash, 10 meters shuffle run, and 20 meters pacer run) characteristics assessed within the Estoril Multifunctional Institute of Viana do Castelo (Viana do Castelo Growth Study). All results were standardized (z-scores) within each gender group and a composite score was used to assess physical fitness as an all.

Children with higher BMI and/or %BF had lower physical fitness levels at any given age (r= -27 to -52, p<0.01), but, interestingly, somatic status showed even stronger relationship with the next wave of physical fitness evaluation (r= -44, -43, -46, -39, and -51, -46, -50, -35, respectively for BMI and %BF for 6-7, 7-8, 8-9, and 9-15 years old). Furthermore, correlations were stronger between physical fitness at 15 years of age and somatic status (BMI/%BF) at 6, 7, 8, and 9 years old (r= -18 / -24, -31 / -31, -32 / -33, and -36 / -35), than for the autocorrelation of physical fitness at those same ages (r= -16, -19, 23, and 28).

These results lead us to conclude that children somatic characteristics (BMI and %BF) are strong predictors of physical fitness at latter puberty years.

THE GREEN-TEA CATECHIN EPICALLOCATechin GALLATE (EGCG/TEAVIGOTM) INCREASES RUNNING ACTIVITY AND RESULTS IN A SKELETAL MUSCLE FIBER TYPE SHIFT IN MICE

Friedel, A., Wyss, C., Elste, V., Raederstorff, D., Wolfram, S.
DSM Nutritional Products Ltd., Switzerland

Epigallocatechin gallate (EGCG/ TEAVIGOTM) is the most active component of the green tea. It is associated with reduced risk of cancer, diabetes and pronounced cardiovascular and metabolic health benefits. In a swim model, it was shown that green tea extract improves endurance capacity (Murase et al., 2004).

The purpose of the present study was to determine the effect of EGCG on running activity and skeletal muscle in mice. Sixty C57Bl/6J mice (5 wks old) initially received a high-fat diet (HF) for 3 months. Thereafter, mice were randomly assigned into 5 groups (n=10): Low fat diet (LF), HF, HF + 0.5% w/v EGCG (HF+EGCG), HF + exercise (HF+EX) and HF + 0.5% w/v EGCG+exercise (HF+EGCG+EX). The exercise groups had unlimited access to running wheels and the distance was recorded daily. At the end (2 months of treatment) maximal running performance on a treadmill was determined, body composition was measured and plasma was taken. Gastrocnemius muscle was excised, frozen in liquid nitrogen and stored for later histological analysis.

Mice receiving HF+EGCG ran significantly greater distances per day in the running wheels compared to mice fed only with HF. The maximal endurance test showed that the EX groups or groups treated with EGCG had significantly longer, whereas the HF+EGCG+EX group ran the longest distance. EGCG reduced the body fat mass in exercising and non-exercising animals. Plasma concentrations of leptin and cholesterol were decreased in the LF group. The histological analysis in the medial part of the gastrocnemius indicated an increased percentage of type I and type IIA fibers and less type IIB and IID/X fibers in mice supplemented with EGCG. The observed fiber type shift in both EGCG groups was more pronounced than the fiber type shift in the exercised high-fat group. Exercise alone resulted in an increased proportion of type IIA fibers.

Our results demonstrate that EGCG increases the desire to exercise, the willingness to run and the motivation to move in animals. It was also shown that EGCG increases the number of oxidative (slow-twitch) muscle fibers, the number of aerobic skeletal muscle fibers which can help to perform endurance exercise.

In conclusion, EGCG/TEAVIGOTM improves the voluntary and maximal running activity of the mice. In skeletal muscle, a fiber-type shift from fast to slow twitch fibers was observed. We hypothesised that EGCG/TEAVIGOTM leads to accelerated training success.

EFFECT OF ORAL GLUCOSE INGESTION ON ENDURANCE TRAINING ADAPTATION PERFORMANCE AND METABOLISM

Akerstrom, T., Yfantl, C., Nielsen, S., Nielsen, A., Pedersen, B.
Rigshospitalet, Faculty of Health Sciences, University of Copenhagen, Denmark

Introduction. Major exercise and sport-organizations recommend athletes to ingest beverages containing carbohydrates during exercise. The argument being that the athlete could then train harder and longer and thus achieve a superior training effect. There is, however, no empirical evidence to support this claim. On the contrary, there is data to suggest that glucose ingestion can modulate the training response. We wanted to investigate whether 1) glucose ingestion during training would allow subjects to train harder if they ingested a glucose drink during the training session and 2) whether glucose ingestion during training would have an impact on performance and metabolism. Methods. Male subjects (n=21) were recruited in a double-blinded intervention study. The intervention group (Glucose-group) (n=11) received an 8% (w/v) glucose drink during training whereas the placebo group (Plc-group) (n=10) drank a placebo. Both groups performed the same supervised 12 week training program on a cycle ergometer. Subjects performed an incremental maximal workload (Pmax) test at the start of each week of training. The subjects trained 4 times per week and the training consisted of continuous and interval cycling at intensities from 55-91% of Pmax and a duration of 1-2.5 hours. The training was designed so that the subjects could not manage all training sessions at the planned workload. If the subject could not manage the workload the resistance was reduced by 5% until the subject could finish the training session. Before and after the training period the subjects performed a Pmax test to determine VO2max, Pmax and the ventilatory threshold (VT) as well as a time-to-fatigue-test at 70 % (TT70%) of Pmax. Furthermore, changes in

STORIL/PORTUGAL, 09-12 July 2008
It has been firmly established that co-ingestion of protein with carbohydrate stimulates post-exercise muscle protein synthesis and leads to a positive net muscle protein balance during recovery. In contrast to the impact of nutritional interventions on post-exercise muscle protein synthesis, little is known about the potential to modulate protein synthesis during exercise. PURPOSE: This study investigates the impact of the co-ingestion of protein hydrolysate with carbohydrate on muscle protein synthesis rate during resistance type exercise activities. METHODS: Ten healthy males were studied in the evening after consuming a standardized diet throughout the day. Subjects participated in 2 experiments, in which they ingested either carbohydrate or carbohydrate with a protein hydrolysate during a 2 h resistance type exercise session. Subjects received a test beverage prior to and every 15 min during exercise, providing 0.15 g/kg/h carbohydrate with (CHO+PRO) or without (CHO) 0.15 g/kg/h protein hydrolysate. Continuous intravenous infusions with L-[ring-2H2]phenylalanine and L-[ring-2H2]tyrosine were applied, and blood and muscle biopsies were collected to assess whole-body and skeletal muscle protein synthesis rates during exercise. RESULTS: Protein co-ingestion lowered whole-body protein breakdown rates by 26±4%, compared to the ingestion of carbohydrate only, and elevated protein oxidation and synthesis rates by 77±17 and 33±3%, respectively. As a consequence, whole-body net protein balance was negative in CHO, whereas a positive net balance was achieved in the CHO+PRO experiment (25.4±0.4 µmol phe/kg/h in CHO+PRO vs CHO; P<0.01). In accordance, mixed muscle protein fractional synthetic rate (FSR) was 49.2±2% higher following protein co-ingestion (0.088±0.012 and 0.060±0.004 %/h in CHO+PRO vs CHO, respectively, P<0.05). CONCLUSION: We conclude that even in a fed state, co-ingestion of protein hydrolysate with carbohydrate stimulates whole-body and muscle protein synthesis rates during resistance type exercise.

POST-EXERCISE ALCOHOL INGESTION DELAYS THE RECOVERY OF DYNAMIC STRENGTH FOLLOWING FOLLOWING STRENUOUS ECCENTRIC EXERCISE

Stannard, S., Barnes, M., Mundel, T.
Massey University, New Zealand

Introduction
Competitive sport participation often involves significant eccentric muscular action which may result in muscle micro-structural damage, reduced muscle performance, and soreness. Coincidently, alcohol is regularly consumed by sports-people during the post-event period. Rapid restoration of muscle function is necessary to enable optimal subsequent training or performance, yet it is not known how alcohol consumption affects the recovery process.

Objective
To compare the effects of acute alcohol intake with that of a non-alcoholic beverage on muscle performance following strenuous eccentric exercise.

Design
Eleven men, 23.9 ± 4.7 years (mean ± SD) performed 300 maximal eccentric contractions of the quadriceps muscles of one leg on an isokinetic dynamometer. They then consumed a beverage containing 1g/kg bodyweight ethanol (as vodka and orange juice). On another occasion they performed another bout on the contralateral leg after which they consumed an isocaloric quantity of orange juice. Maximal isokinetic (concentric and eccentric) and isometric torque produced across the knee, and plasma creatine kinase concentrations were measured before and at 36 and 60 hours following each exercise bout.

Results
Alcohol ingestion following eccentric exercise significantly reduced maximal isometric, eccentric and concentric torque, and average eccentric and concentric torque, at 36 and 60 hours compared to orange juice (all p < 0.05). Post-exercise plasma creatine kinase concentrations were not different between conditions.

Conclusions
Moderate consumption of alcohol post-exercise increases decrements in dynamic and static strength following strenuous eccentric exercise. To ensure optimal recovery, participants in sports involving eccentric muscle work should avoid alcohol in the post-event period.

WEIGHT LOSS RESISTANCE IN SOME OBESE WOMEN IS ATTRIBUTABLE TO MUSCLE ENERGETIC EFFICIENCY, WITHOUT DIRECT RELATION WITH LEPTIN

Lima, R., Melo, C., Marchini, J., Urasaki, R., Jirapegu, J.
University of São Paulo; São Judas Tadeu University, Brazil

This work aimed to test the following hypothesis related to adaptive thermogenesis: some obese women don’t lose weight after a physical activity program, and it could be due to a leptin stimulated reduction in energy expenditure. 26 sedentary obese women, aged from 25 to 50 years old, were studied. They were kept on physical activity program for 4 months, three times a week (30 minutes of aerobic and 30 minutes of resistance exercise). They were evaluated at the beginning and at the end of the program: food consumption, physical activity level, body composition (by DXA), body mass index (BMI), waist circumference (WC), resting (REE) and daily (DEE) energy expenditure, V02, VCO2 and RER from aerobic power test, with the calculation of muscular efficiency (GME), fasting leptin, TSH and glu-

body composition was assessed by DXA-scanning and substrate utilization was investigated during a 1-hour exercise-test at 65% of Pmax (1h-test) by infusing a labelled glucose tracer (6,6-2H2-Glc). Before, immediately following, and 3 hours after the 1h-test muscle biopsies were taken, which were analyzed for activity of metabolic enzymes and glycogen content. Results: The total amount of work performed during the training period was not different between the 2 groups. In line with this, VO2max increased significantly from 4.2 and 4.1 to 5.1 and 4.9 l/min in the Glc-group and Plc-group, respectively, but was not different between groups. In addition, Pmax and the power at which VT occurred also increased significantly in both groups with no differences between groups. Time to fatigue and total work during the TTF70% test and the fraction of VO2max where VT occurred did not change after training and was not different between groups. Both groups increased lean body mass and decreased fat mass with no difference between groups. Conclusion/Discussion. The effect of glucose ingestion on training adaptation appears to be limited. No difference between the Glc- and Plc-group in the ability to maintain a high workload during training or any of the p
case. To perform the final evaluation, the women were distributed in two groups: G1= final BMI < initial BMI, and G2= final BMI >/= initial BMI (BMI= body mass index). Leptin levels were reduced after the program (G1: from 47.92±7.44 ng dl-1 to 40.34±8.76 ng dl-1, p<0.05 and G2: from 50.22±6.60 ng dl-1 to 42.45±7.81 ng dl-1, p<0.05), but only 50% of the evaluated women reduced their BMI (G1(n=13): from 37.1±4 to 36.5±5 kg/m2, p<0.05, and G2(n=13): from 35.5±3 to 35.3±3 kg/m2 p>0.05). REE was not different from initial to final values, for both groups. During the aerobic power test, G2 showed reduction in VO2 at 30W (G1: from 7.8±1.0 to 7.5±1.1 mL Kg-1.min-1; p>0.05 and G2 from 8.2±1.6 to 7.3±1.2 mL Kg-1.min-1; p<0.05) G2 improved muscle efficiency to perform the aerobic power test (+11.4% at 30W, +10.42 at 50W and +2.08 at 70W higher than G1). Leptin not completely explained the VO2 values (from 17.1 to 40% of the statistical explanation). As conclusion, some obese women present higher muscular efficiency and therefore higher resistance to lose weight, but there are weak evidences regarding the role of leptin in these results.

**INTERRELATIONSHIP BETWEEN LACTATE AND CARBOHYDRATE UTILISATION**

Alkhatib, A., Beneke, R.
1. London Sport Institute, Middlesex University, United Kingdom

**INTRODUCTION:** Indirect calorimetry is a valid and reliable indicator for estimating fat and carbohydrate oxidation rates. Lactate indicates the glycolytic activity, and its concentration in blood (BLC) is a standard measure of exercise intensity. The breakdown of carbohydrate via glycolysis results in pyruvate, which is either aerobically combusted or converted into lactate. The relative rate of pyruvate combustion (RPY) is determined by pyruvate dehydrogenase complex activity (PDH) in which pyruvate availability is a key regulator. Nevertheless, the ratio between lactate and pyruvate is regulated by the near equilibrium enzyme lactate dehydrogenase (LDH). Consequently, lactate may be used as an indicator of RPY. Sigmoid approximations have previously been used to describe the behaviour of many metabolic systems including the relationship between lactate and pyruvate combustion (Beneke 2003). The purpose of this study is to test whether RPY can be described as a function of BLC in incremental exercise testing.

**METHODS:** 21 healthy males (Age 26.3±6.0 years, Height 179.4±8.1 cm, Body mass 74.9±12.5 kg) completed an incremental load cycling test at 50 rpm. Starting with 1 W kg-1 body mass, power output was increased by 0.5 W kg-1 body mass every 2 min stage. Capillary blood samples were drawn from the hyperaerobic earlobe at rest and at the end of each stage. Oxygen uptake (VO2) and carbon dioxide production (VCO2) were measured, and analysed for estimating carbohydrate and fat oxidation using indirect calorimetry. The relative rate of pyruvate combustion (RPY) was calculated as a percentage of the full pyruvate combustion which is considered as when VO2 equals VCO2. RPY was further approximated as a sigmoid function of lactate (RPY = 100 / (1+kel / BLC2) where kel is the constant of half maximal pyruvate combustion.

**RESULTS:** Describing RPY as a function of BLC explained 86±0.09% of the variance in RPY. Estimates of kel were 1.82±0.095 [mmol l-1], and ranged from 0.54 to 4.4 [mmol l-1]. RPY appears more or less saturated at 96.5±8.1% corresponding with BLC levels of 4.9±2.0 mmol l-1.

**CONCLUSION:** RPY may be described as a function of BLC. This may be useful in using BLC to explain the inter-individual variations in the relative utilisation of carbohydrate and fat during incremental exercise.

**EFFECTS OF HEAVY STRENGTH TRAINING WITH DEEP OR SHALLOW SQUATS ON MUSCLE CROSS SECTIONAL AREA AND MUSCLE FUNCTION**

Raastad, T., Karlsen, S., Madsgaard, S., Boesen, M., Langberg, H.
Norwegian School of Sport Sciences, Norway

Heavy strength training and explosive strength training results in muscular adaptations as increase in muscle cross sectional area and in muscle length (1). Theoretically, heavy strength training at long muscle lengths may lead to a greater increase in muscle length and cross sectional area than training at short muscle lengths. Furthermore, different changes in muscle cross sectional area and muscle length should in turn result in marked differences in muscle function. The purpose of this study was to investigate the effects of heavy strength training in the squat exercise with short or long range of motion on thigh muscle hypertrophy and muscle function.

Eighteen males (20-38 years) were randomized into two groups performing either deep-squats (femur parallel with the floor) or shallow-squats (110° in the knee joint) with the same relative intensity (3-10 RM sets) and training volume. However, the external load was approximatively twofold higher in the shallow-squat group than in the deep-squat group. All subjects performed 3 workouts per week and 4-7 sets per exercise. Contractile properties of the knee extensors were measured in maximal isokinetic contractions at angular velocities of 60°/s and 300°/s and in maximal isometric actions at knee angles of 40°, 75° and 105° (full extension). Cross sectional areas of thigh muscles were measured at five sites with MRI. Values are given as means±SE.

Cross sectional area of m. quadriceps increased significantly at all measured sites in the group training deep-squats [4-7%], while significant changes in the group training shallow-squats only was observed at the two most proximal sites [2-4%]. In the hamstrings no significant changes in cross sectional area was observed. Isometric knee extension strength increased significantly in the deep-squat group at a knee angle of 105° (7.2%), but no significant changes were observed at 75° and 40°. No significant changes in isometric strength were observed in the shallow-squat group, but a tendency towards increased strength was noted at a knee angle of 40° (6.4%). Isokinetic strength at 60 and 300°/s increased by 7±3% and 8±2% respectively in the deep-squat group, while no significant changes was observed in the shallow-squat group. In the test at 300°/s, the knee angle of peak torque was increased by 4±2% in the deep-squat group while no change was observed in the shallow-squat group.

In conclusion, the group training deep-squats experienced more pronounced hypertrophy of m. quadriceps than the group training shallow-squats and this difference was translated to larger increases in muscle strength measured both in isometric and isokinetic tests. In addition, some indications of muscle length changes was observed in the deep-squat group with more pronounced strength increases at longer muscle lengths and increased knee angle of peak torque in the isokinetic tests.
DIFFERENCES IN TIME TO TASK FAILURE ARE NOT EXPLAINED BY THE WORK PERFORMED BY THE ELBOW FLEXOR MUSCLES

Rudloff, T., Justice, J., Matthews, S., Enoka, R.
University of Colorado, Boulder, United States

Time to failure for sustained submaximal contractions of the elbow flexors is briefer when supporting an inertial load (position task) of 20% of maximum compared with exerting an equivalent torque against a rigid restraint (force task). Because the fluctuations in limb acceleration increase more rapidly during the position task than do the fluctuations in force during the force task, it has been suggested that the muscles perform more work during the position task and thereby fatigue more rapidly. The purpose of this study was to compare the fluctuations in force and the times to failure when the elbow flexors performed the force and position tasks at low and high target forces. In a counterbalanced order with each task performed on a separate day, the subjects sustained the force and position tasks at 20% and 60% MVC force as long as possible. The subjects were seated with the forearm horizontal and in a neutral position, and the net muscle torque exerted by each subject was identical for the force and position tasks at each target force. Electromyographic (EMG) activity was recorded in both heads of biceps brachii, brachioradialis, and triceps brachii using surface electrodes. The force fluctuations were quantified as the coefficient of variation (CV) for force based on measurements obtained with a force transducer in both tasks. Time to failure for the position task at 20% MVC was briefer than that for the force task (126 ± 44 s and 846 ± 228 s, P = 0.03), whereas it was similar when the contraction intensity was at 60% MVC (95 ± 17 s and 89 ± 19 s, P = 0.8). The amplitude of the average EMG (% MVC) for the elbow flexors during both tasks was greater for the 60% MVC target force (58 ± 12% MVC) than for the 20% MVC target force (30 ± 6% MVC, P < 0.001). The rate of increase in EMG activity was similar for both tasks at 60% MVC target force, but was greater for the position task compared with the force task at the 20% MVC target force. The force fluctuations during the two tasks were similar at both target forces: the coefficient of variation for force was 2.6 ± 1.2% and 1.8 ± 0.2% during force and position tasks at the 60% MVC target force (P = 0.3) and 2.3 ± 0.8 and 2.3 ± 0.2% at the 20% MVC target force (P = 0.9). The similarity in the force fluctuations during the two tasks suggests that the work performed by the elbow flexor muscles did not explain the difference in the time to failure for the force and position tasks at the lower target force.

THE EFFECTS OF A 12 WEEK PEDOMETER-BASED WALKING INTERVENTION ON INFLAMMATORY MARKERS IN ADULTS NOT MEETING THE PHYSICAL ACTIVITY RECOMMENDATIONS

Gray, S., Baker, G., Wright, A., Fitzsimons, C., Mutrie, N., Nimmo, M.
University of Strathclyde, United Kingdom

Purpose
Across Europe, in 2005, 4.35 million deaths can be attributed to cardiovascular disease (CVD) accounting for approximately half of all deaths, with this figure rising each year (European Cardiovascular Disease Statistics 2005). Physical activity has long been prescribed to combat the high levels of CVD with the current recommendations being that adults should participate in a minimum of 30 minutes of moderate intensity physical activity [PA] on at least 5 days of the week [1]. Systematic low grade inflammation is associated with the aetiology of CVD, however the effects of increasing physical activity on markers of inflammation remains to be established. The aim of the current study, therefore, is to investigate if a 12 week pedometer-based walking intervention results in a reduction in inflammatory markers in adults not currently meeting the physical activity recommendations.

Methods
Recruited from the West of Scotland community 48 participants (37 females and 11 males) were randomised to either a control (n=24) or intervention group (n=24). The control group were instructed to maintain their normal walking for the 12 week study period. The intervention group received a PA consultation followed by a 12-week graduated walking programme aimed at increasing pedometer step-counts by an additional 3,000 steps/day, 5 days/week from week 7 onwards. Blood samples were collected at baseline and at 12 weeks and analysed for high sensitivity C-reactive protein (hsCRP) via an automated analyser and for interleukin-6 (IL-6), soluble IL-6 receptor (sIL-6R) and tumor necrosis factor-alpha (TNF-alpha) by enzyme linked immunosorbent assay (ELISA). Analysis was performed, using 2(group) by 2(time) mixed factorial repeated measures ANOVAs. Data are presented as mean (S.D.)

Results
The control group had an average daily step count of 6610 (3090) at baseline and this value did not change (P>0.05) at 12 weeks. In the intervention group average daily step count was 6684 (3443) at baseline, increasing (P<0.05) to 10837 (3463) at 12 weeks. In spite of this increase in walking there were no significant reductions in any of the inflammatory markers measured (P>0.05).

Conclusion
A progressive increase in walking, in the current population, for 12 weeks had no effect in reducing the inflammatory markers measured in the present study. It is likely, therefore, that a higher duration or intensity of exercise may be required to reduce the CVD risk associated with systemic low grade inflammation.

HAMSTRINGS MUSCLE ATROPHY FOLLOWING 35-89 DAYS OF UNLOADING

Norrbrand, L., Ekberg, A., Alkner, B., Tesch, P.
Karolinska Institutet, Department of Physiology and Pharmacology, Stockholm, Sweden

While it is generally held that the postural knee extensor muscles show greater atrophy than the knee flexors in response to disuse or unloading, data reported in the literature are not consistent. Thus, this study compared changes in hamstrings and quadriceps muscle volume in men and women after long-term unloading.

Methods: A total of seventeen otherwise healthy middle aged men and women were subjected to either 35 of unilateral (left leg) lower limb suspension (ULLS; 1) or 90 d of bed rest (BR; 2). Before and after ULLS and BR, and on day 29 of BR, volume of the hamstrings and quadriceps muscles was assessed by means of magnetic resonance imaging.
Results. There was a decrease in hamstrings muscle volume (5.5%; p<0.025) following ULLS. Volume of the weight bearing limb showed no change (p>0.05). Similar decrease was noted after 29 d of BR (6.3%; p<0.025). Half of the muscle loss shown on d 89 of BR (12.6%; p<0.025) occurred within 29 d of BR. The atrophy was greater (p<0.025) for quadriceps (18.6%) compared to hamstrings on d 89 of BR. There was a trend (p<0.10) towards greater quadriceps than hamstrings muscle atrophy after 29 d of BR (9.5%) and 35 d of ULLS (8.8%).

Conclusion: These results are in agreement with the belief that the quadriceps muscles are more prone to undergo atrophy than the hamstrings muscles in response to lack of weight-bearing. Yet, the loss of hamstrings muscle volume was substantial (ca. 70% of the quadriceps atrophy on d 89) and deserves attention. Hence, rehabilitation and countermeasures resistance exercise programs, targeting the lower limbs following or during longer episodes of disuse or unloading should incorporate the hamstrings muscles.

THE EFFECT OF SINGLE AND MULTIPLE SET STRENGTH TRAINING ON HEAT SHOCK PROTEINS IN M. VASTUS LATERALIS AND M. TAPEZIUS IN UNTRAINED MEN

Hanssen, K., Rønnestad, B., Kvamme, N., Raastad, T., Hallen, J.
Norwegian School of Sport Sciences, Norway

Introduction.
Heat Shock Proteins (HSPs) play an essential role in both cell protection and cell remodeling in response to different stressors, like exercise (1). Various kinds of strenuous exercise acutely increases HSP expression in muscles (3, 4, 5), but the HSP response to long-term regular exercise is less studied. However, increased levels of HSPs are reported in human muscles after 5-8 weeks strength training (2). The purpose of this study was to examine the effect of 1 and 3 sets strength training on the levels of HSP70 and B-Crystallin in a leg muscle and an upper body muscle. We hypothesised that 3 sets strength training would lead to a greater increase in the HSPs than the 1 set protocol.

Methods.
Twenty-five untrained men were randomly assigned into two groups. One group performed 3 sets in legs exercises and 1 set in upper body exercises (3L-1UB), while the other group performed 1 set in legs exercises and 3 sets in upper body exercises (1L-3UB). The subjects performed 3 workouts per week during 11 weeks. Biopsies were obtained from m.vastus lateralis and the upper part of m. trapezius before, after 2 weeks and after the training intervention. After homogenization, the cytosolic fractions were analysed by Western blotting for HSP 70 and B-Crystallin. Values presented are means ± SEM, p<0.05.

Results.
The levels of HSP70 and B-Crystallin were significantly increased in m.vastus lateralis after 2 weeks (66 ± 23% and 76 ± 22%, respectively) and post intervention (68 ± 22% and 88 ± 21%, respectively). In m. trapezius a significant increase was observed in HSP70 and B-Crystallin after 2 weeks (39 ± 16% and 49 ± 22%, respectively), but the levels after 11-weeks training was not significantly different from baseline levels. There were no significant differences in the heat shock protein response between the training groups in neither m.vastus lateralis nor m. trapezius.

Discussion/Conclusion.
The main findings were a rapid increase in both HSP70 and B-Crystallin, but thereafter HSP levels seemed to stabilize with only minor changes observed between 2 and 11 weeks of training. Training with 3 sets per exercise did not result in a larger HSP response than training with only one set per exercise. The HSP response seemed to be larger in m. vastus lateralis than in m. trapezius and this could be due to the fact that there were only one exercise involving upper part of trapezius (shoulder press) and two exercises involving m. vastus lateralis (leg press and knee extensions).

DIFFERENT MORPHOLOGICAL ADAPTATIONS TO ECCENTRIC VERSUS CONCENTRIC TRAINING IN OLDER INDIVIDUALS

Narici, M., Longo, S., Maganaris, C., Reeves, N.
Manchester Metropolitan University, Universita' degli Studi di Milano, United Kingdom

According to Hill's force-velocity relationship (1938), for any given shortening or lengthening contraction velocity, each value of force should belong to the same level of neural activation. It follows that if muscle loading during concentric (CON) and eccentric (ECC) contractions is applied with the same absolute load, motor units must be necessarily de-recruited during the ECC phase. Thus when comparing the effects of CON training to those of ECC training, loading of the muscle in these two conditions should be matched for the same relative intensity to avoid MU de-recruitment in the ECC phase. The present study tested the hypothesis that a training protocol based on pure eccentric loading performed at the same relative intensity would produce greater strength gains and hypertrophy than concentric training only. Nineteen older volunteers took part to this study; 9 were assigned to a CON training group (aged 74±3 yr, mean±SD, 4 males, 5 females), and 10 to a ECC training group (aged 67±2 yr, 5 males, 5 females). Both groups underwent progressive resistance training three times/week for 14 weeks using knee extension and leg press exercises (Technogym, Italy). For each contraction mode, the training load was set to 80% of the 5RM, i.e. at 80% of the CON 5RM and 80% of the ECC 5RM. Before and after training the following parameters were measured: quadriceps cross-sectional area (CSA) by MRI, vastus lateralis muscle fascicle length (LF) and pennation angle (PA) by ultrasound, muscle strength expressed as CON and ECC 5RM. Training resulted in a significantly greater increase in 5RM in the ECC group (46%-55%, P<0.001) than in CON group (14%-22%, P<0.001). The increase in quadriceps CSA was slightly greater in the ECC group (4.0%, P<0.001) compared to the CON group (2.5%, P<0.001). Despite a modest, but significant, difference in hypertrophy between the two groups, the changes in muscle architecture markedly differed between the CON and ECC groups. Lf increased by 21% (P<0.001) in the ECC group, but only by 8% in the CON group (P<0.001). Instead, PA increased by 11.3% (P<0.001) in the ECC group and by 35% (P<0.001) in the CON group. These results show that, in addition to greater gains in muscle size and strength, ECC training involves different morpho-
logical adaptations than CON training. These observations may indicate that the addition of sarcomeres in series and in parallel differs between CON and ECC training.

OP-PM14 Physiology 14 - Circulation

DYNAMICS OF FOREHEAD SKIN MICROCIRCULATION DURING EXERCISE
Coluk, B., Schmid-Schönbein, H., Besting, A., Perlitz, V.
Marmara University, Turkey

We demonstrated in forehead skin microcirculation the presence of a rhythm at an intermediate frequency range (0.12-0.18 Hz) between the respiratory and the 0.1 Hz rhythm, which emerged in response to psychomotor drive reduction. First evidence for a possible central origin came from observations that respiration was tightly coupled to this intermediary rhythm at a preferred synchronization ratio 2:1. In a comparative nonlinear analysis of data from canine, we were further able to detail central dynamics of discharge rates in small unspacific reticular brainstem neurons. The rhythm of these discharge rates exhibited a statistically significant range in response to pharmacological drive reduction.

In the present study, we tested the autonomy of this intermediary rhythm by selectively elevating pressure-flow levels in the systemic circulation with a special physical exercise protocol that allowed maintaining a relaxed mental state (harmonic exercise, HE). In ten subjects, time series of respiration, arterial blood pressure, heart rate, forehead skin microcirculation (photoplethysmography, PPG), and locomotion pace were recorded continuously. We used Morlet-wavelet based time-frequency-distributions to identify frequency components and post-event-scans to detect coordination patterns (software package Procalysis). During HE, we observed a high amplitude rhythm at 0.16±0.019 Hz (range 0.12-0.22 Hz) in the forehead skin microcirculation of all subjects studied. This rhythm prevailed for 60.2±23.7 % of total HE time (range 30.8-94.6%), and was neither affected by simultaneous fluctuations present in arterial blood pressure of 0.1 Hz nor by respiratory related oscillations. Synchronization of the rhythm with respiration was observed at 1:2, 1:3 and 1:4 integer number ratios for 31.6±24.9 % of total HE time (range 11.9-94.6%). As this rhythm submerged low amplitude 0.1 Hz and respiratory induced fluctuations emerged. This transition was accompanied by a twofold increase of heart beat amplitudes in the PPG.

Conclusions: These findings during exercise conditions provide further support for our hypothesis of a central origin, presumably in the reticular formation of the lower brainstem. We are convinced that there is reason to assume that rhythmic neuronal activity at an intermediate frequency range between the two major autonomous rhythms, the 0.1 Hz rhythm and the respiratory rhythm, produces this oscillatory activity in forehead skin microcirculation.

TOTAL HAEOMOGLOBIN MASS OF ELITE KENYAN RUNNERS
Pfrommer, N., Thoma, S., Quecke, L., Guilekunst, T., Völzke, C., Wachsmuth, N., Niess, A., Schmidt, W.
University of Bayreuth, Germany

Introduction: East African runners are among the most successful endurance athletes worldwide. To discover underlying physiological reasons research focused on muscular and metabolic factors. Data concerning the limiting factors of oxygen transport to the muscle, i.e. heart size and haemoglobin mass are missing. Since most of the East African runners proceed from moderate altitude a special advantage due to improved oxygen transport by the blood is frequently hypothesised.

Purpose: The aim of the present study, therefore, was to investigate total haemoglobin mass (Hb-mass), blood volume (BV) and heart size of elite Kenyan runners. A second goal was to monitor possible cardiac and haematological de-adaptation processes during a sojourn at lowlands.

Methods: Ten Kenyan runners (group K, competing between 1.500m and marathon) living and training at moderate altitude (~2150m) performed a 6-weeks lasting training camp at 350m in Germany. The training volume (~210km/week) was managed by their own trainers and was similar to that normally performed in Kenya. Hb-mass and BV were determined using the optimized CO-rebreathing method on the first day after arrival to Germany and weekly during their whole stay. In addition BV and haemoglobin concentration [Hb] were also examined before departure at altitude. VO2max was determined in three field tests (running speed increased by 2km/h every min) and one laboratory test on a treadmill (speed increased by 2km/h every 3 min). 13 German elite runners served as a control group (group G).

Results: The Kenyan runners were characterized by significantly lower body mass (K 57.2 ±7.0kg; G 66.5 ±6.9kg) and BMI (K 18.5 ±0.9; G 20.9 ±0.9), but similar percentage body fat (K 9.9 ±2.1%, G 10.7 ±2.2%). During the training camp body mass increased by 3.0 ±1.8 kg and fat mass by 1.0 ±1.3kg. Relative VO2max did not differ between the groups (K 71.5 ±5.0 ml/kg/min; G 68.8 ±2.9 ml/kg/min) and absolute VO2max did not change during the 6 weeks at low altitude. Relative Hb-mass from 803 ±83g to 767 ±90g, p<0.001, VO2max from 5828 ±703ml to 5466 ±661ml, p<0.01. Hb tended to decrease 1.04 ±1.0g/dl when commuting altitude but did not differ at sea level between the groups (K 15.4 ±1.0g/dl, G 15.1 ±0.8g/dl). The heart size was slightly lower in the Kenyan group (heart volume: K 14.0 ±1.5ml/kg, G 14.9 ±1.7ml/kg, left ventricular volume: K 4.8 ±0.5ml/kg, G 5.2 ±0.7ml/kg) and did not change at low altitude.

Conclusions: The hypothesis that blood transport is improved in Kenyan runners can be rejected. Longer stays at lowlands even decrease their Hb-mass. Since also heart size tends to be relatively small we conclude that the oxygen transport system is obviously not the reason for the excellent endurance performance of Kenyan runners.
EXERCISE-INDUCED PLASMA VOLUME EXPANSION AND POST-EXERCISE PARASYMPATHETIC REACTIVATION

Buchheit, M., Laursen, P., Al Haddad, H., Ahmadi, S.
Faculty of Sport Sciences, University of Picardie, Jules Verne, 80025, Amiens, France

The aim of the present study was to investigate the effect of exercise-induced plasma volume expansion on post-exercise parasympathetic reactivation. Eleven moderately-trained men performed, before (D0) and two days after (D+2) a single supramaximal exercise session, 6-min of submaximal running where heart rate (HR) recovery (HRR) and HR variability (HRV) indices were calculated during the first 10 min of recovery. Relative plasma volume changes (RPV) were calculated using changes in hematoctit and hemoglobin measured over consecutive mornings from D0 to D+2. Parasympathetic reactivation was evaluated through 1) the rate of post-exercise HRR, 2) the absolute number of heartbeats recovered in one minute (HRR60s), 3) the HRV vagal-related indexes calculated during the last 5-min stationary period of recovery and 4) the time course of the root-mean-square for successive R-R interval differences between successive 30-s segments (mSSD30s). Compared to D0, RPV (+4.8%, P<0.01), HRR60s and all vagal-related HRV indices were significantly higher at D+2 (all P<0.05). In contrast, the rate of HRR was not different between trials. Changes in vagal-related HRV indices were positively related to PV (all P<0.01). Nevertheless, there was no association between changes in HRR indices and RPV. Present results show that the short-term improvement in post-exercise parasympathetic reactivation two days after a single session of supramaximal exercise might essentially be related to exercise-induced plasma volume expansion. Results also confirm that post-exercise HRR and HRV indices characterize distinct independent aspects of cardiac parasympathetic function, with HRR linked more to vagal tone and HRV indices related more to parasympathetic modulation.

ACUTE HYPOBARIQ HYPONAXIA INDUCED MYOCARDIAL OXIDATIVE DAMAGE IN OLD AND YOUNG RATS

Agascioglu, E., Colak, R., Ficicilar, H., Kosar, N., Bastug, Demirel, H.
University of Hacettepe, Turkey

Although high altitude exposure results in increased oxidative damage in the tissues of rats, whether the levels of myocardial injury augmented with the severity of the altitude is not known. Since aging has been shown to associated with increased levels of oxidative damage and aged animals may have impaired adaptive response to stresses, the effects of high altitude on myocardial oxidative damage in aged animals is a matter of subject. Therefore, this study investigated the effects of high altitude on myocardial oxidative damage in aged animals. In addition, we examined if acute exposure to mild levels of altitude modify the levels of the myocardial damage induced by severe hypobaric hypoxia. Both 4 (young) and 20 month-old (old) Wister Albino rats were randomly assigned to following groups: 1) control in=5 in young and 6 in old, 2) 6000m (mild levels of hypobaric hypoxia, n=6 for each group) 3) 8000m (severe levels of hypobaric hypoxia, n=1) and 4) 6000+8000m (32h after mild levels of hypobaric hypoxia, animals exposed to severe levels of hypobaric hypoxia, n=1). Duration of hypobaric hypoxia was 6h. About 1h after the last exposure to hypobaric hypoxia, hearts were removed and advanced oxidation protein products (AOPP), lipid hydroperoxides (LHP), protein carbonyl (PCO), total and protein thiols (T-SH, P-SH) along with Hsp72 levels were determined. Although aging associated with increased levels of AOPP, PCO, LHP on each altitude, these values were not different than that of young animals when corrected with the basal levels. Compare to 6000m, 8000m altitude results in higher levels of myocardial AOPP, PCO and LHP formation in both young and old hearts. On the other hand, T-SH and P-SH levels decreased with the increasing levels of altitude. Compare to 8000m, exposure to 6000m before severe hypobaric hypoxia did not modify the levels of any parameter studied. There were no changes in Hsp72 levels across all groups. Our findings support the notion that aging associated with increased levels of oxidative damage. However, acute hypobaric hypoxia could not cause any additional oxidative damage to old myocardium.

USING DIGITAL BALLISTOCARDIOGRAPHY TO DETECT AUTONOMIC NERVOUS SYSTEM CHANGES IN THE CONCUSSED ATHLETE

Neary, P., Busse, E., MacQuarrie, D., Goodman, D.
University of Regina, Canada

Recent research from our laboratory showed that heart rate variability (HRV) is altered in the concussed athlete during mild exercise, suggesting anomalies in autonomic function (1, 2). Although HRV is a valuable tool for assessing and monitoring autonomic activity, advanced recording techniques may provided a more accurate measurement of this dysregulation. Recent technological advances are available where micro-accelerometers can be used to monitor cardiac function. Digital ballistocardiography (dBG) measures the seismic activity of the heart during a cardiac cycle, and accelerations during systole and diastole produce very-low-frequency compression waves which can be recorded and matched with the EKG waveform. The resulting dBG provides an illustration of the mechanical functioning of the heart. We hypothesized that dBG could be used to detect changes in neural innervations to the heart during rest and after mild exercise in the normal (N) and concussed (C) athlete. To evaluate the utility of using dBG to assess autonomic function, 2 asymptomatic C athletes were monitored at rest and after mild knee extension exercise (1 min) at Day 4-11 post-concussion. HR was calculated beat to beat. These data were compared with 2 N control athletes. On average 30 dBG waveforms showed that atrial contraction force was 56.5±14.3 (rest) and 60.5±5.5 milli-gravity (mg) (post-exercise) in the C, while it was 70.1±15.5 (rest) and 102.5±54 mg (post-exercise) in the N. Ventricular contraction force was 62.0±19.0 (rest) and 122.5±74.5 mg (post-exercise) in the C, while it was 101.0±15.0 (rest) and 205.5±79.5 mg (post-exercise) in the N. Resiling HR at baseline was not different between the C (55 bpm) vs N (52 bpm), but post-exercise there was a greater variability in the concussed (SD=13.7 bpm) vs the normal (SD=7.0 bpm) athlete. Day-to-day reliability for the dBG variables was n=0.94. Based on our results, the dBG has the ability to determine all timing of the cardiac cycle, and the slope, velocity, and amplitude of each of these cycles (eg. atrial contraction, mitral valve open and close, aortic valve open and close, rapid ejection period, early diastole amplitude). From rest to exercise the normal population increases the slope and amplitude of each of these signals and adjusts the various time periods to meet the cardiac demand. While the timing and duration of the events were considered normal in our C subjects (n=2), the amplitudes of the atrial and ventricular waves were highly variable indicating altered autonomic function. This is the first study to our knowledge that has examined the mechanical changes in cardiac function using dBG to reflect ANS function in the concussed athlete. References.

CARDIOVASCULAR RESPONSES TO DAYTIME SIESTA: IS IT SLEEP PER SE OR PRE-SLEEP ACTIVITY THAT MEDIATES LOWER BLOOD PRESSURE?

Zaregarizi, M., Edwards, B., Leary, A., Murphy, M., George, K., Harrison, Y., Atkinson, G.
Liverpool John Moores University, United Kingdom

Our recent finding that the daytime sleep-onset period is associated with a marked drop in blood pressure (Zaregarizi et al., 2007) leads us to question whether the siesta habit reduces the blood pressure (BP) of hypertensive patients normally at home, and the amount of pre-siesta physical activity is important in contributing to a lowered BP. We answered these questions via a large-scale epidemiological study and a controlled experiment.

In study (i), 439 hypertensive patients were allocated to non-siesta (n=393), siesta-without-sleep (n=35) and siesta-with-sleep (n=11) groups, matched for medication, age, gender and body mass. Wrist-activity, heart rate (HR) and BP were recorded every 20 min for 24-h using ambulatory monitors worn during everyday living. In study (ii), 6 normotensive adults, mean (SD) = 39 (6), y, exercised at 09:30 h following a night of restricted (4 h) sleep. Participants exercised at either 70%VO2max for 30 min, or at 40%VO2max for a duration which equated total work-done. At 14:00 h, participants napped. Polysomnographic data allowed us to describe a 10-min period of relaxed wakefulness before lights-out, the time between lights-out and stage 1 sleep onset and the time between stage 1 and 2 sleep onset.

Changes in BP and HR over these 3 phases were compared between trials. Data are described as mean (SD).

In study (i), the lowest systolic/diastolic BP of 125(6)/79(4) mmHg was found between 16:00 and 17:00 in the siesta-with-sleep group compared to 139(6)/79(4) and 140(4)/82(2) in the non-siesta and siesta-without-sleep groups (P<0.05). There was no difference in 24-h BP profiles between the non-siesta and siesta-without-sleep groups (P>0.05). The 24-h profile in physical activity was different in the siesta-with-sleep group compared to the other two groups in line with the afternoon behaviors that were adopted (P=0.03). There was also evidence that the siesta-with-sleep participants were more active during the morning. In study (ii), systolic BP was 4±3 mmHg lower during phases (i), (ii) and (iii) of the nap onset period, respectively following the more intense exercise compared to exercise at 40% VO2max (P<0.05). Diastolic and mean arterial BP and HR during the nap were not significantly different between the exercise trials (P>0.05).

Our epidemiological data confirm that afternoon siesta can reduce the BP of hypertensive patients, but only if sleep is taken. Those who slept during siesta also scheduled more physical activity in the morning period, which could also reduce BP during subsequent siesta via post-exercise hypotension. Data from study (ii) suggest that 30 min of exercise at 70% VO2max can indeed mediate a lower blood pressure during subsequent afternoon sleep compared to light exercise. Therefore, the reduction in BP during siesta with sleep might be, in part, mediated by a hypotensive effect of prior exercise.

OP-PS06 Psychology 6 - General 2

ELITE RUGBY COACHES’ COMMUNICATIONS IN MATCH

Mouchet, A.
Paris 12 University and CRR of French Federation in Rugby, France

This research is organised with the National Technical Direction of the French Union in Rugby. The problematic consists in informing the private and public facets of the coaches’ communications with players during the match. We try to characterize communications by different aspects : intention, frequency, object, modalities, and their impact on the game production. The theoretical frame aims to encircle the implicit and tacit competences constituents. Coaching process is complex, dynamic and depending from the context (Lyle, 2002).

The methodology has for ambition to supply a detailed and ecologically valid portrait about coaches and about the coaching process (Gilbert & Trudel, 2004). We study all the technical staff members involved in the coaching process, using case studies with methods triangulation (Mouchet, 2005). We articulate :
- interviews before the match about coaches conceptions,
- behaviors and communications recording during contest,
- explicitation interviews (Vermersch, 2002) after the match about coaches subjective lived,
- analysis of game evolution. We use for this last aspect the video of the game and an observation tool.

Results are in the course of treatment. The first elements about coaches’ conceptions put in evidence :
- The main addressees of orders: numbers 9 and 10 for the strategic aspects; the captain if he’s a different player, for aspects relative to the group management.
- The variety of used distribution channels, according to the opportunities of meeting with the players during the game, or the use of persons authorized to enter on the ground (for example medical staff).

On the other hand it is surprising to notice the absence of elements strongly shared in coaches’ conceptions about the nature of communications. The only element quoted explicitly by 50 % of the coaches concerns ‘ strategy ’. But the optimal use of these strategic regulations seems to require from coaches a fine analysis of events and the necessity of developing two aspects:
- Functional modalities of communications distribution in the course of contest,
- Players’ responsibility and self-sufficiency in the management of the game.

Data treatment of the communications in game is in course at this moment. The first elements seem to indicate preferential modes used by coaches depending on their own experiences and characteristics as coach or player. But also depending from the local context of the match.

THE EFFECT OF TWO DIFFERENT BREATHING FEEDBACK TECHNIQUES ON PSYCHOPHYSIOLOGICAL PARAMETERS IN A SPORT SPECIFIC STRESS TEST

Finkenzeller, T., Amesberger, G.
Sport Psychology, Austria

Many sport psychologists utilize relaxation techniques to reduce stress and enhance performance (Schwartz & Andrasik, 2003). Besides common techniques (Progressive Muscle Relaxation, Autogenic Training) device-guided relaxation techniques are becoming more widespread. The aim of our study was to investigate the effects of two different breathing feedback trainings on peripheral and central physiological parameters and to evaluate the transfer of the techniques to a stress-related situation.

Forty-five sport students were randomly assigned to three different groups. The respiratory sinus arrhythmia (RSA) biofeedback training group practiced to synchronize their alteration in heart beat with breathing. The respi rate group learned to adjust their breathing to a sound which paces the breathing to a rate less than 10 breaths per minute. The third group received no intervention (control group).

A training session lasted 15 minutes and was performed three times a week for a period of five weeks. At the beginning and at the end of the five week period the subjects underwent a sport specific stress test which consisted of several cognitive and coordinative tasks (e.g. memory game, balance test) that were embedded into different relaxation phases (baseline relaxation at the beginning and intertrial relaxation phases between the tasks). Peripheral (SC, Temp., ECG, Breathing, EMG of m. frontalis) and central parameters (EEG) were recorded during training and test conditions.

Regarding the alterations in parameters of the 2nd, 8th and 15th session, the RSA group revealed significant increases in coherence between heart rate and breathing [F(2,26)=5.47, p=0.03, eta2=0.30], in heart rate variability [F(1,26)=6.25, p=0.01, eta2=0.33] and SDNN [F(2,26)=4.26, p=0.02, eta2=0.32]. Concerning the stress test, a time (pre-post)*group (RSA-respirate-control) effect occurred for coherence [F(2,27)=3.67, p=0.04, eta2=0.21] and SDNN [F(2,29)=5.08, p=0.01, eta2=0.26] during baseline relaxation. Both intervention groups increased coherence and SDNN from time 1 to time 2, whereas these parameters decreased in the control group. Additionally, a comparison of baseline relaxation and intertrial relaxation data revealed a time*group effect for coherence [F(2,27)=3.45, p=0.046, eta2=0.24]. While the differences between baseline and intertrial relaxation remained stable for both intervention groups over time, the control group showed less discrepancy between baseline and intertrial relaxation at time 2 than they did at time 1.

In sum, both breathing techniques had an instantaneous effect on improving psycho-physiological relaxation of athletes. Furthermore, results indicate that improving psycho-physiological relaxation via breathing techniques might also be helpful in stress-related situations and contribute to a better performance of athletes.

THE EFFECTS OF FEEDBACK INTERVENTIONS (FI) ON COGNITIVE PERFORMANCE OF ATHLETES ON A SPORT-SPECIFIC SELECTIVE ATTENTION TASK

Wuerth, S., Krenn, B., Amesberger, G.
Universitaet Wien, Austria

Athletes are often confronted with feedback information on their performance that direct attention to the self, e.g. I am better than others (normative Feedback) or My performance was much worse than I anticipated (self-related feedback). According to the Feedback Intervention Theory (Kluger & DeNisi, 1996), feedback relating on the self may debilitate performance even when FI is positive.

In order to test whether FI that direct attention to meta-task processes deteriorates performance of athletes, a computerized test measuring selective attention in sport-specific situations was designed with DirectRT 2006 software (© empirisoft). The test consisted of two parts. Within each part, 15 video clips containing sport scenes [1941 ms length] were presented. Subjects were asked to indicate how many athletes they were able to recognize in each clip (selective attention task). Reaction time was limited.

Before completing the first 15 trial sequence, athletes had to prognose their performance on the test (percent of correct answers). After finishing the first part subjects were given a fictitious feedback on their performance with normative (positive - p or negative - n) and self-related (p or n) information (e.g. you were much worse than you anticipated. Additionally, you were much worse than others who completed the test n:n combination). Hence, four different FI groups were established (pp, nn, pn, and np), completed by a control group which received no feedback. After a three minute relaxation phase, subjects completed the second 15 trial sequence. Correct answers were recorded for each trial.

Participants were n=96 sport students (39 female, 57 male) who were all active in different kinds of sport. Subjects were randomized to FI groups.

MANOVA results show that the different feedback intervention strategies did not effect athletes’ performance (i.e. the percentage of correct answers) in the second part of the test [F(4,91=1.37, p=2.5]. However, when focusing on the two groups who received consistent feedback (negative-negative or positive-positive, respectively), results reveal that athletes who received positive feedback tended to increase their performance [F(1,38)=3.88, p=0.06], whereas athletes who received negative feedback did not.

It was hypothesized that feedback relating on the self deteriorates athletes’ performance on a sport-specific cognitive task, even when Fi is positive. Our results, however, did not support this hypothesis. Athletes either perform at the same level, or even increase their performance.

Further analyses have to show whether these results are affected by personality traits or task characteristics.

EFFECT OF ACHIEVEMENT GOAL PROFILES ON PEER INTERACTION AND PERSISTENCE IN YOUTH SPORT

Roberts, G., Ommundsen, Y., Sørensen, M., Miller, B., Sisjord, M., Fasting, K.
Norwegian University of Sport Science, Norway

The purpose of this study was to determine whether the dispositional goal orientation profiles that have been reported in the literature would be observed in a sample of youth sport participants, and to investigate the differences between the goal profiles on perceptions of the motivational climate, peer relationships and drop out data. The sample consisted of a cross-sectional study of 1294 youths aged between 12-16 years of age (Male n = 787, Female n = 507) experienced youth sport participants. Participants responded to a questionnaire addressing achievement goals, perceived motivational climate, perceived peer acceptance, quality of friendship, perceptions of being bullied, and we performed a follow up procedure on whether the participants continued or dropped out of their respective sport the following season. Four profiles emerged from the cluster analysis that were similar to previous research (Hodge & Petlichkoff, 2000, Smith, Balagué & Duda, 2006). The profile groups were found to be different on all of the peer interaction variables, but not the drop out rates. The overall trend was for participants who were higher in task orientation to have more positive peer relationships. They were lower in conflict, higher in companionship, peer acceptance and lower in the perception of being bullied. In general, the findings support the predictions coming from achievement goal theory (e.g., Nicholls, 1989), and suggest that better peer relationships are fostered with task achievement goals.

ANALYSIS OF THE EFFECTS OF A PSYCHOLOGICAL INTERVENTION PROGRAMME IN THE RATE OF DEPRESSION IN PHYSICALLY ACTIVE ELDERLY PEOPLE

Amparo, L., Samulski, D., Mortimer, L.
Universidade Federal de Minas Gerais, Brazil

The World Health Organization defines the term Quality of Life (QL) as a search for harmony on the physical, psychological and social aspects of life. It is the absence of certain symptoms and/or behaviors that can interfere on the adaptation of a person to a new situation. This adaptation process more abruptly with the elderly when compared to younger people. It is perceived in Brazil a lack of attention to the QL of elderly, at the same time that this population is in a progressive increase. The ageing process promotes physical changes that may result, mainly, in stress, anxiety and depression. The depression in old age is associated with a loss of self-esteem and physical and cognitive declines, resulting in the inability of the elderly to satisfy their needs and impulses or to defend themselves against threats to their safety. The depressive patterns in this age group are altered in its symptomatic appearance through bio-psycho-socio-cultural inferences. An exercise program should be directed to the improvement of the physical capacity of the individual, leading, eventually, to a reduction of the deleterious effects resulting from the aging process, maximizing the social contact of the subjects, trying to reduce the psychological problems such as anxiety and depression. Thus, participation in physical activity programs allows the elderly to discover capacities that were considered lost group activities promotes sharing of experiences, results and advances, as well as social activities. The aim of this study was to analyze the effects of a psychological intervention program on the QL of elderly physically active individuals, through the levels of depression. The study also compared the results with groups of sedentary people (elderly also). The Beck Inventory was used to investigate depression. The psychological program was elaborated according to the test results and consisted of 20 sessions. The tests were then reapplied and a follow up test was applied 1 month after. The sample consisted of 60 voluntary people (60-72 years old) distributed in experimental, control and placebo group. Significant improvement was found on the active group that received psychological support. On the placebo and control group (both active) that had no psychological support the alterations were low. On the sedentary group and on the group without intervention there were no significant alterations on the results (depression level). We conclude that regular physical activity combined with psychological support promotes important benefits for the QL of elderly people more than when the two are done separately. This confirms the need of a permanent program (physical activity and psychological intervention) utilizing a bio-psycho-social approach.

THE DEVELOPMENT OF A QUALITY DECISIONAL INDEX FOR THE MATCH ANALYSIS OF OFFENSIVE ONE-ON-ONE SITUATIONS IN BASKETBALL

Esteves, P., Araújo, D., Correia, V., Travassos, B., Barreto, H.
Technical University of Lisbon, Portugal

INTRODUCTION: In order to reach a better understanding of the game dynamics, sport performance analysis, is nowadays branded by a multidisciplinary nature of contributes (Reilly & Gilbourne, 2003). However, much of the match analysis does not explain the continuous interaction between the player and the competition environment. Decision-making behaviour is usually not included in these match analyses. In this work we consider the 1 vs 1 situations that finished with an attempt to shot. In order to analyze the dyad we considered the interaction between players as a symmetric relation defined for the distance between the basket and both players and their interpersonal distance (Araújo et al., 2006). The aim of this paper is to provide a match analysis tool for decision-making behaviour in basketball. To achieve this goal, we present a quality decisional index (QDI) (Esteves, Araújo & Barreto, in press) which allows the measuring of the temporal course of this behaviour in a one-on-one situation in basketball.

METHOD: In order to show that it is an accurate and reliable tool for analyzing information regarding players' behaviour in the game, we used notational analysis data from one-on-one situations that occurred in a basketball game (Portuguese main league). This notational procedure allowed us to gather the needed variables for the quality decisional index \( QDI = 0.7 \times S/A \times 0.1 \times LB/n1v1 + 0.2 \times FS/n1v1 \), where SA is the number of shots attempts, SS is the number of shots scored, LB is the number of lost balls, n1v1 is the number of occurrences of 1v1, and FS is the number of fouls situations suffered by attacking player of the dyad. The QDI calculated values were correlated with the ones obtained through the Most Valuable Players equation (MVP), which is used by the official Portuguese basketball statistics.

RESULTS: There were significant positive correlations between QDI and MVP values obtained. When correlating the variables QDI and MVP, calculated per intervals of 5 min, significant positive relationships \( r > .6 \) were verified. Nevertheless, there were no significant correlations between the same variables when cumulative values were considered.

DISCUSSION: The results showed that the QDI describe the efficacy of decision-making behaviour in this type of situations (1v1 attack and with the possibility of trying) in short time intervals (5 min). Its external validity was obtained with the positive significant correlations with the MVP-values.

OP-TT09 Training and Testing 9 - Elite

THE RELATIVE CONTRIBUTION OF SWIMMING, CYCLING AND RUNNING TO OVERALL PERFORMANCE IN ELITE OLYMPIC DISTANCE TRIATHLON

Green, D., Jenkins, D.
Australian Institute of Sport, Canberra, Australia

Olympic Distance (OD) triathlon consists of a 1.5km swim, 40km cycle and 10km run performed in sequential order. The aim of the current study was to: i) quantify the relative contribution of each discipline to overall performance in draft-legal OD triathlon, and ii) investigate if the quality of field (QOF) or the presence of wetsuits changed the relative contribution of each discipline.

Swim, cycle, run and overall performance were analysed for athletes finishing within 10% of the winner in 110 ITU World Cups, ITU World Championships and Olympics from 1996-2005. All performances were related to the median of the top 10 performances. Percentages behind the winners overall time were used to account for differences between courses, while differences between each discipline were calculated in seconds to provide an absolute representation of the contribution to overall performance. There were 4366 male and 3121 female data points analysed.

The greatest variation in performance (SD from median of top 10 times) was found to be in the run for both men (100.7s) and women (114.9s) compared to swimming (27.7, 45.7s) and cycling (71.3, 81.6s), even though the duration of the run is typically half that of the cycle leg.

For male triathletes, correlations to overall performance were found to be higher for running (r=0.95) and cycling (r=0.90) than for swimming (r=0.59); once combined, these variables accounted for 95% of the variation in overall performance. When comparing high and low QOF, significant differences in correlations were noted for running (r=0.96 vs r=0.95; p<0.05), cycling (r=0.94 vs r=0.89; p<0.01) and swimming (r=0.63 vs r=0.54; p<0.05).

Female triathletes showed a similar trend, albeit with lower correlations, for the relationship of running (r=0.85), cycling (r=0.76) and swimming (r=0.53) to overall performance, collectively, these variables explained 85.6% of the variation in performance. QOF analyses revealed significant differences between swimming (r=0.66 vs r=0.58; p<0.05) and cycling (r=0.84 vs r=0.71; p<0.01), but not running (r=0.89 vs r=0.89; p>0.50) when comparing high to low QOF.

Classification tree analyses revealed the presence of a wetsuit did not feature in any terminal nodes and therefore was not considered to contribute to predicting overall performance.

This study has confirmed that running is critically important to performance in elite OD triathlon but swimming is not as important. This may have been expected given that running is the final discipline of a triathlon, however it is somewhat surprising given its shorter duration compared to the cycling component of the event. Cycling was also shown to be a major predictor of overall performance, even though drafting promotes the formation of large groups. The QOF changed correlations for cycling and swimming, but did not appear to influence the importance of running to overall performance.

COMPARING THE PORTUGUESE AND THE SOUTH AFRICAN RUGBY TEAMS DURING THE RUGBY WORLD CUP (RWC 2007)

Vaz, L., Sampaio, J., Gomes, I., Vicente, J.
University of Trás-os-Montes e Alto Douro - Portugal, Portugal

Introduction

Research in team sports has focused in the factors that identify player and team performance. Rugby game analysis can allow to: i) create models of players’ and team normatives, ii) identify the game-related statistics that best justify sport success iii) identify tendencies and evolutions in the sport. The aim of the present study was to compare the average game-related statistics from the Portuguese and the South African team.

Methods

The sample was constituted by 11 rugby games, 4 were played by the Portuguese team and 7 were played by the South African team during the Rugby World Cup 2007 (IRB, 2007). The games were analyzed though descriptive statistics and independent t-tests.

Results

The obtained results allowed identifying significant differences in the game-related statistics and the game-result variables for the two teams (p<0.05). The Portuguese rugby team performance (game averages) was 60 runs, 77 passes and 28 kicks. The South African rugby team performance was 58 runs, 106 passes and 33 kicks. The Portuguese team points scored came from 4 tries, 3 conversions, 3 penalty kicks and 1 drop kick. Conceded 29 tries, originate from 16 losses lineout situations, 2 scrum, 3 penalty goal, 5 kick and 3 turnovers. South African team scored through 53 tries, 25 conversions, 2 penalty kicks not having obtained points through the drop kick in 6 attempts. Conceded 9 tries, originate from, 2 losses of ball in lineout, 2 in scrum, 3 kicks and 2 turnovers. The average ball possession time for Portuguese team in poll stage was 14 minutes and 37 seconds and for the South African team was 15 minutes and 56 seconds.

Conclusions

The comparison among the obtained results allowed diagnosing significant differences between the Portuguese and South African rugby teams for tries, conversions and penalty kicks. The statistic results of the game and of the game analysis in relation to the game actions (runs, passes and kicks) were not significant to differentiate teams (p>0.05).

We concluded that the differences found in game and result variables and between the Portuguese and South African rugby teams allowed to find enough reasons so that we can describe behaviours to understand some significant differences between variables and teams in competition. Coaches can use these results for players’, team preparation and for directing the competition.
A MODEL OF THE PROCESS OF REGAINING BALANCE AFTER PERTURBATION FROM QUIET STANCE: WITH APPLICATION TO TRAINING IN ELITE JUDO

Lopez Diaz de Durana, A., Stirling, J., Zakynthinaki, M., Cordente Martinez, C., Sillero Quintana, M., Sampredo Molinuevo, J.

Technical University of Madrid, Spain

Using tools from dynamical systems we investigate stability and the maintenance of balance in elite Judokas. We model and analyze the ground reaction forces resulting from an athlete being perturbed from quiet upright stance, for the two legged and single legged condition. The maximum correctable angles between the resultant ground reaction forces and the vertical in the anteroposterior and mediolateral directions are obtained via a force platform. A closed critical curve is fit through these maximum correctable angles outside which the perturbations cannot be corrected and the motion of the body back to the position of quiet stance is analyzed. We then analyze the curve to identify non-symmetric behavior caused by muscle imbalances, postural problems, structural problems and differences in the ranges of motion on either side of the body. We also show how the model can be used in elite judo regarding injury prevention and identifying competitive strengths and weaknesses which may be addressed and corrected via training once they have been discovered.

A COMPARISON BETWEEN ELITE AND WELL TRAINED CROSS-COUNTRY SKIERS IN PHYSIOLOGICAL RESPONSE TO VARIATIONS IN INTENSITY DURING PROLONGED EXERCISE

Björklund, G., Holmberg, HC.

Mid-Sweden University, Sweden

Introduction: Cross-country ski racing includes continual variations in intensity due to terrain and tactics. Consequently, the recovery between periods with higher intensity may affect the outcome of the race. Both blood metabolites and respiratory variables are used for standard performance evaluations for endurance athletes, although there is a lack of information if respiratory variables respond similar to blood lactate and acid/base values during prolonged variable exercise. Therefore, the aims with the present study were to 1) evaluate whether respiratory variables are associated with blood lactate and acid/base variables, 2) how these variables might predict physical performance and 3) whether a calculated heart rate-oxygen uptake (HR-VO2) relationship is valid during variable intensity exercise. Methods: 12 cross-country skiers classified as elite (E, n=6) and formerly well-trained (FWT, n=6) performed two roller ski tests. 1) An incremental test to establish maximal oxygen uptake (VO2max), maximum heart rate (HRmax) and lactate threshold (LT). Submaximal and maximal VO2 and HR during the incremental test were used for calculating the individual HR-VO2 linear relationship and 2) a 48-min long variable intensity protocol (VIP) at alternating exercise intensities, 90% (HI90) and 70% (MI70) of lactate threshold (LT). Submaximal and maximal VO2 and HR during the incremental test were used for calculating the individual HR-VO2 linear relationship and 2) a 48-min long variable intensity protocol (VIP) at alternating exercise intensities, 90% (HI90) and 70% (MI70) of lactate threshold (LT). Cardiorespiratory variables and venous blood samples were continuously collected throughout the VIP. Comparisons between E and FWT were performed using a two-tailed unpaired Student’s t-test and a ANCOVA analysis was used to determine which physiological variable best could prognosticate time to exhaustion (TTE). A simple linear regression was used to establish the relationship between HR and VO2. Results: Blood lactate concentrations [La] were higher and base excess [BE] lower for FWT from the first MI70 (P<0.05). The expected HR were higher during the MI70 exercise intensities regardless of group affiliation (P<0.05). The blood [La] response predicted time to exhaustion earlier than respiratory variables (P<0.05). Discussion: Blood lactate and acid/base fluctuations were not reflected by RER and the ventilatory equivalents. Furthermore, blood lactate is to prefer, in comparison to ventilatory variables, to study performance related recovery processes during endurance exercise with variations in intensity. The expected HR-VO2 relationship was not valid during VIP.

NO CHANGES IN FATIGUE RESISTANCE AND CENTRAL FATIGUE FOLLOWING 4 WEEKS OF BALLISTIC STRENGTH TRAINING

Taube, W., Leukel, C., Gehring, D., Gollhofer, A.

University of Freiburg, Germany

In some sports disciplines, strong ballistic contractions have to be repeated over a longer period of time. The aim of the present study was to assess changes in fatigue resistance and changes in central fatigue after exhaustive ballistic contractions in response to ballistic strength training (BST). Nine subjects (26±3 years) performed BST (few repetitions with maximal contraction speed) over a period of 4
weeks whereas five subjects (25±3 years) served as controls. Maximum rate of force development (RFD) during ballistic contractions was tested in the tibialis anterior muscle before and after BST. Fatigue resistance was measured by counting the number of contractions until fatigue. Fatigue was defined as the time, when subjects could not manage 75% of their MVC any longer. In order to assess peripheral fatigue, electrical stimulation of the peroneal nerve was used to elicit the maximal M-wave (Mmax) in the tibialis muscle and the corresponding twitch. By means of transcranial magnetic stimulation (TMS), motor evoked potential (MEP) recruitment curves were recorded. Comparison of changes in parameters obtained with peripheral nerve stimulation and cortical stimulation allows deduction of the amount of central fatigue. In the pre-measurement, fatiguing ballistic contractions did not alter Mmax and twitch torque, demonstrating that peripheral fatigue was not existent or at least minor. In contrast, the slopes of the MEP recruitment curves were reduced following ballistic contractions. These results indicated that mainly central fatigue was responsible for exhaustion. Following BST, subjects demonstrated enhanced RFD but did not change any of the fatiguing parameters. The results of the present study suggest that high intensity BST with low number of repetitions does not improve fatigue resistance and has no beneficial influence on central fatigue.

PEAK OXYGEN UPTAKE USING A TRAINING DEVICE FOR COMBINED RESISTANCE AND AEROBIC EXERCISE IN SPACE AND ON EARTH

Tesch, P., Ainegren, M., Östberg, J., Swaren, M., Holmberg, H., Pozzo, M.

Mid Sweden University, Sweden

Astronauts traveling in Orbit are mandated to perform both aerobic and resistance exercise to combat cardiovascular and muscular deconditioning. A non-gravity dependent flywheel resistance exercise device (FWD), proven to be effective in blunting muscle atrophy when used by bedridden subjects, has been configured to allow for aerobic exercise as well. The current study aimed at determining aerobic energy yield and related physiological demands during exercise using this novel apparatus.

Methods Eight men and women (23±3 yrs, 65±5 kg, 170±6 cm) performed all-out, indoor, stationary rowing exercise randomly on either a commercially available Concept II ergometer (CII) or the FWD. Using a magnetic brake system, the FWD and similar to the CII, produced mainly concentric resistance exercise with the aid of the inherent inertia of rotating flywheels. Progressive exercise protocols (increased frequency and magnetic force) assessed peak oxygen uptake and heart rate, rate of perceived exertion and post lactate concentration.

Results Peak oxygen uptake averaged 3.18±0.50 and 3.11±0.49 l/min, respectively during exercise using CII and FWD. Peak oxygen uptake, plasma lactate concentration, heart rate and rate of perceived exertion were not different (p>0.05) across exercise using these two devices. However, time to exhaustion was somewhat (p<0.05) longer for the FWD.

Conclusion Collectively the current results suggest that the novel method of offering an aerobic exercise stimulus is as effective as the most established technology for indoor rowing used by crew. Given that the space agencies have recognized the need for effective exercise countermeasures hardware that has a feasible mass and envelope and features allowing for multiple purposes (e.g., concentric/eccentric resistance and aerobic exercise in a single piece of apparatus, the current technology should be considered for use in space.
Injuries to tendons represent a major problem in sports. Tendons are fibrous, tension-bearing elements interposed between the muscles and bones designed to transmit the forces generated by the muscles to the skeleton effecting limb movement. It is well established that skeletal muscle can adapt to changes in functional requirements and to increases in loading e.g. with exercise through quantitative mechanism based on changes in muscle mass and fibre size through muscle hypertrophy, and a qualitative mechanism based on a change in fibre type of the muscle fibres. The change in muscle power increases the forces distributed from the muscles through the tendons 5 and increases the stress on the connective tissue within the muscle as well as on the tendons in series with the muscles fibres. This may lead to a situation where the forces on the tendons exceed the strength of the tissue with the risk of sustaining injuries. It may thus be essential for the tendons to precede the potential to adapt to these changed by increases in strength and vascularisation to avoid injury. This is supported by data indicating a close relationship between cross-sectional areas of muscles and their tendons 6-8. In order to maintain this relationship and withstand the increase in load the tendons need to adapt to the new situation by increasing tissue strength either by hypertrophy, increased cross-links or increased tissue density. Overuse of tendon tissue resulting in pain and malfunc-
tion represents a major problem within sports and ergonomics 9-12 stressing that adaptation of the tendon tissue is not always sufficient to withstand the increase in loading on the connective tissue during physical activity. However in spite of the high incidence of tendon overuse injuries and compared with muscle tissue, only little is known about the adaptive response of tendons to changes in loading. It has been shown that 12-week of eccentric resistance training can reduce pain in runners suffering from chronic Achilles tendino-
sis 13, but the mechanism behind the effectiveness of this treatment is unknown. In a recent study on elite soccer players suffering from chronic Achilles tendinosis we showed that the local effect of a heavy-resistance eccentric training on top of their regular training and soccer activity results in an increased turnover of the peritendinous connective tissue 14. After training collagen synthesis was significant increased in the initially injured tendon whereas no change was found in the healthy tendons in response to training indicating that eccentric rehabilitation has strengthened the tendons. Whether this strengthening of the tissues alone can explain the positive effect of eccentric training is however not clear, just as it is not known if eccentric training can be use to all types of overuse injuries in tendinous tissue.

INTEGRATION OF PODIATRY ASSESSMENT AND GAIT ANALYSIS IN THE TREATMENT OF RUNNING INJURIES

Dixon, S., McNally, K., Jaques, R.
University of Exeter, United Kingdom

Injured athletes increasingly attend podiatry clinics to obtain customised orthotic devices. Traditional podiatry assessment relies primarily on static measurements (1). The availability of automatic tracking systems for realtime monitoring of three-dimensional movement and systems for measurement of plantar pressure provide methods for obtaining dynamic data that can potentially inform the treatment of athletes with injury problems. The aim of this paper is to describe the use of running gait analysis to help determine appropriate treat-
ment modalities for injured athletes. A typical assessment includes a podiatry examination and the collection of over-ground running data. Three-dimensional movement data are used to monitor rearfoot inversion-eversion, ankle dorsi-plantar flexion, lower leg (tibial) internal rotation, knee flexion, knee ab/adduction and knee internal rotation. Five running trials are performed, and the resulting mean initial and peak joint angles are compared with published averages for running populations (2). Right and left sides are also compared for individual clients. Barefoot plantar pressure data are collected to identify characteristic features of the footstrike during running. Case studies are presented to illustrate the use of gait analysis to complement podiatry assessment. For example, a runner recovering from a cuboid stress fracture was found to have a pressure profile suggesting increased load on the lateral aspect of the foot and no rearfoot eversion on the side of the stress fracture. The greater inversion of the foot indicated by these data are suggested to be linked to the development of this injury. A runner with left knee pain was found to have limited ankle dorsi-flexion on the left side during running and high internal rotation of the tibia and knee for the left side. This internal rotation was suggested to be a compensation for the limited rearfoot eversion and to be linked to the knee pain. A netballer who had recently recovered from a left navicular stress fracture was found to have a high static range of motion at both the ankle and subtalar joints for the left side compared with the right, but a limited rearfoot eversion during running. This was suggested to be a compensation for the previous injury. It is acknowledged that there is a degree of subjectivity in the interpretation of these data to inform the treatment of sports injuries. However, the examples provided demonstrate that the additional data provided can complement traditional clinical measures, leading to a more evidence-based approach. Through the increased use of such an approach, an improved understanding of links between structure and function will be developed, ultimately resulting in a more objective process.

THE IMPORTANCE OF PSYCHOLOGICAL PREPARATION IN INJURY PREVENTION

Donaghy, M.
Queen Margaret University, United Kingdom

Background: The impact of stressful life events on the risk of incurring sports injuries has been widely accepted although the directly explained variances are small. In addition there is some support that situation-dependent emotional states and poor coping resources influence the risk of injury in specific athletic populations. However the empirical evidence from intervention studies in injury prevention appears to be scant. The purpose of this study was to examine the recent scientific evidence for psychosocial factors predictive of sport injuries and the relative efficacy of psychological strategies in reducing vulnerability to sport injuries. Methods: A systematic search was carried out for literature published between 1998-2008 on EBSCO host CINAHLplus, PsycINFO, SPORT Discus, MEDLINE 78 potential articles were identified. After all exclusions 7 observational, cohort, prospective studies and 2 reviews were retrieved for scrutinisation. No RCT’s were found.

Results: The theoretical basis for the importance of psychological preparation in injury prevention is convincing however the evidence from intervention studies to date offers limited support that psychological measures have utility in predicting or preventing injury. The methodological quality of the studies is limited by lack of heterogeneity, poor design, inconsistencies in evaluation strategies and a lack of RCT’s.

Conclusions: While there is some support that cognitive-appraisal models of sport injury provide an explanation of athletic injury risk, there is insufficient evidence to make any firm conclusions regarding the efficacy of psychological interventions. Further well designed studies are required. It is recommended that psychological factors such as anger and aggression, concentration and reaction are considered alongside coping resources and other physiological indicators of allostatic load such as level of stress hormones.

CARDIAC ADAPTATIONS ON ENDURANCE AND STRENGTH TRAINING - A CRITICAL REVIEW

Scharhag, J.
Institute for Sports and Preventive Medicine, Germany

Athlete’s heart has been described for the first time over 100 years ago by Herrschin in cross country skiers. In 1975 Morganroth hypothesized two forms of cardiac adaptation on exercise by echocardiography: 1) an eccentric hypertrophy with an increase in left ventricular (LV) cavity dimensions and LV mass in endurance athletes caused from volume overload during exercise, and 2) a concentric hypertrophy with an increase in LV wall thickness and LV mass without changes in LV cavity dimensions resulting from pressure overload during strength or resistance training. Although over the following years further studies were able to demonstrate an increase in LV enddiastolic diameters and LV wall thickness in endurance athletes, controversial data were reported for LV dimensions in strength athletes. As some authors described a concentric hypertrophy, others did not find elevated LV wall thicknesses and masses in strength athletes. Beside the need to relate cardiac dimensions to body dimensions, also the possible use of anabolic steroids and their influence on the heart has to be considered, as greater LV wall thicknesses and masses have been demonstrated in anabolic steroids abusing bodybuilders whilst strength athletes and body builders without the use of anabolic steroids did not present a concentric hypertrophy.

It also has to be considered that echocardiography underlies a relative high inaccuracy when small differences between athletes of different disciplines and untrained control subjects or cardiac adaptations on exercise are compared. Therefore, a few studies used magnetic resonance imaging (MRI), which is more accurate but more expensive and less available than echocardiography, to examine cardiac adaptations on exercise. These studies confirmed the echocardiographic findings in endurance athletes and, in addition, a balanced eccentric hypertrophy of the left and right ventricle (RV) was reported. In two cross-sectional MRI studies, LV mass in strength athletes was lower than in endurance athletes and similar or only moderately higher in comparison to untrained control subjects. MRI derived LV enddiastolic volumes in strength athletes were also similar to untrained controls, whereas endurance athletes demonstrated the highest LV enddiastolic volumes. In an own recent MRI study, strength athletes presented higher LV and RV masses and enddiastolic volumes in comparison to untrained control subjects matched for body dimensions - with similar ratios for LV and RV masses and enddiastolic volumes in both groups. In conclusion, more evidence for the Morganroth hypothesis exists for an eccentric hypertrophy in endurance athletes than for a concentric hypertrophy in strength athletes. However, cardiac adaptations on exercise are probably not simply “black or white”, but there will be a greyscale of cardiac adaptations on exercise, and a number of confounding variables has to be considered in previous and future studies.

PERFORMANCE LIMITATION IN HEALTH AND DISEASE

Roecker, K.
Med. Uniklinik, Germany

The so-called cardiopulmonary fitness is a central criterion in metabolic exercise testing of health or disease. The commonly applied measurement of maximum oxygen consumption derives only accumulative diagnostic information. While widespread in clinical diagnostics for heart or lung patients, measurement of peak VO2 enables for preclusive diagnostics only. For the differential diagnosis of disease related factors, use of further measures and methods is essential in the exercise laboratory: Blood lactate levels, heart rate, other breath-gas related measures, rates of perceived exertion or calculation of the anaerobic threshold are thereby applied in routine exercise tests. But complex line-ups sometimes challenge a conclusive diagnostic interpretation of exercise tests, especially in the clinical environment. The physician or scientist must be aware of the interaction of various performance limiting factors and he has to consider how these limitations are expressed into the test results.

The aspects of cardiopulmonary performance limitation in health and disease are subject of current discussion in the field of exercise physiology. Mental, muscular, pulmonary, metabolic, cardio-circulatory or even neuronal factors are included in this discussion. Hence, this presentation will shortly overview modern concepts of cardiopulmonary performance limitation and value its relevance for the interpretation of exercise test results.
FUNCTIONAL AND STRUCTURAL VASCULAR ADAPTATION TO EXERCISE TRAINING

RELEVANCE OF BIOMARKERS OF EXERCISE-INDUCED MYOCARDIAL STRESS IN ATHLETES

König, D.
University of Freiburg, Center for Internal Medicine, Germany

During recent years, assays for the determination of cardiac troponin T (cTnT) and cardiac troponin I (cTnI) as well as brain natriuretic peptide (BNP or NT-proBNP) have significantly improved the diagnostic power to detect subclinical cardiac damage and dysfunction.

Increased concentrations of biomarkers reflecting myocardial stress such as cardiac troponin I and T and brain natriuretic peptide (BNP) have been observed following strenuous, long-lasting endurance exercise. The pathophysiological background is still not fully elucidated and the interpretations of increased post-exercise concentrations range from (i) evidence for exercise-induced myocardial damage or dysfunction to (ii) non-relevant spurious troponin elevations, presumably caused by assay imprecision or heterophilic antibodies.

In contrast to cardiac troponins that indicate a structural damage to myocardial cells, an increase in BNP is a biomarker reflecting functional myocardial overload or heart failure. In patients, both, resting values as well as the magnitude of exercise-induced rise in BNP have shown to be associated with the severity of myocardial insufficiency. Whereas short maximal bouts of exercise e.g. ergometry to exhaustion do not induce an increase in NT-ProBNP, long-lasting endurance events such as marathon running or triathlon competitions were associated with marked increases in NT-proBNP. There seems to be a trend for higher concentrations with increased exercise duration and age of the participants. Explanations for increased NT-proBNP concentrations following strenuous long-lasting endurance events include neurohumoral activation of BNP release as well as a temporary myocardial systolic and/or diastolic dysfunction involving both right and left ventricles due to mechanical or volume overload.

Today, we have no sports-specific recommendations which levels in post-exercise concentrations of these cardiac biomarkers may be tolerated or regarded as normal after strenuous endurance exercise. Therefore, a rise in these markers should always result in a comprehensive cardiac examination. However, there are also no accepted scientific statements if or when these markers should be measured following exercise.

Consequently, we clearly need more studies to elucidate the scientific background and to investigate the existence of sports-specific ‘cut-off-levels’ for cardiac troponins and brain natriuretic peptide.

IS-SH08 Talent development and sports career

TALENT VERSUS NON-TALENT IN SPORTS: PSYCHOLOGICAL DIFFERENCES

Serpa, S., Barreiros, A.
Technical University of Lisbon, Faculty of Human Kinetics, Portugal

Understanding the psychological processes of sport talents has been one of the major aims of researchers and practitioners. The goals have been either founding the best selection procedures, or to develop strategies that may increase the psychological adaptation of the young athletes. Research on perfectionism in sports is not very common, although it has increased in the last decade. It is suggested that perfectionism is important to the athletes’ adaptation to competition and that top athletes are characterised by adjusted perfectionism. Adjusted or positive perfectionism seems to be related to high achievement patterns, motivation and task orientation, while negative perfectionists seem to be oriented to avoid failure and perceive the environment as threatening. Literature also suggests that sport young talents and low level young athletes have different interactive patterns with life and sports situations.

The aim of this research was to study perfectionism in Portuguese young soccer players as a component of young talents. Young talents were compared to non-talented players taking into account two phases of sports career (under-17 and under-19). Participants were 82 talented (participation in regional or national teams) and 129 non-talented players aged 13-18. The tool used was the Portuguese version of the Multidimensional Perfectionism Scale-MPS, 5-points Likert scale (Frost, Marten, Lahart & Rosenblate, 1990), administered to the athletes. When comparing the general sample of talents with non-talents, results suggest that talented players have higher values of achievement patterns (3.71 x 3.30) and organization (4.00 x 3.71), as well as lower levels of doubts about the actions (2.59 x 2.82) and parental criticism (1.67 x 1.99). No differences are found when comparing under-17 with under-19 players in the talented group. However, non-talented older subjects reveal significant differences when compared to the younger ones in parental criticism (2.07 x 1.75) and parental expectations (2.70 x 2.30). Thus, we may conclude that talented players have higher adjusted and lower negative perfectionism when compared with the non-talented players. On the other hand, talented players seem to be stable regarding the perfectionism patterns along the career, unlike the non-talented players, and the parents’ role in their children’s perfectionism suggest the importance of the social influence in talents development reported in the international literature. Results will be discussed taking into account the coaching processes regarding the development of the psychological characteristics of sports talents.

COACH-ATHLETE RELATIONSHIPS - CURRENT APPROACHES AND NEW DATA

Alfermann, D.
University of Leipzig, Germany

Coaches are said to be the most influential agents in the process of athletes’ career development. In the past, popular approaches to measure and investigate coach-athlete interaction have been the Multidimensional Model of Leadership (Chelladurai & Riemer, 1998)
and the Meditational Model of Smoll and Smith (1989). Both models postulate a significant relationship of perceived and actual behavior of coaches to athletes’ psychological development, like satisfaction and motivation. A third approach is focused on the motivational climate. Seifriz, Duda and Chi (1992) postulate a mastery climate and a performance climate with different impact on athletes motivation and satisfaction. In two former studies we could show that leadership style and motivational climate not only contribute to athletes’ psychological development but also to skill development (Alfermann, Lee & Würth, 2005).

All three approaches do not consider the emotional relationship between coach and athlete. As an alternative, Sophia Jowett developed a questionnaire, the CART-Q, to measure the social relationship between coaches and athlete (Jowett, 2007). Based on the CART-Q we developed a German version of the questionnaire and administered it to coaches and athletes. Data on factorial structure, reliability, and correlations with existing measures of leadership style and motivational climate are presented.

THE DEVELOPMENT OF THE ATHLETE-COACH RELATIONSHIP THROUGHOUT THE ATHLETIC CAREER OF ELITE FLEMISH FEMALE JUDOKAS

Zinzen, E., Dom, E., Wyllie, P., Reints, A., De Caluwé, D.
Vrije Universiteit Brussel, Belgium

Little research has been conducted on the development of the athlete-coach relationship throughout and after the sports career. Using a semi-structured interview five male coach-female judoka dyads that worked together for at least two athletic stages were studied, taking coaches and athletes’ role in consideration during the athletic stages of initiation, development, perfection and discontinuation (Wyllie, and Lavallee, 2004). Judokas were selected for at least one European championship or had retired. Interpersonal constructs of closeness, co-orientation, and complementarity (Jowett & Meek, 2000) were used for comparing coaches and judokas’ behavior and coaches’ style of leadership were labeled using the Leadership Scale for Sports (Chelladura & Riemer, 1995). During the initiation stage, little closeness within each dyad was perceived. Coaches got to know athletes using observations. Co-orientation was still limited. Coaches nor judokas thought about results. Complementarity consisted of a motivational role of the coach using technical feedback, doing fun interactive games and gradually leading them into the world of judo. Judokas were motivated depending on the amount of fun experienced. Technical was a very important factor. The leadership style of the coach could be labeled as ‘Positive Feedback’. During the developmental stage more closeness within the dyads was found. Personal bonds between athletes-coaches became more important with the amount of trust in the coach growing fundamentally. Coaches supported athletes more often at tournaments. Co-orientation was expressed via coach-pupil communication with verbal communication changing to a two way communication. Coaches used open ended questions about training sessions. Judokas asked for specific exercises aimed at how to deal with particular opponents. Results and outcomes became important. The extent of complementarity varied a great deal among the five dyads. While technique continued to be a very important factor, tactics and competitions also came to play a central role during this stage. The coach leadership style could be labeled ‘Training and Instruction’ and ‘Social Support’. During the stage of perfection, communication between coaches and judokas was reciprocal and goals were set together. Athletes’ commitment to the sport, discipline and lifestyle became very important. Coaches motivated the judokas by conducting evaluation conversations and making them aware of their capabilities and performances. Coaches’ leadership styles ‘Training and Instruction’ and ‘Social Support’ became even more salient, but also more and more democratic. This new style may well be identified as ‘Democratic behavior’. During the discontinuation stage contact between coach-athlete became looser and more adult. In conclusion, it can be said that the characteristics of closeness, co-orientation and complementarity of the judoka-coach relationships adopted different forms throughout the athletic career.

BEST PRACTICES? SPORT SCIENCE AND BIOMEDICAL PHYSICAL ACTIVITY DISCOURSES IN THE UNITED STATES

Zieff, S.
San Francisco State University, United States

This project examines the various, and often competing, physical activity discourses developed within the biomedical and physical education domain during the past 35 years. Since the 1970s and the proliferation of irrefutable evidence of the health benefits of regular physical activity, government agencies, educational institutions, and biomedical research entities have worked to identify the determinants, barriers, and disparities that influence individual and societal physical activity behavior. Websites and published materials of such organizations as the Centers for Disease Control (CDC), the American College of Sports Medicine (ACSM), and the Surgeon General of the United States, will be considered for their efforts to encourage physical activity as personal responsibility while increasingly acknowledging the social, environmental, policy, and other barriers to engagement in physically active behavior. Explanations for physical inactivity are also explored as they parallel this paradigm shift from individual to social responsibility.
Changes in leg-spring behavior during a constant velocity run to exhaustion in elite triathletes

Rabita, G., Slawinski, J., Girard, O., Hausswirth, C.
National Institute of Sports, INSEP, Paris, France

Introduction
The spring-mass model has been recently used to investigate the effect of fatigue during running (Dutto et al., 2002; Hunter et al. 2007). These authors, who evaluated the leg-spring behavior during a running that lasted between 45 to 90 minutes, demonstrated a decrease of the leg stiffness (K_leg). Slawinski et al. (2008) has investigated the effects of fatigue induced by a supra lactic threshold running on the leg stiffness. This study did not show significant change in K_leg between runs performed before and after a 2000 m run. However, no measure was realized during the fatiguing test. The purpose of the present study was to explore whether fatigue induced by a high intensity constant velocity run 95% of VO2max leads to change in leg-spring behavior.

Methods
A group of 9 triathletes, 6 males [23.2 (SD3.2) years; 181.7 (SD2.4) cm; 68.3 (SD5.4) kg] and 3 females [25.0 (SD4.4) years; 166.7 (SD4.2) cm; 58.3 (SD3.2) kg] participated in the study. Two runs were required. The first run was a graded exercise test to determine the velocity corresponding to 95% of VO2max. Mechanical parameters were measured during Tlim from 5 force plates (Kistler; 500 Hz) integrated on a 5 m distance into the ground. Leg stiffness (K_leg) was calculated classically (McMahon and Cheng, 1990). Step temporal parameters were also analyzed with repeated measures ANOVA and Scheffe post hoc tests.

Results
Mean values of VO2max were 5.1 (SD 0.3) m.s-1 during the incremental test. For the constant velocity run, mean time (Tlim) was 10'43" (SD 2'37''). Leg stiffness was found to decrease (from 11.2 to 10.2 kN.m-1) with exhaustion (P=0.01). Vertical Force peak during contact (Fpeak) decreased significantly with fatigue from 1963 (SD262) to 1772 (SD219) N while the changes in leg spring compression (L) from 0.168 (SD0.007) to 0.175 (SD0.015) m was not significant. Despite a slight but significant increase (P=0.048) in contact time (from 0.199 [SD0.067] to 0.204 [SD0.005] s), the step frequency increased (from 3.03 [SD0.02] to 3.10 [SD0.02] Hz, P=0.015) because of a greater decrease (P<0.0001) of the aerial time (from 0.131 [SD0.02] to 0.119 [SD0.01] s).

Discussion
The results of the present study show that K_leg was significantly influenced by the fatigue resulting from a constant velocity run. The decrease of this mechanical parameter was more influenced by force changes during the contact phases than changes in leg spring compression. The analysis of temporal parameters suggests that, at this speed (around 5 m.s-1), the increase of the step frequency (despite a higher contact time) could be the strategy in elite triathletes to maintain the constant velocity. This strategy tends to decrease the force that has to be supported during the contact phase and then leads to a decrease in leg-spring behavior.

EMG of lower limb muscles and biomechanics of pedalling during a high intensity exercise performed until exhaustion

Dorel, S., Couturier, A., Drouet, J., Champoux, Y., Hug, F.
Institut National du Sport, France

Introduction
In contrast with several factors such as workload, pedaling rate or body position, the influence of fatigue on the pattern of muscles activation and/or the profile of forces exerted on pedals is more open to discussion (Hug and Dorel, in press). If some studies suggest that it could be mainly attributed to progressive recruitment of additional motor units (and hence an increase in EMG RMS for some muscles), it...
could also be assumed that fatigue induces changes of the coordination of the lower limb muscles. From a biomechanical point of view, only one study recently focused on the alteration of torque profile and index of effectiveness during a high intensity cycling exercise but EMG was not recorded (Sanderson et al., 2003). The aim of this study was, therefore, to simultaneously examine the coordination of the main lower limb muscles and biomechanics of pedal force production during a high intensity cycling exercise performed until exhaustion.

Methods
After a first session during which they achieved a classical incremental maximal cycling protocol, ten trained cyclists performed an exercise at 80% of the maximal power sustained during the first session (i.e. 328±22 W) until they were completely exhausted. The cycle ergometer (Excalibur Sport, Lode®, Netherlands) was equipped with instrumented pedals specifically designed for pedaling load measurements by VelUS group. Mechanical variables (effective force, total force, index of effectiveness: IE) and surface EMG of ten lower limb muscles (TA, SOL, GL, GM, VL, RF, VM, BF, SM, GMax) were continuously recorded during the protocol.

Results
Between the start and the last minute, GMax and BF RMS showed a significant increase of 29% (P<0.01) and 15% (P<0.05) respectively, whereas GM and TA RMS showed a decrease of 10 and 15% (P<0.05), respectively. Maximal total force and effective force as well as positive impulse values were significantly greater in the final (428 N, 400 N and 75.4 N.s) than in the first minute (409 N, 379 N, 69.1 N.s, P<0.01) and the negative impulse value was smaller in the first than in the final minute (-7.1 N.s vs. -8.3 N.s, P<0.05). The mean value of the overall IE did not change significantly but the cross-correlation technique indicated that instantaneous effectiveness during the last part of the upstroke phase (i.e. near the top dead central) decreased at the end of exercise.

Conclusion
These results provide additional evidence that fatigue leads riders to become less effective during the recovery phase, which increases the demand for forces during the propulsive phase. Neuromuscular adaptations (especially the increased activity of hip extensors and decreased activity of ankle extensors and flexors) observed with the occurrence of fatigue are strongly related to these results and could partly explain these adjustments in the force production.

GENDER SPECIFIC KINEMATICS AND MUSCLE ACTIVITY DEPENDING ON RUNNING SURFACE

Wissmann, I., Gulden, C., Brueggenmann, G.P.
German Sport University Cologne, Germany

Introduction
According to the literature, running injuries differ between female and male runners (Taunton et al., 2002). This is considered to be related to gender specific running mechanics (Ferber et al., 2003). Running mechanics is related to muscle activation. Within men, running kinematics as well as muscle activation are known to depend on running surface (Nigg et al. 1995, VonTscharner et al., 2003). Little is known concerning surface related running mechanics in female runners. Therefore the purpose of this study was to get information about kinematics and muscle activity of female and male runners while running on different surfaces in order to see if there are gender specific differences in kinematics and muscle activation and if muscular and kinematical responses to surface changes are gender specific.

Methods
14 subjects (5 female, 9 male) were tested during running barefoot (v=3.75+0.25m/s) on grass and on tartan. Surface EMG (10 steps per subject) was recorded (3000 Hz) from mm. tibialis anterior, peroneus longus, gastrocnemius lateralis (GL), semitendinosus, vastus medialis (VM) and tensor fasciae latae (TFL). Three-dimensional kinematics of knee and ankle joint were recorded by 12 infrared highspeed cameras (VICON, 250 Hz).

Results
Muscle activation and kinematics were different between gender groups in both running conditions. Changes in surface condition led to changes in muscle activation and kinematics within all subjects. Except for knee abduction/adduction time history, kinematical responses to surface changes were in trend similar between gender groups. EMG responses to surface changes were gender specific and in several muscles (GL, TFL, VM, FMI) converge between gender groups.

Discussion
Data indicate that dynamic segment alignment is different between gender groups. Possible explanations are gender specific differences in muscle strength, anthropometry, connective tissue properties or foot sensitivity.

Understanding gender specific running kinematics and muscle activation may lead to valuable information for future gender specific footwear design and prevention of running injuries.

HERITABILITY OF SPEED PERFORMANCE AND ITS BIOMECHANICAL CHARACTERISTICS

Gouvai, M., Boudoulos, K., Kissouras, V.
National and Kapodistrian University of Athens, Greece

The relative influence of genes and environment to the diversity of human performance has been extensively studied by using the twin model and deriving heritability estimates, based on comparisons between monozygotic (MZ) and dizygotic (DZ) twins (Kissouras, et al., 2007). However there is a scarcity of data regarding the heritability of running speed as well as its biomechanical characteristics and related functional abilities. For this purpose 12 pairs of twin brothers (5 MZ and 7 DZ), aged 19-29 years, performed an all out 60m run, while its kinematic characteristics were assessed with electronic photocells (Brower Systems) and high frequency cameras (125 Hz). In addition, the twins performed jumping trials on a force plate (Kistler 928AA) and isometric trials on an isokinetic dynamometer (Cybex II+). Data obtained were analysed using single-factor analysis of variance. The variance of intrapair differences (Clark equation) was used for
the computation of heritability estimates, provided that differences in genetic variance between the twin types (F I test) were significant at the level of 5% and the differences between means (t-test) and total variance (F I test) of both types of twins were not significant. These genetic hypotheses were not supported for running speed and hence the computation of heritability estimate was abandoned. However, the hypotheses were satisfied for biomechanical characteristics of the run and the computed heritability estimates were 0.891, 0.858 and 0.803 (p<0.05) for stance time, ankle angle and knee angle during landing respectively. The genetic hypotheses were also satisfied for critical functional abilities and heritability estimates were found to be 0.924 for take off velocity, 0.896 for velocity needed to attain maximum power and 0.931 for vertical displacement (p<0.05) during drop jumps from a 40cm height, jumping trials related to the utilization of elastic energy. Regarding the maximal isometric trials, heritability estimates were 0.841 and 0.846 for rate of force development at 100ms from the left and the right ankle plantar flexors respectively. In conclusion, genes do not seem to play a significant role to individual differences in running speed but they could explain some differences in its contributing factors such as the duration of stance phase, the utilization of elastic energy and the rate of force development.

ASYMMETRY OF UNILATERAL LEG STIFFNESS
Eriksrud, O., Smith, G.
Norwegian School of Sport Sciences, Norway

Vertical stiffness of the musculoskeletal system has been studied extensively using mass-spring modeling, however most studies involve the investigation of the bilateral stiffness of the lower extremities with only few examining unilateral leg stiffness (Dalleau 1998). The purpose of this study was to determine the relationship between bilateral and unilateral vertical stiffness during hopping. This was a part of a larger study evaluating how parameters such as stiffness during hopping and running are different between three distinct athletic populations.

Methods:
13 subjects (11 power lifters and 2 distance runners) were tested in bilateral and unilateral hopping for 15 seconds on a floor mounted force plate (AMTI). The average stiffness of 10 consecutive hopping cycles was used for analysis. Vertical stiffness was determined using the model of Morin et al. (2005) which is based on contact and flight time to predict force and displacement. For statistical analysis, the more stiff and the more compliant leg were identified and compared using paired t-test (N=13). In addition, dominant and non-dominant leg were identified and compared using paired t-test (N=12 as dominance was not identified for one subject).

Results:
Bilateral stiffness (18.7 ± 3.7 kN·m-1) was significantly greater than unilateral vertical stiffness (p<0.05). For unilateral stiffness comparisons, the stiff and compliant legs differed by about 14% (14.7 ± 3.6 vs 12.8 ± 3.2 kN·m-1, p<0.05). Dominant and non-dominant legs were not significantly different (13.7 ± 3.4 vs 12.5 ± 2.1 kN·m-1 respectively, p=0.10). Within subject variability across 10 hops was similar for each leg grouping (CV of 10-12%).

Discussion:
Dalleau et al (1998) distinguished leg contributions to running by identifying one leg as propulsive and the other as a stiffer, “stick” leg. While mean values were not significantly different, the dominant leg was generally stiffer in unilateral hopping than the non-dominant side. For 75% of subjects the stiffest leg was the dominant leg. Whether this dominant vs. non-dominant stiffness difference continues during bilateral hopping was not examined here as separate force measures were not obtained.

Conclusion:
Significant asymmetry of vertical stiffness was found between legs in unilateral hopping. The dominant leg was stiffer than the non-dominant side for most subjects.

CHANGES IN MAXIMAL AND EXPLOSIVE STRENGTH, EMG AND MUSCLE THICKNESS OF LOWER AND UPPER EXTREMITIES INDUCED BY COMBINED STRENGTH AND ENDURANCE TRAINING IN SOLDIERS
Santtila, M., Kyröläinen, H., Hakkinen, K.
Finnish Defence Forces, University of Jyväskylä, Finland

Military tasks are often exposed to multistressors, which are very challenging for the soldier’s physical and mental performance (Nindl et al. 2002). They consist of demanding tasks like carrying or lifting heavy loads and materials, digging foxholes or prolonged marches with extra loads of combat gear of 25-65 kg in harsh circumstances. Therefore, in the military operations require high levels of both aerobic and neuromuscular performance. The purpose of present study was to examine to what extent an 8-week endurance based military training (NT) period interferes with muscle strength development in the conscripts compared to that caused by sport related military training with added strength (ST) or added endurance training (ET). More specifically, we examined effects of these three training modes on maximal isometric force, maximal rate of force development (RFD), electromyography (EMG) and muscle thickness of the lower and upper extremities.

In the beginning of basic training (BT) season male conscripts were divided into ET, ST and normal training (NT) groups (n=24 in each group). Their mean age was 19.2±0.9 yrs., height 1.79±0.06 m, initial body mass (BMI) 73.8±12.4 kg, and body mass index (BMI) 23.0±3.8. The overall physical loading of the military training was the same in ET, ST and NT but the groups differed with regard to three specific training sessions per week (cycling, nordic walking and running for ET, strengthening for ST and overall sport related physical training for NT). The measurements included isometric force-time parameters of the leg and arm extensors and EMG activity from the vastus lateralis, vastus medialis, rectus femoris and triceps brachii muscles. The 8-week BT combined with added ST and ET significantly improved maximal bilateral isometric force of the arm extensors in ST by 11.8% (p<0.001), ET by 13.9% (p<0.001) and NT by 7.8% (p<0.05). ST and ET showed significant increases in maximal EMG activity of the trained arm muscles. A significant increase was also observed in maximal RFD of the upper extremities only in ST by 28.1% (p<0.05). Both ST and ET increased their maximal leg extension strength by 12.9% (p<0.01) and 9.1% (p<0.05), respectively, while no significant change occurred in NT (5.2%, p=0.45). No significant changes were observed in the
shape of the force-time curves of the leg extensors as well as in muscle thickness of the lower and upper extremities. The present BT training with a large amount of endurance based military training interfered with strength development, and especially, explosive power development of the lower extremities in the ST group. The optimal improvements in neuromuscular characteristics may not be possible without some decreases in the amount of the endurance based military training and/or some increases in the amount of the strength training during the BT.

CHANGES IN THE RAT CARDIAC PROTEOME IN RESPONSE TO INTENSITY-CONTROLLED ENDURANCE EXERCISE

Burniston, J.
Liverpool John Moores University, United Kingdom

Endurance training improves cardiac performance and provides greater protection against heart disease. The rodent model of intensity-controlled treadmill running replicates the prescription of endurance exercise in humans and can be used to investigate molecular adaptations in the heart. To further understand the beneficial effects of exercise, I have combined this model with an inductive proteomics approach to discover differences in protein expression between hearts of endurance-trained and sedentary animals.

Rats (n = 6, 280 ± 10 g) were exercised on a motorised treadmill within a metabolic chamber linked to a gas analyser, and their peak oxygen uptake (VO2peak) was measured using an incremental exercise test. Animals assigned to the exercise group trained for 30 min at 70% of their VO2peak, 4 days per week. Each animal’s VO2peak was measured at 2-week intervals and based on these data the treadmill speed or incline was increased in order to maintain a consistent relative training intensity. Rats were killed 4 h after a final VO2peak test and their cardiac proteome compared with weight-matched control animals (n = 6, 330 ± 5 g). Proteins were isoelectrically focused on immobilised pH gradient strips (pH 3-11 non-linear) and resolved by denaturing gel electrophoresis. Protein spots of interest were digested with trypsin and analysed using matrix-assisted laser desorption ionisation tandem time of flight mass spectrometry, and the peptide- and fragment-ion spectra were searched against the Swiss-Prot database using Mascot (www.matrixscience.com).

The average VO2peak of animals in the exercise group increased by 23% (P=0.008) over the 6-week training regimen, and the cardiac protein content of exercised animals was 11% greater (P=0.043) than that of the weight-matched controls. Proteome expression analysis identified 23 protein spots that differed significantly (P<0.05) between exercised and control groups. Increases were measured in the expression of myofibrillar proteins (e.g. alpha- myosin heavy chain and cardiac alpha-actin), and proteins associated with fatty acid metabolism (e.g. heart fatty acid binding protein, acyl-CoA dehydrogenase and mitochondrial thioesterase-1) and the maltate-aspartate shuttle (aspartate aminotransferase and cystolic maltate dehydrogenase). In addition, endurance training induced a shift in the gel pattern of heat shock protein 20 indicative of phosphorylation, and analysis of fragment ion spectra mapped this modification to serine 16.

These findings are consistent with microarray data that show elevated expression of genes associated with fatty acid metabolism differentiates adaptive from maladaptive cardiac hypertrophy. Phosphorylation of heat shock protein 20 at serine 16 is associated with improved cardiomyocyte contractility and protection against apoptosis, and has been identified as a therapeutic target against heart disease. These data show that endurance exercise is able to achieve this effect.

EFFECTS OF A SINGLE RESISTANCE EXERCISE BOUT ON MYOGENIC MARKERS IN SKELETAL MUSCLES OF ELDERLY MASTER WEIGHT LIFTERS AND SEDENTARY CONTROLS

Wessner, B., Tschan, H., Ferunaj, P., Erindi, A., Guschelbauer, R., Bächl, N.
University of Vienna, Institute of Sports Sciences, Austria

Introduction: Ageing is associated with a progressive loss of muscle mass and strength often resulting in reduced functional capacity. On a molecular basis it has been shown that ageing alters gene expression of muscle growth and remodelling such as the insulin-like growth factor-1 (IGF-1) or myostatin resulting in an impaired muscle protein turnover and/or a reduced function of muscle stem cells. It is known that resistance exercise training provides an effective measure to increase muscle mass and strength even in older individuals. However, the molecular response to exercise in the elderly seems to be diminished in comparison to younger subjects. In this study we hypothesized that elderly subjects who regularly underwent professional resistance exercise training such as elite weight lifters respond differently to a single bout of resistance exercise than sedentary age-matched controls.

Methods: Eight elderly (61±/-9 yr) still active master weight lifters (WL) and 8 elderly (61±/-8 yr) sedentary controls (SC) were recruited from the Tirana (Albania) area. They were free of disorders that might have affected their ability to complete resistance exercise and testing for the study. Subjects were not obese (BMI < 30) and none of the sedentary controls had undergone leg resistance training within the past 5 yr. At least 2 d after assessment of 1-RM on a leg extension device, a unilateral leg extension exercise session was applied (3 sets, 70-75% of the 1-RM until voluntary fatigue, 2-min rest between the sets). Three hours after termination of the exercise, skeletal muscle biopsies were taken from m. vastus lateralis using the Bergstrom needle technique. The tissue was immediately stored in RNAlater solution and frozen until analysis. After extraction of RNA from 10-15 mg tissue and cDNA synthesis, q RT-PCR was performed to measure mRNA levels of two splicing variants of IGF-1 (IGF-1Ea and MGF), the growth inhibitor myostatin as well as the transcription factors myogenin, and MyoD. mRNA levels of these genes were normalized to mRNA levels of GAPDH. Results: Both groups did not differ in age, BMI, height, and weight. As expected the relative 1-RM was significantly higher (+24%, p<0.05) in WL than in SC. On a molecular basis the single exercise session caused a loss of myostatin mRNA in both groups (52% in SC, -36% in WL, p<0.01). Although myostatin levels were similar in the control legs of both groups between the groups myostatin mRNA levels of exercised legs were significantly lower in SC (13%, p<0.01). We could not detect any differences in IGF-1Ea, MGF and myogenin neither after exercise nor between the groups.

Conclusion: This study clearly showed that a single bout of exercise is able to affect myostatin levels in trained as well as in untrained elderly individuals without affecting other myogenic markers. However, as this study provides only data from a single time point after exercise a further study is needed to address possible time effects.
MOLECULAR FACTORS INVOLVED IN THE ANGIOGENESIS PROCESS OF EXERCISED MOUSE HEARTS

Bellaïche, M., Battaglia, G., Bianco, A., Palma, A., Farina, F.
University of Palermo, Italy

In the literature controversial results concerning to the myocardial capillary growth induced by exercise training are present and angiogenesis appears to depend on the animal age, exercise type and time course of exercise-induced adaptations in the coronary microvasculature (1). In our previous studies hearts from mice trained for 30 and 45 days by endurance protocol showed hypertrophy due to a significant increase in the capillary area (2). This modification was associated with an increase in vimentin and connexin-43 expression in interstitial connective tissue cells suggesting an enhanced request of vascular remodelling and growth factors and a new role of Cx43 in cardiac angiogenesis. In order to study molecular mechanisms involved in this process, we also examined the expression of vascular endothelial growth factor receptors (VEGFR) that have been shown to be fundamental regulators in the cell signalling of angiogenesis. We observed that the expression of VEGFR-1 and VEGFR-2 was differently regulated by endurance training and their expression pattern was affected by the time points of training protocol.

Among primary prerequisites for angiogenic process are included: 1) physical and haemodynamic forces, tissue ischaemia and hypoxia, 2) vascular relaxation by nitric oxide, 3) degradation of the basal membrane by matrix metalloproteinases (MMPs).

The aims of present study were to analyze the expression of hypoxia inducible factor-1α/β (HIF-1α/β) and inducible nitric oxide synthase (iNOS), and activity of matrix metalloproteinases 2 and 9 (MMP-2, MMP-9) in capillary growth of trained mouse hearts.

Sixty-three male Swiss mice, ten-week-old, were divided into control untrained groups (C0, C15, C30, C45) and groups trained for 15 (T15), 30 (T30) and 45 (T45) days by treadmill. The expression of HIF-1α and iNOS were respectively examined by western blot and RT-PCR analyses. MMP-2, MMP-9 activity was analyzed by gelatin zymography.

Results showed that HIF-1α expression was higher in T30 group than control, T30 and T45 animals. iNOS expression increased in T15 and T30 mice compared to control and T45 animals. MMP-9 activity showed an increase in T15 group compared to control, T30 and T45 groups. In T30 and T45 mice MMP-2 activity resulted to be slightly lower than control animals.

Expression profile of HIF-1α and iNOS suggests their involving in early events of angiogenesis process induced by endurance training. For instance, a hypothetical pathway might include HIF-1α as an upstream regulator of iNOS and induce capillary proliferation. Indeed, it is known that both factors are activators of VEGF system. The regulation of MMP-2 and MMP-9 activity suggests a role of these proteins in cell matrix remodelling in response to exercise.

ANGIOTENSIN CONVERTING ENZYME INSERTION/DELETION POLYMORPHISM IS NOT ASSOCIATED WITH FAT FREE MASS OR STRENGTH IN POSTMENOPAUSAL BRAZILIAN WOMEN

Lima, R., Pereira, R., Leite, T., Cestari, C., Bottaro, M., Ferreira, C., Oliveira, R.
Universidade Católica de Brasília, Brazil

The age-associated loss of fat free mass (FFM) and muscle strength is broadly referred as sarcopenia and is related to physical disability among older individuals (Baumgartner et al., 1999). Although the heritability of FFM and strength have been well described (Carmelli and Reed, 2000), the identification of specific allelic variants contributing to these phenotypes requires future investigations. It has been suggested that the angiotensin-I converting enzyme (ACE) insertion/deletion polymorphism is associated to muscle-related phenotypes (Hopkinson et al., 2004), however, this observation is not consensual (Fooland et al., 2000). The present study examined the association between the ACE insertion/deletion polymorphism with FFM and muscle strength in postmenopausal Brazilian women. After exclusion criteria were applied, a total of 246 volunteers (age 66.51 ± 6.37 years) underwent knee extension isokinetic peak torque assessment using the Biodex System 3 dynamometer and FFM measurements by dual energy x-ray absorptiometry. ACE genotypes were determined by polymerase chain reaction and differences between genotype groups were examined by analysis of covariance. Genotype distribution was in Hardy-Weinberg equilibrium (DD 30.2%; ID 47.6%; and II 22.2%). The ACE insertion/deletion polymorphism was not associated with body FFM (0.908) and relative appendicular FFM (0.224). Furthermore, no difference between genotype groups was observed for quadriceps strength (p = 0.823). In summary, the present findings suggest that the ACE insertion/deletion polymorphism is not associated with FFM or strength in postmenopausal women. Further studies in different sample population are required to confirm these results.

EXERCISE-INDUCED EXPRESSION OF ANGIOGENIC GROWTH FACTORS IN SKELETAL MUSCLE AND IN CAPILLARIES OF HEALTHY AND DIABETIC MICE

Kivelä, R., Silvennoinen, M., Lehti, M., Jalava, S., Vihko, V., Kainulainen, H.
University of Jyväskylä, Finland

Background
Diabetes has negative, and exercise training positive, effects on the skeletal muscle vasculature, but the mechanisms are not yet fully understood. In the present experiment the effects of running exercise on the mRNA expression of pro- and antiangiogenic factors were studied in healthy and diabetic skeletal muscle. The responses in capillaries and muscle fibers, collected from the muscle with laser capture microdissection, were also studied separately.

Methods
Healthy and streptozotocin-induced diabetic mice were divided into sedentary and exercise groups. Exercise was a single bout of 1 h running on a treadmill. Gastrocnemius muscles were harvested 3 h and 6 h post exercise, and angiogenesis-related gene expressions were analyzed with real-time PCR. In addition to muscle homogenates, capillaries and muscle fibers were collected from the muscle with laser capture microdissection method and analyzed for vascular endothelial growth factor A (VEGF-A) and thrombospondin-1 (TSP-1) mRNA expression.

Results

Of the proangiogenic factors, VEGF-A and VEGF receptor-2 (VEGFR-2) mRNA expression increased significantly (P < 0.05) in healthy skeletal muscle 6 h post exercise. VEGF-B also showed a similar trend (P = 0.08). No significant change was observed post exercise in diabetic muscles in the expression of VEGF-A, VEGFR-2 or VEGFR-1. The expression of angiogenesis inhibitor TSP-1 and angiogenic extracellular matrix protein Cyr61 were significantly increased in diabetic muscles (P < 0.05-0.01). Capillary mRNA expression resembled that in the muscle homogenates, however, the responses were greater in capillaries compared to muscle homogenates and pure muscle fibers.

Conclusions

The present study is the first to report the effects of a single bout of exercise on the expression of pro- and antiangiogenic factors in diabetic skeletal muscle, and it provides novel data about the separate responses in capillaries and muscle fibers to exercise and diabetes. Diabetic mice seem to have lower angiogenic responses to exercise compared to healthy mice, and they show markedly increased expression of angiogenesis inhibitor TSP-1. Furthermore, exercise-induced VEGF-A expression was shown to be greater in capillaries than in muscle fibers.

A SINGLE SESSION OF CIRCUIT RESISTANCE EXERCISE ENHANCES ABCA1 EXPRESSION IN HUMAN PERIPHERAL BLOOD LYMPHOCYTE

Maraki, H., Ghanbari-Niaki, A., Marzijeh, S., Fatemeh, R.

Birjand University 3, Tarbiat Modares University1,4, and Mazandaran University 2, Iran

A T P-binding cassette transporters (ABCs) belong to a large family and include 49 mammalian transmembrane transporters that transfer a variety of substrates across the lipid bilayers in an energy-dependent manner. ABCA1 is a member of this family which plays a crucial role in plasma HDL-C remodeling. The purposes of this study were to investigate peripheral blood lymphocytes (PBL) ABCA1 expression, plasma lipids, lipoprotein levels in response to single session of circuit-resistance exercise (CRE). Twenty-five young female college students (age 19-29 yr, height 155-171 cm, body weight 45-65 kg, BMI 18.49-24.17 kg/m2) volunteered and randomly divided control, exercise, 3 sets of 3 non-stop circuits, 1 min rest intersets). Plasma was collected before and immediately after exercise for extraction of PBL ABCA1 mRNA and glucose, lipids, and lipoprotein measurement. PBL ABCA1 mRNA expression was significantly (P<0.001) increased in all exercise intensities with more pronunciation in mixed and 60% of 1RM groups. Plasma glucose concentrations were significantly increased in all exercise intensities with more pronunciation in mixed and 60% of 1RM groups. Plasma glucose concentrations were significantly increase immediately following exercise in all groups. Plasma HDL-C was significantly higher (P<0.005) in mixed group. Changes in plasma TC, TG, LDL-C, and VLDL-C concentrations were not significant. A significant TC/HDL-C and LDL/HDL-C ratios was observed in mixed group. In conclusion, a single session of CRE increased PBL ABCA1 expression and this increase was more pronounced in mixed group with higher HDL-C concentration. It seems CRE with mixed intensities is more suitable for PLB ABCA1expression and Plasma HDL-C change.
SPEED REGULATION DURING HILL RUNNING: A FIELD STUDY USING GPS, ECG, ACCELEROMETRY AND A PORTABLE METABOLIC ANALYSER

Townshend, A., Worthingham, C., Stewart, I.
Queenland University of Technology, Australia

Introduction

Though self-selected walking speeds have been investigated extensively, limits in available technology have constrained similar studies of outdoor running. This investigation utilised recent advances in portable monitoring systems to characterise the way in which runners continually regulate their speeds during overground running. A specific focus was on running in hilly terrain as this puts a premium on optimising the rate of energy expenditure through the control of running speed.

Methods

Eight well trained distance runners (VO2 max 69.8 ± 5.4 mls.kg.min⁻¹) ran three laps of a course incorporating uphill, downhill (approximately ± 8% grade) and level sections. A single-lead ECG supplied continuous heart rate data, while a tri-axial accelerometer and continuous speed data from a GPS receiver provided cadence and stride length estimates. Oxygen cost and ventilation data were collected breath by breath with a portable metabolic analyser, allowing comparison with indices of physiological capacity collected earlier in a laboratory trial.

Results

Runners ran faster on lap 1 (3.88 ± 0.40 m.s⁻¹), than lap 2 (3.66 ± 0.34 m.s⁻¹), but while four runners increased speed from laps 2 to 3 (+3.9%), the other four decreased (-1.7%). As expected, runners varied their speed inversely with gradient; (uphill 2.93 ± 0.27 m.s⁻¹, downhill: 4.35 ± 0.46 m.s⁻¹, level: 3.83 ± 0.34 m.s⁻¹). In addition, between subject variation of downhill running speed was 145% and 72% greater than corresponding values for uphill and level sections expressed relative to the runner’s individual ventilatory threshold, oxygen uptake was lower on downhills (82.1% ± 7.5%) than level sections (90.3% ± 8.5%) or uphills (101.2 % ± 10.1%). Stride length and cadence both increased on downhills and decreased on uphills, however, initial results suggest speed was primarily regulated by changes in stride length (88%) rather than cadence (13%).

Discussion

This study is among the first to examine continuous changes in gait parameters, energy cost and speed during outdoor running. The larger variability in downhill speeds, coupled with the finding that speeds were not limited by physiological cost, suggest that there is greater scope for improving performance on downhill sections. This requires that factors limiting downhill running speed be identified. Stride length and cadence data may partially reflect some of these limits. Runners who started faster than their speed at ventilatory threshold slowed from lap 2 to lap 3, while those who started slower accelerated in the final lap. This suggests that small departures from optimum starting pace may have major effects on performance at the end of the exercise bout. In turn, this could be a crucial factor in determining race outcome on hilly courses.

HEART RATE VARIABILITY AND PHYSICAL ACTIVITY MEASURED SIMULTANEOUSLY DURING WAKING HOURS

Hautala, A., Kiviiniemi, A., Kinnunen, H., Huikuri, H., Tulppo, M.
Verve Research, Finland

PURPOSE: Heart rate variability (HRV) during ambulatory condition has been proposed to be affected by individual differences in frequency, duration, and extent of daily physical activity (PA) [1-3]. However, the association between PA and different spectral components of HRV during daily activities is not well known. We examined correlation between simultaneously measured HRV and PA during waking hours in healthy subjects.

METHODS: Fifteen healthy adults (seven men, eight women; age 36±3 yr, body mass index 25±3 kg/m²) wore a Polar accelerometer and an R-R recorder (Polar Electro Oy, Kempele, Finland) for 24 hours. We identified PA bouts during waking hours from minute-by-minute accelerometer data as metabolic equivalent (MET) values, and calculated mean METs for 30 minutes. Spectral components of HRV were analyzed concurrently at epochs of 30 minutes. Within-individual correlation analyses were performed to study relations between HRV and PA.

RESULTS: The mean PA time was 14:58±0:37 hours and the mean METs was 1.97±0.13 (range 1.62-1.99 METs). In the within-individual correlation analyses between PA and HRV of 30 min epochs, HR associated clearly with PA (r=0.78, p<0.0001). Similarly, high-frequency (HF, 0.15-0.4 Hz) power of HRV was related to PA (r=-0.57, p=0.031). Low-frequency (LF, 0.04-0.15 Hz) or very-low-frequency (VLF, 0.003-0.04 Hz) power of HRV were not associated with PA (r= -0.37, p=0.102 and r= -0.22, p=0.310, respectively).

CONCLUSION: The PA is most powerfully associated with HR and vagally mediated short-term HRV during daily activities. The association between PA and long-term HRV indices is relatively low during daily activities. These findings may emphasize the intrinsic, physiologic origin of long-term HRV, which is only partly modulated by PA.

BONE SPEED OF SOUND, PHYSICAL ACTIVITY AND CALCIUM INTAKE IN OVERWEIGHT VERSUS NORMAL-WEIGHT PRE- AND LATE-PUBERTAL GIRLS

Klentrou, P., Yao, M., Ludwa, I., Corbett, L., Falk, B.
Brock University, Canada

In females, adiposity provides a protective effect for bone during adulthood. However, increased body fat may be associated with low bone strength during childhood. The purpose of this study was to compare bone strength, as reflected by speed of sound (SOS), of pre-pubertal and late-pubertal overweight and obese girls with normal-weight age-matched controls. Data of 58 girls include pre-pubertal normal-weight (PPn, body fat 20%, n=19), pre-pubertal overweight and obese (PPo, body fat 25%, n=10), late-pubertal normal-weight (LPn, body fat 25%, n=10) and late-pubertal overweight and obese (LPo, body fat 25%, n=10).
(LPn, body fat 20%, n=15) and late-pubertal overweight and obese (LPo, body fat 25%, n=14) groups. Using quantitative ultrasound (Sunlight OmnisenseTM), bone SOS was measured at the distal radius and mid-tibia. Habitual physical activity was measured for one week using accelerometry and energy intake was assessed by a 24-hour recall. No differences were found between groups in daily total energy, calcium or vitamin D intake. The average daily calcium intake for all groups (1152±1165 mg) was below the recommended daily intake values for their age (1300mg as per FAO/WHO 2002), with no differences between groups. No differences were observed in habitual physical activity between the adiposity groups, although PP girls were active between the ages of the day compared with the LP girls (16% for both PPn and PPs versus 6% for LPn and 4% for LPo, respectively). Younger girls had significantly lower radial SOS (3770±90 versus 3988±60 m/s for PPn and LPn, respectively), and tibial SOS (3699±99 versus 3871±86 m/s for PPn and LPn, respectively) than late-pubertal girls. Although the differences were not statistically significant, tibial SOS tended to be lower in the overweight and obese groups (3637±107 m/s and 3833±103 m/s for PPo and LPo, respectively) as compared with the above values for the normal-weight controls (p=0.06). In addition, partial correlation analysis, controlling for age, revealed that radial SOS was negatively correlated (r=-0.28, p=0.04) with percent body fat. These results suggest a possible negative effect of adiposity on bone SOS among girls. However, more research is required to elucidate the effects of adiposity, physical activity and nutrition on bone in the different stages of growth.

**EFFECT OF LOW-DOSE ENDURANCE TRAINING ON HEART RATE VARIABILITY AT REST AND DURING AN INCREMENTAL MAXIMAL EXERCISE TEST**

Martinmäki, K., Häkkinen, K., Mikkola, J., Rusko, H.  
University of Jyväskylä, Finland

Recreational physical activity promotes health and regular endurance training has additional health benefits, including improved cardiovascular health and fitness and decreased mortality (Haskell et al. 2007). One possible pathway by which endurance training benefits cardiovascular health is through causing a shift in autonomic control of heart rate (HR) towards increased vagal dominance. Not much information is available about the minimum amount of endurance training for improving autonomic HR control and cardiovascular fitness. Autonomic HR control, particularly quantified by spectral analysis of heart rate variability (HRV) (Aksealf et al. 1985). The aim of the present study was to evaluate the effects of low-dose endurance training on autonomic HR control. We assessed the HRV of 11 untrained male subjects [36.8 (7.2) years] at rest and during an incremental maximal aerobic exercise test prior to a 7-week preparatory period and prior to and following a 14-week low-dose endurance training period, including low to high intensity exercise twice a week. High frequency power (HF, 0.15-2 Hz) and low frequency power (LF, 0.04-0.15 Hz) were computed by short-time Fourier transform (STFT) that can be applied to non steady-state HR settings (e.g. Martinmäki et al. 2006). Venous blood noradrenaline (NADR) and adrenaline (ADR) concentrations were determined as blunt estimates of sympathetic nervous system activity at rest.

The results showed that the preparatory period induced no change in either aerobic power or autonomic HR control. The low-dose endurance training period increased peak aerobic power by 12% (p < 0.01) and resulted in lower HR (p < 0.01) and higher HFP (p < 0.05) and LFP (p < 0.01) at the same absolute exercise intensity levels, but not at rest. Despite no change in resting HR, NADR at rest was lower after the endurance training period. There was no difference in the pre- and post-training ADR values.

In conclusion, the present low-dose endurance training period that slightly improved cardiovascular fitness was sufficient to induce enhanced vagal control during exercise, but insufficient to alter autonomic HR control at rest. More frequent and/or intense training would most likely have been needed to induce changes in resting autonomic HR control in these healthy untrained subjects.

**THE ROLE OF SPIROEROGYMETRY IN SWIMMING FOR THE ASSESSMENT OF SWIM ECONOMY**

Reer, R., Ziegler, M., Braumann, K.  
University of Hamburg, Germany

Spiroergometry in the swim flume as an online method in combination with metabolic and cardiocirculatory parameters facilitates the simultaneous, reciprocally influencing differentiation between physiological (metabolic-cardiocirculatory) and technical-coordinative performance within the framework of performance diagnosis and training control. Results of a study with 36 male swimmers (age: 26.6+/-4.9 years; years of practice: 13.9+/-5.2 years) showed that in lower exercise intensities (0.90-1.10 m/s) endurance swimmers had lower and in higher exercise intensities (1.15-1.40 m/s) endurance swimmers had higher (on average by approx. 9%) VO2 values compared to sprint swimmers (sp), who carried out an standardized stepwise spirometry in the swim flume (initial velocity: 0.90 m/s; increase of 0.05 m/s every 3 min, break of 1 min after each exercise step) showed that in lower exercise intensities (0.90-1.10 m/s) and in higher intensities (1.15-1.40 m/s) sp had higher (on average by approx. 9%) VO2 values compared to sp. dVO2/dv was lower for sp at higher exercise intensities. Stroke frequencies, lactate values and heart rates were on average higher for sp on equal exercise levels, for lower and higher exercise intensities.

In another study, 32 swimmers (age: 17.9 +/- 4.0 yrs.) performed a standardized stepwise test in the swim flume (first step: 1.10 m/s, increase: 0.09 m/s every 3 minutes, break: 1 minute between each step) with and without a mask. While performing the test with a mask, the spirometric data were registered in an online manner. During the test without a mask, the mask was put on immediately after the end of each exercise step and the spirometric data were registered during the one-minute break (rebreathing method). With reference to the data from extrapolation applying the exponential regression equation y=ae-bx, it could be demonstrated that the test results with and without a mask did not show any substantial differences (1.10 m/s: 2350+/-397 ml vs. 2183+/-598 ml; 1.19 m/s: 2616+/-441 ml vs. 2557+/-616 ml; 1.28 m/s: 2924+/-483 ml vs. 2810+/-470 ml; 1.37 m/s: 3247+/-549 ml vs. 3195+/-606 ml; 1.46 m/s: 3620+/-533 ml vs. 3779+/-700 ml). It can be concluded that spiroergometry in swimming may play an important additional tool in the field of performance diagnosis and training control as well as talent search. Due to the fact that spiroergometry monitors alterations in swimming technique by registration of changes in oxygen consumption, spiroergometry may be suitable to gain more knowledge of a swimmer’s economic and technical capabilities. The present data indicate that the rebreathing method may be suitable for employment in the pool. Therefore, the rebreathing method could serve as a link for interpretation of spirometric data ascertained during the afterload phase in the pool and those registered online in the swim flume.
INTRODUCTION: We defined that the latent time of H wave of medial gastrocnemius (MG) significantly shortened after arm crank exercise which intensity was 60% peak oxygen uptake. And we clarified that the latent time of H wave returned to the pre exercise level with recovery examination. Human histochemical studies have shown that muscle fibers type differs between the MG and the soleus (SOL). There is an approximately equal distribution of slow type and fast type twitch fibers in the MG, while the SOL has about 70-90% slow and 10-30% fast twitch fibers. It is an unknown whether a similar result of H wave of MG is provided for the SOL. The purpose of this study was to investigate of the changes in latent time and amplitude of the H-reflex of soleus during recovery examination after arm crank exercise which intensity was 60% peak oxygen uptake. METHODS: Ten young males volunteered to participate in this study. After the H-reflex of SOL was elicited at time of rest, subjects performed arm crank exercise which intensity was 60% peak oxygen uptake for 10 minutes. When the exercise was completed, subjects were kept lying in the prone position, and H-reflex was measured immediately after exercise and recovery examination. The H-reflex of SOL was evoked by the electrical stimulation of the tibialis nerve in the popliteal fossa continuously for 10-15 times in all of one per four seconds interval. Analysis of the H-reflex signal showed an average 4-8 times wave patterns, the amplitude of the H wave was maintained the same. We compared relatively evaluated latent time by the use of the value that deducted the latent time of positive peak of M wave to the latent time of positive peak of H wave. The analysis of cardiac autonomic nervous system activity examine the R-R interval data for 30 seconds, which was calculated by the MemCalc methodology before each H-reflex. log HF was an index of cardiac parasympathetic nervous system activity. RESULTS and DISCUSSION: The latent time of H wave of immediately post exercise was -0.18±0.22 ms and significantly shorter than that of H wave of the pre exercise (P<0.05). The latent time of H wave gradually returned to the pre exercise with the recovery examination (ANOVA: P<0.05). The amplitude of H-reflex significantly inhibited in 3 of 10 subjects (P<0.05) and exited in 3 of 10 subjects (P<0.05) after arm crank exercise. It is considered that the spinal interneuron had occurred inhibition and excitation in immediately post exercise. The log HF of immediately post exercise was significantly inhibited as compared to at rest (P<0.05). The log HF also returned to a rest value with progression of recovery time (ANOVA: P<0.05). Those data suggests that autonomic nervous system activity has a meaningful influence on the threshold of motoneuron of the spinal cord in SOL. The present study show that SOL receives same results of H wave of MG after arm crank exercise which intensity was 60% peak oxygen uptake.

DIFFERENT RESISTANCE TRAINING PROTOCOLS INFLUENCE BASAL METABOLIC RATE AND RESPIRATORY RATIO IN NONDIETING INDIVIDUALS

Paoli, A., Marcolin, G., Ippolito, D., Neri, M., Bianco, A., Pacelli, F.

University of Padova, Italy

Even if exercise is considered fundamental for weight control, energy consumption during exercise may be less important than increase of energy expenditure after physical activity known as EPOC (Excess Post Exercise Oxygen Consumption) (1,2). Data of previous studies showed that EPOC is influenced more by exercise intensity than duration (3), but there are few data about effects of different kinds of resistance training on post exercise oxygen consumption. We tested the acute effects of a traditional weight training (TT) versus Rest Pause Training technique (RP) on energy expenditure, respiratory ratio, heart rate and lactate, immediately and 22 hours after 1 bout of exercise. TT was based on 4 sets of 12 repetitions with 2 minutes rest while RP was based on 6 Maximal Repetition, 20 sec recovery, 1 set to failure, 20 sec recovery, another set to failure, all this protocol was repeated twice with 2'30" of rest. We measured Respiratory Ratio (RR) and Rest Energy Expenditure (REE) of 8 resistance-trained males between 7 and 8 AM after night fasting. The week before testing athletes avoid training to limit disturbing factors. Athletes performed TT for quadriceps and latissimus dorsi (leg press 4 sets of 12 reps, pulley 3 sets of 12 reps, lat pulldown 3 sets of 12 reps with 2 minutes of rest between sets) and after a week, in the same conditions, subjects performed a RP session for legs and latissimus dorsi of same exercises. Student t-test showed significant differences for Lactate, VO2, RR and REE values. More specifically Lactate was higher after RP session than TT session (10.5 mmol/l RP versus 4.4 mmol/l TT); VO2 was higher 5’ after the end of training in RP session (9 102/min RP versus 7 102/min TT); heart rate was higher during RP than TT (115 bpm RP versus 115 bpm TT). After 22 hours post training REE was higher in the RP session than TT (1998 Kcal/die RP versus 1905 Kcal/die TT) while RR was lower (0.81 RP versus 0.87 TT). Our data suggest that high intensity resistance training technique as Rest Pause may increase REE in the 24th post exercise and reduce RR improving fat consumption after exercise.

FUNCTIONAL AND PROTEOMIC ANALYSIS OF HUMAN SKELETAL MUSCLE FOLLOWING NEUROMUSCULAR ELECTRICAL STIMULATION

D’Antona, G., Gondin, J., Brocca, L., Caliaro, F., Bellinzona, E., Maccatrazzo, L., Pellegrino, M.A., Bottinelli, R.

University of Pavia, Italy

Transcutaneous neuromuscular electrical stimulation (NMES) exerts significant effects on the skeletal muscle phenotype and function through increase of muscle mass, force and exercise capacity. As a consequence, NMES has been used as a tool for muscle strength training in athletes, in addition to a conventional conditioning routine, and in subjects variably enrolled in rehabilitation. The major advantage of NMES over voluntary training is the lower risk of traumatic lesions and falls in subjects with high degree of sarcopenia and the possibility of a very standardized training. Whereas the impact of NMES on skeletal muscle mass and function has been described in detail, no information are available on the molecular mechanisms underlying such adaptations. In this study, ten, young (18-35 years of age), healthy, male subjects were subjected to 24, 18-min sessions of isometric (bilateral) NMES of the quadriceps muscle over a period of 8 weeks with 3 sessions per week. Needles biopsies were taken from the vastus lateralis muscles pre- and post-training. Maximum voluntary contraction (MVC) and neural activation were found to be significantly higher post-training (+20% and +9% respectively). MHC isoform distribution showed a significant shift from MHC-2X towards MHC-2A and MHC-1, i.e. a fast to slow transition. Real-time PCR analysis of changes in MHC expression showed the same pattern. Interestingly, α-cardiac, embirional and perinatal MyHC isoforms, considered as transitional isoforms, were expressed at the levels of mRNA but not at the level of protein. Fluorescently stained proteomic maps showing ~600 spots were obtained pre- and post-training and differentially expressed proteins were identified and subdivided in different categories.

MUSCLE SWELLING AND ISCHEMIA-REPERFUSION CONDITION IN RESPONSE TO WALK EXERCISE WITH RESTRICTED LEG BLOOD FLOW

Fujita, S., Kimura, N., Brechue, W.F., Sato, Y., Abe, T.

University of Tokyo, Japan

INTRODUCTION

Studies have consistently shown that exercise intensity of >60% 1-RM is required to induce skeletal muscle hypertrophy. However, we have recently shown that chronic walk training combined with blood flow restriction of exercising limbs increases thigh muscle size and strength (1). Although we observed a significant growth hormone (GH) response after a bout of walk exercise with blood flow restriction (WBFR), it is not clear whether muscle hypertrophy can be explained solely by an anabolic hormone response. Recently ischemia-reperfusion condition and cell swelling, both of which may occur with WBFR, have been suggested to stimulate cell growth. Therefore, the purpose of the current study was to examine acute changes in leg muscle oxygenation, hormonal responses and muscle swelling after an acute bout of WBFR to further delineate the possible mechanisms of WBFR induced muscle hypertrophy.

METHODS

Ten young men performed treadmill walk at 50 m/min for five 2-min sets, with a 1-min rest between sets with blood flow restriction (WBFR) and without flow restriction (CTRL). Blood flow restriction was applied by placing an elastic cuff around the most proximal portion of each leg and inflating the cuffs to 200mmHg. A near-infrared spectroscopy was used to measure the muscle tissue oxygenation (MO2) and without flow restriction (CTRL). Blood flow restriction was applied by placing an elastic cuff around the most proximal portion of each leg and inflating the cuffs to 200mmHg. A near-infrared spectroscopy was used to measure the muscle tissue oxygenation (MO2)

RESULTS

Hematocrit (10%), albumin (14%), and MB-CSA (7%) of thigh increased significantly immediately after exercise in WBFR as compared to baseline (P<0.05), but not in CTRL, suggesting a water shift and muscle swelling with WBFR. Serum GH (79%) and free-testosterone (20%) increased significantly in WBFR from baseline (P<0.05), but not in CTRL. Due to venous blood pooling with flow restriction, BV was significantly higher in WBFR than in CTRL during exercise (P<0.05). Before start of walking, MO2 decreased in response to blood flow restriction (P<0.05). MO2 was significantly lower during exercise (16%) and stayed significantly lower during rest periods (19%) in WBFR as compared to CTRL (P<0.05), showing no indication of ischemia-reperfusion during exercise-rest interval.

CONCLUSIONS

Current study supports a previous finding that an acute bout of WBFR increases anabolic hormone concentrations. Furthermore, acute increase in mid-thigh MB-CSA, suggestive of muscle cell swelling, may trigger muscle anabolic and/or anti-catabolic signaling. On the contrary, we did not observe a significant ischemia-reperfusion condition during WBFR. Further studies are necessary to clarify the roles of anabolic hormones and muscle swelling in muscle hypertrophy associated with walk training with blood flow restriction.

THE MUSCLE LENGTH DEPENDENCY OF THE MAXIMAL RATE OF ISOMETRIC FORCE DEVELOPMENT

De Haan, A., Buse, T., De Ruiter, C.

VU University Amsterdam, Netherlands

During many movements in daily life and sports, such as cycling, running, jumping and kicking, time for skeletal muscles to build up force is limited and consequently rapid force development is needed (De Ruiter et al. 2007). In the present study it was investigated how the maximal rate of isometric force development (MRFD) depends on muscle length. Depending on the time available for muscle activation, it was expected that the length dependency of MRFD would be different from that of maximal isometric force (Fmax), which force level is reached much later during a contraction. Based on studies on shortening contractions, it was specifically hypothesized that MRFD would be obtained at a length below optimum length for maximal isometric force production (Lo).

In situ rat medial gastrocnemius muscles (muscle length: ~35mm; fibre length ~14mm) with intact blood flow were maximally activated at a physiological temperature (35 °C). It is known that relatively high stimulation frequencies are needed for obtaining MRFD at different muscle lengths (De Haan et al. 2003). In this manner the present experiments mimicked maximal ‘explosive’ in vivo muscle contractions during which all motor units are recruited instantaneously and may fire at very high rates. MRFD and force time integral (FTI), reflecting the entire time history of activation, were calculated for different times (10-50 ms) of activation.
The highest absolute MRFD was obtained 1.94±0.42 mm below (p<0.05) Lo. When expressed relative to Fmax obtained at each individual length the optimum of MRFD was found at Lo-4.4 mm. For FT100ms and FT200ms, optimum length was obtained ~2 mm respectively ~1 mm above (p<0.05) Lo, whereas the optima for FT10ms, FT140ms and FT150ms were ~1mm below (p<0.05) Lo. In addition, at low lengths (<Lo-4mm) and for all activation times FTIs were relatively more decreased than Fmax.

It is concluded that length dependency of force output during rapid force development differed from that of maximal isometric force, specifically maximal rate of isometric force development was seen at a muscle length ~2 mm below the optimum muscle length for maximal force production.

COMPARISON BETWEEN ELECTRICALLY EVOKED AND VOLUNTARY ISOMETRIC CONTRACTIONS OF THE ELBOW FLEXOR MUSCLES FOR CENTRAL AND PERIPHERAL FATIGUE

Jubeau, M., Muthalib, M., Millet, G., Maffiuletti, N., Nosaka, K.
School of Exercise, Biomedical and Health Sciences, Australia

Muscle fatigue is represented by a reduction in maximal voluntary contraction force (MVC) resulting from central and peripheral factors. It has been reported that muscle fatigue is greater after repetitive contractions evoked by electrical muscle stimulation (EMS) than voluntary contractions (VOL) at the same force output. However, it is not known if the mechanisms underlying the decrease in MVC are the same between EMS and VOL for a given MVC loss. It is possible that the contribution of central and peripheral fatigue on a reduction in MVC is different between EMS and VOL. This study tested the hypothesis that EMS would induce greater peripheral fatigue than VOL, when the magnitude of decrease in MVC of the elbow flexor muscles was matched between the two

The sample consisted of 619 female sport and PE students who were enrolled in three universities in the Czech Republic (n = 214), five universities and colleges in Norway (n = 193). The method of data gathering was the use of a questionnaire. Sexual harassment was measured through three questions based on a former study by Fastin and Sundgot-Borgen (2000). The experiences of authoritarian coaching behavior were measured through four questions about different types of authoritarian behavior. These four questions were answered only by the students who had been trained by both male and female coaches (n=399).

The findings will be discussed in relation to the unbalanced power distribution that often exists between a female athlete and a coach. The findings will also be discussed in relation to implications for coaching education.

"PROMOTING GIRLS’ SPORTS PARTICIPATION" - A QUESTION OF POWER AND NORMALISATION

Svender, J.
The Swedish School of Sport and Health Sciences, Sweden

Sport is an essential identity-producing arena and gender is a crucial part of the identities shaped and formed there. Previous research claims that the relationship between women and sport appears to be more problematic than that between men and sport, since sport is still discursively positioned as a masculine practice.

In Sweden, being a member of the sports movement is almost as common for girls as for boys. More than two out of every three boys and every other girl between the ages of 7 and 15 is a member of a sport club. The sports movement is considered to be a significant institution for socialisation - not the least gender construction.

Regarding gender as something that is produced and enacted through discourses, prompts an investigation into the discourses that form, and are formed by, the practice of sport. Inspired by feminist Foucauldian theory, the aim of the research is to analyse the discursive construction of "girls" in a large-scale government initiated sports project. Local sport clubs were in this context encouraged to work with projects that "promoted girls’ sports participation", for which they could apply money. Project applications written by sport clubs in three traditional male-dominated sports constitute the empirical material of the study. The study’s central questions, as well as the analytical ones, are: what does "promoting girls’ sports participation" mean, what is to be done and why? How are girls portrayed and what kinds of girls are targeted in the projects?

The analysis shows that girls and their participation in sport are portrayed in a rather homogenous way: girls are something “special”, and that so far their participation in these male dominated sports has been limited. This seems to motivate a separation of girls and their sports from “ordinary” activities, which implicitly means activities for boys.

Using Foucault’s concept of normalisation, distinguishing girls by accentuating their specialty make sense. Forming categories and ascribing them certain characters, interests and competences, in the way it is done in sports projects, makes these projects - and the sport itself - possible and meaningful. But in practice, this normalisation could be a way of governing and disciplining individuals in certain directions, i.e. a form of modern power, in Foucault’s words. One consequence of normalisation is that projects aiming at “promoting girls’ sports participation” target certain girls and the resulting category of girls is attributed certain features. The group of girls is thus stereotyped and homogenised, something that limits the possibility of alternative and flexible identities and makes other types of girls invisible. From a feminist point of view, these are crucial issues.

ELITE ATHLETES’ PERSPECTIVES ON PROVIDING WHEREABOUTS INFORMATION: A SURVEY OF ATHLETES IN THE NORWEGIAN REGISTERED TESTING POOL

Hanstad, D.
Norwegian School of Sport Sciences, Norway

Aim: According to current anti-doping regulations, all elite athletes have to provide information about their whereabouts to the relevant anti-doping organisation(s). This system was introduced in 2003 to protect ‘clean’ athletes and to be able to carry out effective out-of-competition testing without advanced notice. Since then the World Anti-Doping Agency (WADA), sport federations and anti-doping organisations have discussed the operation of the system while athletes have been only minimally involved. This is an important omission since the co-operation and compliance of athletes may be important, at least in part, in determining the effectiveness of the system. This paper fills this gap by reporting on the perspectives of a sample of elite athletes in the Norwegian registered testing pool on anti-doping work in general and the whereabouts system in particular.

Method: A cross sectional survey of all the athletes in the Norwegian registered testing pool (n = 236, response rate = 80.8%) was carried out. A structured questionnaire was used to explore elite athletes’ views on the whereabouts systems.

Results: 43 % of the athletes agreed that the whereabouts information system made a contribution to a cleaner sport. However, 19.1 % of the athletes did not trust the technical part of the system; 62.2 % disagreed with the rule that three warnings for not providing whereabouts information leads to a doping sanction after; and 56.6 % of the athletes thought that the system was unfair because of international variations in the system.

Discussion: This study is the first to reveal some of the views of elite athletes in the Norwegian testing pool on anti-doping work and the whereabouts system. An important finding is that the whereabouts information system had, despite all good intentions, outcomes other than those planned and intended by anti-doping organizations. One consequence of this is that this has lead to a negative attitude towards anti doping work among some athletes. Thus athletes’ views might fruitfully be integrated with other perspectives of WADA’s policy and procedures, when anti doping work is developed further.

TOP-LEVEL FOOTBALL COACHES’ PRACTICAL SENSE OF TALENT

Christensen, M.
University of Southern Denmark, Denmark

Introduction: For many years, it has been the ambition of coaches and administrators of top-level athletes to be able to identify distinct characteristics in young athletes which enable them to become excellent and successful in their sport. However, before these feats of excellence are achieved, a complex process of identification, development and selection takes place. Therefore, it is a much-desired quality in top-level coaches to be able to identify “true” talent. This study explores the ways in which talent identification is carried out among top-level football coaches, and it aims to identify specific structures of expert knowledge related to talent identification. The underlying basis of the study is the assumption that “talent can only be talent and recognized as such where it is values” [1], and that talent identification in top-level football is a question of the coaches’ trained eye [2] and tacit knowledge [3]. In other words, the coaches’ practical sense [4] of talent apparently plays as central role in talent identification.
The theoretical foundation of the analysis is Pierre Bourdieu’s theory of practice and the concept of practical sense, i.e. the incorporated feel for the game. From this point of view, the study explores eight Danish National Youth Team football coaches’ expert knowledge and ways of identifying talents. The data compile from biographical, in-depth interviews [5] with the coaches. The in-depth interviews are conducted and analyzed using meaning condensation and meaning categorization.

Results:
The results are grouped in two themes characterizing core elements of the coaches’ practical sense: 1) visual experience and pattern recognition as the basis of the coaches’ expertise, and 2) recognition of individual paths and personal styles among the coaches. Furthermore, an agent based model of top-level coaches’ classificatory schemes in connection with talent identification is generated.

Conclusion:
The study supports the theory that talent identification in top-level soccer is strongly connected to the coach’s practical sense. The study points at the importance of being aware of the person “behind” the coach, given that his practical sense will be the main identifier of future talents.

‘FROM TRACKSUITS TO SUITS’: A FIGURATIONAL ANALYSIS OF ORGANIZATIONAL CHANGE IN SPORTS DEVELOPMENT IN ENGLAND
Smith, A., Bloyce, D., Mead, R., Morris, J.
University of Chester, United Kingdom

Drawing on aspects of figurational sociology, which has grown out of the work of Norbert Elias, in this article we seek to examine: (i) the reality of ‘doing sports development’ within a period of rapidly changing social and political policy climate from the perspective of sports development officers (SDOs) themselves, and (ii) the ways and extent to which SDOs managed their experiences of organizational change. The study was based on semi-structured interviews conducted with 16 SDOs in the west-midlands and north-west of England. The main themes that emerged from the interviews included SDOs’ perceptions and experiences of organizational change, their preferred views of sports development, and their experiences of sports development in practice. It was also clear from the SDOs comments that the kinds of organizational change that they experienced was strongly associated with a perceived increasing bureaucracy of their

RESULTS:
The results are grouped in two themes characterizing core elements of the coaches’ practical sense: 1) visual experience and pattern recognition as the basis of the coaches’ expertise, and 2) recognition of individual paths and personal styles among the coaches. Furthermore, an agent based model of top-level coaches’ classificatory schemes in connection with talent identification is generated.

CONCLUSION:
The study supports the theory that talent identification in top-level soccer is strongly connected to the coach’s practical sense. The study points at the importance of being aware of the person “behind” the coach, given that his practical sense will be the main identifier of future talents.

CONSUMPTION FOR ANOTHER PEOPLE: A STUDY ON SYMBOLIC CONSUMPTION HABITS OF TURKISH WOMEN IN LEISURE TIME
Sabirli, T., Argan, M., Sevil, T., Aydn Sönmez, G.
Anadolu University, Turkey

Invitation day is a leisure activity that Turkish women in different ages get together and make some kinds of activities. Women, participating to invitation days in Turkey purchase symbolic consumptions for preparation before invitation days. The aim of the study is to determine the priorities of Turkish women as a symbolic consumption for the invitation day. A questionnaire was used in the study to collect the data. The questionnaire consisted of three parts. First part of the questionnaire is to determine the equipments for the invitation day and consisted of 9 items. Second part is to determine the decorative modification for the invitation day and consisted of 7 items. 5-likert scale was used to evaluate these items. Second part of the questionnaire is consisted of demographic factors and participation characteristics of the women. Questionnaire was applied to a total of 379 women, participating to “days” as a leisure activity in different levels.

Methods:
The theoretical foundation of the analysis is Pierre Bourdieu’s theory of practice and the concept of practical sense, i.e. the incorporated feel for the game. Male subjects (N=57, 19.7 ± 0.3 yrs.) were measured by a treadmill test until exhaustion to evaluate VO2\(_{\text{max}}\) (ml/min/kg) in the beginning of BT (baseline). Serum samples for testosterone (T) and cortisol (C) were collected between 6:30-7:30 am (basal) and before and after the 45-min submaximal marching test (EX) of 70% of VO2\(_{\text{max}}\) at baseline, in the middle (wk4) and at week 7 (wk7) of BT. Body mass (BM), fat free mass (FFM) and fat mass (FM) were measured by bioimpedance (InBody 720). The symptoms of overloading was assessed by weekly questionnaires. Totally 33 subjects were healthy on the test days and were able to perform all three EX. Basal T did not change throughout the whole BT, while basal C decreased from wk4 to wk7 (p<0.001). EX induced an increase in T at every time point (p<0.05 - 0.001), but C increased due to the EX only at wk4 (p<0.01). From baseline to wk7 FM increased (p<0.05), whereas BM and FM decreased (p<0.001). The change in FM from baseline to 7 wk was negatively related to baseline basal T (r=-0.55, p<0.001). Subjects who felt themselves overloaded at wk6 and wk7 had higher (p<0.05) basal C both at baseline and at wk4 compared with their not overloaded counterparts. Furthermore, symptoms of overloading at wk4 were positively related to baseline BM (r=0.38, p<0.05) and negatively to baseline VO2\(_{\text{max}}\) (r=-0.37, p<0.05), and symptoms of overloading at wk6 were positively related to change in basal C from wk4 to wk7 (r=0.41, p<0.05). From wk4 to wk7 the change in T was positively related to the change in FFM (r=0.49, p<0.01). Those 39% of the subjects who showed decreases in T and FM from wk4 to wk7 had no increase in C during EX at baseline, which was observed in the other subjects (-11% vs. 16%, p<0.05). The present results indicate that the subjects who were more susceptible to overloading during a stressful military training period were fat and unfit as well as the subjects who had high basal serum C levels and weak exercise related increase in C when entering military service. In addition, the subjects whose basal serum C levels increased during the training period were more vulnerable for symptoms of overloading at the end of BT. The results showed that serum C could be a useful tool in monitoring the risk for overloading.

### DISCRIMINANT PHYSIOLOGICAL RESPONSES TO HIGH-INTENSITY INTERMITTENT EXERCISE BETWEEN PROFESSIONAL AND AMATEUR SOCCER PLAYERS

Rampinini, E., Sassi, A., Morelli, A., Menaspà, P., Carloomago, D., Azzalin, A., Couffs, A.
Sport Service MAPEI srl, Italy

Soccer is team sport that requires prolonged, high-intensity, intermittent exercise. During match play, players change activity every 5s and perform approximately 1300 different actions with 200 of these being completed at high-intensity. Additionally, decisive phases during a soccer match often require players to work at high-intensity, usually consisting of several repeated efforts. It seems logical that soccer players that cope better with high-intensity bouts of intermittent running would be suited to playing at higher levels. At present, however, it is unknown if players at higher levels are better able to cope with high-intensity intermittent exercise bouts. Therefore, the aim of this study was to compare performance and the physiological responses to specific high-intensity intermittent running tests in professional and amateur soccer players.

#### THE HEART RATE PERFORMANCE CURVE DURING INCREMENTAL CYCLE ERGOMETER EXERCISE IN HEALTHY YOUNG FEMALE SUBJECTS

KF-University Graz, Medical University Graz, University of Vienna, Austria

The deflection of the Heart Rate Performance Curve (HRPC) was shown to give the anaerobic threshold (CONconi et al. J. Appl Physiol. 52, 1982, 4, 869-873 although there has been a substantial debate on the validity of the concept (see review Bodner and Rhodes Sports Med 2000; 30: 31-46). This non-invasive determination of the anaerobic threshold relies on the existence of a clear deflection of the HRPC. Most recently we described the HRPC to be non-linear and not uniform in a great number of healthy male subjects (Hofmann et al. Med Sci Sports Exerc 1997, 29: 762-768). However, studies including female subjects are sparse.
Aim of the study was to describe the pattern of the HRPC in a homogenous group of healthy female subjects. Results from 235 female (F) sports students (age: 20.4 +/- 2.6 yrs; height: 166.9 +/- 8.6 cm; weight: 59.5 +/- 6.0 kg) were included in the study. All students performed a maximal incremental cycle Ergometer exercise starting at 20 W and increasing work load by 15 W.min-1 until subjective maximal effort. Tests were routine tests for medical check up at the start of the sports science study. Heart rate (Polar Electro, Finland), gas exchange variables (MetaMax I, Cortex Biophysik, Germany) were obtained at rest, throughout exercise and during recovery. Blood lactate concentration (Biosen S-line, EKF Diagnostik, Germany) was obtained from blood samples collected from ear lobe at rest, after each work load increase and during recovery. The first (LTP1) and the second (LTP2) lactate turn point were determined and used as reference regions for subsequent HR analysis. The HRPC was analysed using a computer supported approach. A second degree polynomial function was calculated between LTP1 and Pmax and the degree and the direction of the HRPC was quantified by factor kHR as described earlier (Hofmann et al. Med Sci Sports Exerc 1997; 29: 762-768).

Female subjects presented a similar pattern of the HRPC’s compared to the male counterparts. The number of regular HRPC’s was greater in number in F (88.9% vers. 85.9%) and the degree of the deflection was more distinct (kHR=0.499±0.226). The number of non-regular and inverted HRPC was less than half in the female subjects (3.0% vers. 7.9%) compared to the male subjects. Linear HR was found comparable to the male counterparts in 81% of cases. No significant difference was obtained for exercise performance variables (power output oxygen uptake), blood lactate concentration and HRRmax between groups of female subjects presenting a different HRPC pattern. However, HR and %HRmax at LTP2 was significantly different between groups and related to kHR (R=0.455, P<0.001).

Similar to age matched male subjects female subjects present a different distribution of kHR with a lower number of inverted HRPC, however, a similar number of subjects showed no deflection at all, questioning the concept of the HRPC method to determine the anaerobic threshold.

**DOES STRENGTH TRAINING-INDUCED FASCICLE LENGTHENING AFFECT CONTRACTILE RATE OF FORCE DEVELOPMENT IN THE HUMAN QUADRICEPS?**

Blazevich, A., Cannavan, D., Horne, S., Coleman, D., Aagaard, P.
Edith Cowan University, Australia

**Introduction**

A muscle's contractile rate of force development (RFD) depends greatly on its rate of activation, and can be improved by both fast and slow forms of strength training. However, an inverse relation between series compliance and RFD during contraction in single muscle fibres has been demonstrated (Falkner & Josephson, 2007). Given that longer fibres have greater series compliance, increases in fibre, or fascicle, length in vivo should negatively affect RFD. Such increases in fascicle length tend to occur with large range of motion strength training, creating a possible paradox for the use of strength training for RFD improvement. Shifts in the length-tension relation of a muscle are fibre/fascicle length dependent, so to investigate the paradox further we tested the hypothesis that strength training-induced shifts in the torque-angle relation (TAR) of the architecturally complex quadriceps muscle would be well related to changes in RFD.

**Methods**

In 21 previously untrained consenting men and women, RFD measured to 30, 50, 100 and 200 ms from the onset of a maximal isometric knee extension contraction, the rate of EMG rise (RER) and mean average EMG voltage (MAV; area under EMG curve) measured from the vastus lateralis (VL) fascicle length and shifts in the EMG-angle relation were examined alongside shifts in TAR. Repeated measures ANOVA (log-transformed) was used to examine training-dependent changes in the measured variables. Correlation analysis was used to examine relationships among the variables. Alpha level was set at 0.05. Testing procedures were approved by the Research Ethics Committee.

**Results**

The training was associated with significant increases in RFD, which were not different between the training groups. After 10 wk training, increases in RFD were strongly related to increases in RER and MAV (i.e. rates of muscle activation), but not shifts in the TAR. Nonetheless, early (5 wk) changes in RFD were negatively correlated with shifts in the TAR, which shifted towards longer muscle lengths. Shifts in TAR were associated with changes in VL fascicle length, whereas the EMG-angle relationship remained unchanged for all muscles.

**Conclusion**

Our data support the hypothesis that training-induced increases in fascicle length may have a negative impact on RFD, at least in the initial weeks of training. Although neuromuscular activity was initially enhanced in those who increased their RFD significantly, the impact was only fully realised after months of training when fascicle length adaptation is complete. These data highlight the importance of muscle architectural adaptations to rapid muscle force generation.

**THE INFLUENCE OF STRENGTH TRAINING VOLUME ON MUSCLE HYPERTROPHY**

Bubeck, D., Dallinger, B., Krause, K., Alt, W.
University of Stuttgart, Germany

Muscle hypertrophy training plays an important role for the periodization in many sport disciplines. The manner and the magnitude of hypertrophy effects are determined by the configuration of the training program. Intensity and volume of the training can be detected as important prerequisites for strength and muscle mass. A great amount of studies dealing with the optimal number of sets in strength training exists but no clear answer to the question of the optimum of sets during hypertrophy training can be given. This is due to different methodical weak points of these studies.

In order to get more informations about the optimum of sets in hypertrophy strength training of well trained athletes, the purpose of this study was to clarify the effects of different training volumes to the morphological and neuromuscular adaptation processes. 35 athletes with a strong background in intensive strength training were randomized divided in two training groups and a control group. Due to injuries and inconsistent realization of the training program only 24 athletes were taken into account presenting the results of the study. Two times a week the training groups performed a special designed training program (full body, 12 different exercises) with strategies to enhance the training intensity immediately 20% training weight reduction after repetition failure - again repetitions until failure. Intensity was 70-80% of MVC within 8-10 repetitions. Differences were only made in the training volume: High volume training (HVT) means 3 sets, low volume training (LVT) only 1 set per muscle group. Training duration was 8 weeks followed by a crossing over after one week of regeneration. Each training set was individually documented by training weight and performed number of reps.
Before, after 8 weeks and after the total training process (16 weeks) CSA and MVC of the m. quadriceps femoris was measured with MRT and isometric strength test. EMG data was recorded during the MVC test in order to detect neurophysiological changes. Additionally body composition and girth were measured.

After the different training phases no changes in CSA of the m. quadriceps femoris were observable in the MRT data. MVC values of isometric knee extension only showed sig. changes in the HVT_LVT group. No sig. changes in IEMG values during the total training process were observable.

Due to the fact that both training groups showed nearly the same amount of non-sig. changes in CSA and MVC it could be stated that within strength trained athletes the training volume is not the hypertrophy determining factor. Additionally it could be assumed that a lower amount of training volume for 2/week is able to maintain strength qualities also in highly strength trained athletes. So the cause for muscular hypertrophy must thereby be found in the intensity of the training stimulus.

ISOKINETIC STRENGTH RATIOS AND RANGE OF MOTION OF THE SHOULDER ROTATOR MUSCLES IN PORTUGUESE MALE JUNIOR (16-18) TENNIS PLAYERS

Nunes, A., Pezarat-Correia, P., Carita, I., Valamatos, M.
Faculty of Human Kinetics, Technical University of Lisbon, Portugal

INTRODUCTION

The goal of the present work was to characterize the shoulder muscle balance between the internal and external rotator muscles in Portuguese male tennis players (ages 16-18).

METHODS

32 young male tennis players classified in the first 50 of the junior (aged 16-18) Portuguese ranking of 2005 participated in the study. Concentric strength measures of ER and IR for both arms were performed on a Biodex Medical System isokinetic dynamometer at 90 and 180º/s. During testing the subjects were seated, the arm was positioned in 45º abduction in the scapular plane and elbow flexed to 90º. Based on a reference position (0º) with the forearm horizontal, rotation movements were performed between 15º of IR and 60º of ER, with a 75º of range motion. The ROM of the ER and IR movements of both shoulders was passively measured by goniometry with the subject lying supine on a table with the arm abducted 90º and the elbow flexed 90º. Mean values and SD were calculated for the isokinetic force and amplitude parameters. To analyse dominant (D) to non-dominant (ND) arms differences the paired samples T test was used (p<0.05). Correlation coefficients were measured to determine relationships between variables.

RESULTS AND DISCUSSION

With the exception of Peak Torque/Body Weight of ER, all the isokinetic parameters of ER and IR force were significantly (p<0.05) higher in the D arm at both velocities. The mean values of ER:IR ratio observed in the D arm (0.61 ± 0.10 at 90º s-1, 0.63 ± 0.09 at 180º s-1) were lower than in the ND arm (0.67 ± 0.13 at 90º s-1, 0.67 ± 0.11 at 180º s-1) but significant differences were only found at 90º s-1 (p<0.014). With respect to shoulder flexibility, there was significant (p<0.001) less ROM of IR and significant (p<0.001) higher ROM of ER in the D shoulder. The total rotation arc was significantly (p<0.05) reduced in the D shoulder (158.6 ± 19.3º) when compared with the nondominant shoulder (166.2 ± 23.7º), meaning that the loss of IR in the dominant side exceeds the gain in the ER amplitude. Negative significant correlations were found between age and ROM of D (r = -0.458; p<0.01) and ND arm IR (r = -0.510; p=0.01). A positive significant correlation (p<0.001) was found in the ROM between both shoulders in both movements, IR (r = 0.787) and ER (r = 0.679). We also found a positive correlation (p<0.05) between shoulders in both velocities and movements for all the isokinetic force parameters (PT, PT/BW, TW, API, indicating that, independently of the specific shoulder adaptations produced by tennis training, the shoulder flexibility and strength depend on the individual characteristics.

CONCLUSIONS

Our results with Portuguese junior tennis players confirm adaptive changes in the dominant arm of tennis players (16-18): deficit in external rotator strength combined with loss in stretching capacity. Those adaptations may predispose the tennis player to shoulder instability and injury.

IS-BN09 Limitations and advantages of musculoskeletal modelling

CROSS-BRIDGE MEMORY AND HISTORY-DEPENDENT PASSIVE PROPERTIES

Herzog, W.
The University of Calgary, Canada

Introduction: The cross-bridge theory of muscle contraction is defined by a series of mechanical and biochemical states that are connected by thermodynamically consistent rate constants which in turn are exclusively functions of Huxley’s (1) so-called x-distance, the distance from the cross-bridge equilibrium position to the nearest actin attachment site. From this theory, it immediately follows that the steady-state force for a given contractile condition must always be the same and independent of the contractile history. However, it has been known for a long time that this is not the case. Abbott and Aubert (2) demonstrated more than half a century ago that steady-state isometric forces following muscle stretch are greater and following shortening are smaller than the corresponding isometric reference force.

For the past 30 years, these observations have been explained with the development of structural non-uniformities on the sarcomere level, but recent evidence has all but dismissed this idea. We asked the question if force enhancement following stretch and force depression following shortening might be explained by a memory in the actin-cross-bridge interactions or a history-dependent passive element.

Methods: We determined history-dependent properties in skeletal muscle for human skeletal muscles, isolated animal muscle preparations, single fibres, single myofibrils and sarcomeres isolated from rabbit psoas and in single actin-cross-bridge interactions using laser trapping (3).
LIMITATION AND ADVANTAGES OF HILL TYPE AND FINITE ELEMENT MUSCLE MODELING

Huijing, P.
Vrije Universiteit Amsterdam, Netherlands

The Hill-type model, involving the pooling of contractile properties into one contractile element (CE) and of all serial and elastic parallel elements of the muscle tendon complex, into one serial elastic component (SEC) and one parallel elastic component, has contributed to our understanding of elastic effects in human and animal movement. The strength of this type of model is of course also its weakest point: it’s relative simplicity. The contractile element acts as one giant sarcomere. This means that in the classical Hill model, no interaction with the environment, other than via myotendinous pathways can be studied. Therefore, distributions of sarcomere lengths (both parallel and serial) are excluded. Even in maximally dissected muscle (intact blood supply and innervation; with epimuscular myo-) can be modeled and major interaction with surrounding tissues is relatively easy to represent. Examples will be given of application of a finite element (FEM) model that also represents intracellular (muscle elements) and extracellular matrix elements. As the name indicates, finite element modeling (e.g. Yucsesoy et al., 2002, 2003, 2007) divides the muscle into a finite number of elements calculating mechanical equilibrium in nodes of each element. FEM assumes continuity, i.e. sarcomeres can not act totally independent of its surrounding sarcomeres within the same or other muscle fibers. Between nodes, stresses and strains are interpolated within the element. A major difficulty is. Penalty functions are used to impose the condition of constant volume for muscle fibers. A major drawback of FEM is a much more complex mathematical context and higher computer time. A major advantage is that actual geometry of muscle can be modeled and major interaction with surrounding tissues is relatively easy to represent. Examples will be given of application of a model that also represents intracellular (muscle elements) and extracellular matrix elements.

ASSESSMENT OF INDIVIDUAL PARAMETERS IN HUMAN MUSCLE MODELLING

Arampatzis, A., Albracht, K., Mademli, L.
German Sport University Cologne, Germany

Assuming homogenous muscle density, muscle volume is a determinant of muscle mass, a parameter, which is needed to gain insight into the specific muscle tension and to determine energy cost and muscle efficiency of certain contractions through modelling[2]. For in vivo measurement of muscle volume, magnetic resonance imaging (MRI) is considered to be the most useful non-invasive imaging device. Despite recent improvements in image processing, a muscle reconstruction by MRI is still laborious and not widely applicable. Therefore we investigate whether it is possible to assess the individual muscle volumes within the triceps surae muscle group (TS) by means of easily measurable parameters based on a theoretical consideration. Magnetic resonance images of the right calf of 13 male subjects were acquired and each muscle of the TS was reconstructed. Muscle length (lm), the maximum anatomical cross-sectional-area (ACSAmax) and muscle volume were obtained from the 3D-Models. In general, muscle volume can be expressed as a fraction of the product of maximum anatomical cross sectional area (ACSAmax) and muscle length (lm). The size of the fraction depends on muscle shape and its coefficient of variance among the examined population was considerable low (SO 6%, GM 4%, GL 7%) in the present study. The product of ACSAmax and lm was, therefore, suitable to assess muscle volume (RMS 4 to 7%). The non rigidity of tendon has a profound influence on the force-length-velocity relationship of the muscle (contractile element) and consequently on its force generating potential. The development of the ultrasound technique enabled the investigation of the mechanical properties of tendon from different muscle-tendon units in vivo in the last years. However, earlier in vitro studies have demonstrated that static and cyclic short term mechanical loading can affect tendon compliance[2]. Although numerous in vitro studies have demonstrated the acute effects of long-lasting static and cyclic mechanical loading on tendon compliance, there is little information about the in vivo effects of long-lasting submaximal and maximal mechanical loading on the compliance of tendon and aponeurosis. Therefore, in a series of experiments we examined the strain-force relationship of the gastrocnemius medialis and vastus lateralis tendon and aponeurosis of young and old adults before and after three fatigue protocols: a) a sustained submaximal isometric contraction, b) submaximal concentric isokinetic contractions until task failure and c) maximal isokinetic contractions until task failure. The results show that neither static nor cyclic long-lasting mechanical loading that produces strains of 2-6% has an acute effect on the in vivo strain-force relation of the tendon and aponeurosis at the lower extremities. Warm-up exercises precondition the tendons and minimize the possibility of an...
alteration in their mechanical properties. Muscle is unable to sustain the force for a sufficient duration during fatiguing contractions to induce an alteration in tendon properties.

IS-PM15 Gatorade Sport Science Institute: The challenges of exercising in the heat

EXERCISE, HEAT SHOCK PROTEINS, AND CYTOPROTECTION

Powers, S.
University of Florida, United States

Cellular adaptation to physiological disturbances is a fundamental requirement for cell survival. Although the molecular events involved in cellular adaptation to stress continue to be investigated, it is clear that the cell’s response to exercise-induced heat stress includes a highly ordered set of events that involve rapid changes in gene expression and the synthesis of several heat shock proteins (HSPs) that participate in the adaptation to stress. This lecture will be presented in a tutorial format and will provide an overview of the protective role that HSPs play in both cardiac and skeletal muscle fibers. First, a brief history and nomenclature of HSPs will be provided. This will be followed by a discussion of the molecular basis for exercise-induced HSP expression in muscle fibers. The lecture will conclude with a discussion of the protective effects of HSPs in muscle fibers during periods of cellular stress.

EXERCISE AND THERMOREGULATION: A MATTER OF TIME

Atkinson, G.
Liverpool John Moores University, United Kingdom

Knowledge about human thermoregulation is fundamental to both exercise physiology and chronobiology (the study of biological rhythms). Chronobiology can help us understand human thermoregulation during exercise in terms of the measurement of core body temperature, the underlying homeostatic mechanisms, as well as the impact of exercising at different times of day on health and performance. Depending, in part, on environmental (Cable et al., 2007) and seasonal (Atkinson and Drust, 2005) factors, core body temperature varies by about 0.4 degrees Celsius over a 24-h period, peaking between 18:00 and 21:00 h (Cable et al., 2007). The diurnal variation in core body temperature persists during and after exercise (Waterhouse et al., 2005), although the magnitude of variation depends on the measurement site of core body temperature (Gregson et al., 2008). Intestinal temperature, measured during exercise with an ingestible thermistor, shows a larger diurnal variation than rectal or oesophageal temperature, probably because of circadian variation in gut transit time. Such interactions between measurement site and time of day could have significant implications for research inferences about thermoregulation and for diagnosing heat injury in athletes. The origin of the circadian rhythm of core temperature is mainly due to circadian changes in the rate of loss of heat through the extremities, mediated by vasodilatation of the cutaneous vasculature (Aldemir et al., 2000). During the initial response to exercise, body temperature rises more quickly and thermoregulatory reflexes are recruited less rapidly in the morning compared to the evening hours (Waterhouse et al., 2007). Synchronisers of human circadian rhythms such as melatonin (Atkinson et al., 2005) and light (Atkinson et al., 2008) have also been found to influence thermoregulation during exercise, as has sleep deprivation (Winors et al., 1999). Such understanding of the chronobiology of thermoregulation may reduce potential hazards due to the time of day when exercise is performed and optimise coping strategies for optimal performance in the heat.

CARDIOVASCULAR LIMITATIONS TO EXERCISE IN THE HEAT

González-Alonso, J.
Brunel University, Uxbridge, United Kingdom

Exercise in the heat poses a severe stress on multiple regulatory systems that inexorably limit both the ability of bodily cells, organs and systems to maintain homeostasis and the capacity of the human body as a whole to perform exercise. While this notion is not new, the precise contribution of the circulatory system to fatigue, particularly the role of locomotor skeletal muscle perfusion and its influence on muscle metabolism, has remained largely elusive until recent years. This talk focuses on how the blunted O2 delivery resulting from restricted blood flow with heat stress and dehydration combined with hyperthermia contribute to the accelerated fatigue occurring during prolonged and high intensity exercise in the heat. Specifically, data will be presented demonstrating that fatigue during prolonged moderate and short maximal exercise is preceded by significant reductions in cardiac output and skeletal muscle and brain blood flow, which in turn lead to a significant drop in the provision of vital oxygen to the locomotive leg muscles and the brain. The diminished peripheral oxygen delivery is associated with a significant reduction in exercising muscle VO2, but does not compromise brain VO2 because of the concomitant larger increase in brain O2 extraction. Importantly, this phenomenon is not exclusive to exercise in the heat, as fatigue is also preceded by cardiovascular strain during maximal and supramaximal exercise in thermoneutral environments. Therefore, our findings points towards the failure of the heart to maintain cardiac output and oxygen delivery, particularly to the locomotor skeletal muscles, as a major limiting factor limiting prolonged and high intensity exercise performance in the heat.

FLEXIBILITY IS FITNESS RELATED TO ARTERIAL STIFFNESS
Yamamoto, K., Kawano, H., Gando, Y., Iemitsu, M., Murakami, H., Sanada, K., Tanimoto, M., Higuchi, M., Tabata, I., Miyachi, M.
Waseda University, Japan

PURPOSE: Fitness, especially cardiovascular endurance, has been identified as determinants of age-related arterial stiffening. Health-related components of fitness include cardiovascular endurance, muscular strength and endurance, and flexibility. Although the flexibility is one of the components of fitness, the relationship between flexibility and arterial stiffness remains unknown. Using the cross-sectional study design, we tested hypothesis that the flexibility associated with arterial stiffness independent of other components of fitness. METHODS: A total 314 adults, 20 to 39 years of age (young), 40 to 59 years of age (middle-aged) and 60 to 77 years of age (older), who were either poor-flexibility or high-flexibility, were studied. The flexibility was evaluated by sit-and-reach test. Cardiovascular endurance and muscular strength were measured by peak oxygen uptake and leg power, respectively. The arterial stiffness was assessed by brachial-ankle pulse wave velocity (baPWV). RESULTS: In young group, the sit-and-reach values of poor-flexibility and high-flexibility were 35.0 +/- 6.2 and 47.9 +/- 5.2 cm, respectively (P<0.001), those in middle-aged group were 32.1 +/- 5.3 and 45.9 +/- 4.9 cm, respectively (P<0.001), and those in older group were 27.1 +/- 6.5 and 42.2 +/- 5.0 cm, respectively (P<0.001) in each age group, age did not differ between poor-flexibility and high-flexibility groups. In older group, baPWV was higher in poor-flexibility than in high-flexibility peers (1542 +/- 245 vs 1361 +/- 202 cm/s, P<0.01). However, in young and middle-aged groups, there was no significant difference between two flexibility groups. In the pooled population, a univariate regression analysis indicated that baPWV correlated with sit-and-reach (r=0.34, P<0.0001), peak oxygen uptake (r=0.42, P<0.0001) and leg power (r=0.19, P<0.001). A stepwise regression analysis revealed that among components of fitness, sit-and-reach and peak oxygen uptake were independent correlates of baPWV. Leg power did not enter as significant predictors of baPWV. CONCLUSION: We concluded that (1) poor-flexibility was associated with the higher arterial stiffness in older group, (2) age-related arterial stiffening was greater in poor-flexibility than in high-flexibility, and (3) flexibility independently associated with arterial stiffness. These findings are consistent with the idea that flexibility is identified as determinants or predictors of age-related arterial stiffening independent of other components of fitness.

ADAPTABILITY OF ALPHA-ACTININ-3 IN SKELETAL MUSCLE
Ogura, Y., Naito, H., Katamoto, S.
Juntendo University, Japan

The alpha-actinins are an ancient family of actin-binding proteins. Mammalian tissues contain four alpha-actinin isoforms, including two skeletal muscle-specific isoforms: alpha-actinin-2 and alpha-actinin-3. The former is found in all skeletal muscle fibres, while alpha-actinin-3 is restricted to fast glycolytic skeletal muscle fibres. Therefore, it is reasonable to consider alpha-actinin-3 as being associated with fast fibre functions, which are responsible for rapid, intense muscle contractions. Recently, several studies have suggested the importance of alpha-actinin-3 in muscle function in humans based on the association of physical exercise performance with polymorphisms of the ACTN3 R577X gene, which encodes alpha-actinin-3. Thus, this protein seems to be one of the key determinants of skeletal muscle adaptability and diversity among individuals; however, the adaptive responses of alpha-actinin-3 to various physiological stimuli remain unclear. Therefore, we investigated the influences of skeletal muscle fibre type transformation on the alpha-actinin-3 expression levels in this study, ten female SD rats were assigned randomly to control (C, n = 5) or hindlimb-unloading (S, n = 5) groups. The S animals were tail-suspended for 30 days to prevent loading of their hindlimbs. After 30 days, the soleus muscles in both groups were sampled to determine the soleus wet weight of the S animals was significantly (P < 0.01) lower than that of the C animals. The %type II MyHC determined using SDS-PAGE, and the fast myosin expression level determined using Western blot analysis, were significantly higher in the S animals than in C animals (P < 0.01 for %type II MyHC, P < 0.01 for fast myosin level). Along with these increases in fast fibres, the alpha-actinin-3 expression level analyzed using Western blot was significantly (P < 0.01) and dramatically higher in S animals than in C animals. The alpha-actinin-3 increases concomitantly with the skeletal muscle fast myosin content in rat. Based on the expression pattern specifically localised in fast type fibres, our results indicate that the fast skeletal myosin content is one factor that determines alpha-actinin-3 adaptation.

NEW ASPECTS OF THE HORMONE AND CYTOKINE RESPONSE TO TRAINING
Steinacker, JM., Prokopchuk, O., Liu, Y.
University of Ulm, Germany

Exercise training is associated with peripheral-cellular and central-cerebral processes, hormonal-neuronal regulation and transmission mechanisms. During the acute training response, peripheral cellular mechanisms are mainly metabolostatic to achieve energy supply and involve associated cytokine and hormonal reactions. During prolonged training, glycogen deficiency occurs; this is associated with increased expression of local cytokines, and decreased insulin secretion and beta-adrenergic stimulation and lipolysis in adipose tissue which loses energy. This is indicated by decrease of adipocyte hormone leptin, which has inhibitory effects on excitatory hypothalamic neurons. Leptin, insulin, and cytokines such as interleukin 6 (IL-6) contribute to the metabolic error signal to the hypothalamus which result in decrease of hypothalamic release hormones and sympathoadrenergic stimulation. Thyroid stimulating hormone (TSH) is correlated to the metabolic hormones leptin and insulin, and may be used as indicator of metabolic control. Because the hypothalamus integrates various error signals (metabolic, hormonal, sensory afferents, and central stimuli), the pituitary’s releasing hormones represent the functional status of an athlete. Long-term overtraining will lead to downregulation of hypothalamic hormonal and sympathoadrenergic responses, catabolism, and fatigue. These changes contribute to myopathy with predominant expression of slow muscle fiber type and inadequacy in performance. Thyroid hormones are
closely involved in the training response and metabolic control. These alterations are influenced by exercise-induced hypercortisolism, and by decreased somatotropic hormones (e.g. IGF-II).

The hormonal and cytokine pattern of prolonged overtraining and performance incompetence syndrome are complex and can only be interpreted together with clinical findings and data on training and performance.

IS-SH10 Pain and injury in sport. Social and ethical perspectives

THE SOCIAL CONSTRUCTION OF CLINICAL DIAGNOSES OF SPORTS INJURIES
Malcolm, D.
Loughborough University, United Kingdom

This paper addresses clinical practice in sport medicine. Twinning notions of medical uncertainty with a figurational sociological approach, the paper draws on relevant literature in sport medicine journals and data derived from interviews with various personnel in English elite rugby union. The paper illustrates how uncertainty characterizes the medical understanding, clinical treatment, and patient experience of concussion. Clinicians consequently come to replace officially prescribed and medically-based diagnostic and treatment guidelines with understandings of concussion dominant in the sport subculture. The rejection of medical guidelines, however, threatens the traditional view of clinicians as experts and thus they invoke strategies which bolster their professional position. The paper advances our understanding by arguing that sport physicians’ negotiations with players and coaches not only structure the treatment of injury, but also the ways in which physicians come to think about, understand, and define clinical conditions.

THE BODY - AND THE UNMENTIONABLE EMOTIONS: A DANISH CASE STUDY ON THE BODY IN PHYSIOTHERAPY
Thing, L
University of Copenhagen, Denmark

The article highlights that emotions have an absent presence in physiotherapy. Research in the sociology of emotions emphasizes the need to see the individual as a whole and argues that emotions and bodyliness are overlooked aspects of human existence. The article introduces the concept of bodily emotion regimes to designate those social rules that govern emotions in a treatment situation. The present case study is an observational study of the rehabilitation of patients with sports-related injuries at a physiotherapy clinic. The study involves 17 women with (acl) knee injuries who were followed during rehabilitation. Concrete events during treatment, and quotations from qualitative interviews with patients undergoing treatment, are used to illustrate the lack of spoken reference to emotions. The taboo on emotions can be seen as a result of the treatment system’s neglect of the body as a living unity of physical, psychic and social dimensions. The neglect of emotions can be characterized as an unintended consequence of the fact that physiotherapy is anchored in medical science and in the positivist mode of measuring and weighing the body. On the other hand the phenomenon can also be explained in terms of the organization of work in the clinic, the way in which time is structured and the fact that treatment takes place in groups.

PREVENTING SUFFERING IN SPORT: HYPERTROPHIC CARDIOMYOPATHY AND THE ETHICS OF GENETIC SCREENING
Müller, A.
Maastricht University, Netherlands

Within the last years the development of genetic diagnoses advanced rapidly. The identification of disease related genes seems to be an effective preventive tool especially in the field of sport. But why is sport different form other areas? One answer is that the detection of genes which are associated with hypertrophic cardiomyopathy (HCM), for example, could prevent athletes suffering severe cardiac incidents or even from dying ‘on the pitch’ when participating in competitive (high performance) sports. Indeed, in the non-sport related context ‘genetic defects’ can be diagnosed as well, but often without a preventive or therapeutic perspective. However, the question at hand is how to interpret the test results? The Italian/ the European recommendations (non-genetic cardiol. screening), worked out by the sport cardiology study group might serve as a model for genetic testing (2, 3). The Italian pre-participation screening recommendations, however, cause some tensions (4). They potentially violate the athlete’s autonomous decision making capacities (even the athlete’s right of self-harm). Consequently, the implementation of a preventive genetic testing can not be decided without taking ethical aspects into consideration (5). On the one hand genetic screening and testing might prevent an athlete from dying. On the other hand a strict exclusion from competitive sports on that basis might be seen as paternalistic. If, however, athletes choose to be tested voluntarily the knowledge about their genetic makeup can be seen as a form of self-empowerment, i.e. to make their own choices (6).

JUMP CAPACITY IN RELATION TO PERFORMANCE OF TOP FEMALE ARTISTIC GYMNASTS

Grande, I., Figueroa, J., Hontoria, M., Bautista, A., San Martin, M., Hervás, M.

University Alfonso X El Sabio 1, Real Federación Española de Gimnasia 2, Spain

Jump capacity has been measured by different studies with female artistic gymnasts (1,2). Jumping height correlated significantly with the mark for floor and horse vaulting exercises (3). Purpose of this study was to determine the relation between muscle power evaluation with vertical jump tests and judges scores of the different Women Artistic Gymnastics apparatus. 16 gymnasts from Junior and Senior Spanish National Team participated for the study. Three measurements were carried out during the preparation period of the World Championship (Stuttgart'07). Jump capacity was measured with a force plate (Kistler Quattro Jump) at 500 Hz. Gymnasts executed Squat Jump (SJ) and Counter Movement Jump (CMJ) tests. Variables selected were height (m), Peak Force (N), Peak Velocity (m/s-1) and Peak Power (W/Kg) of highest jump execute at each test. Jump tests were carried out during the week before a competition or an official technical control. International judges evaluated all exercises. We selected Difficult Value (DV), Composition Value (CV) and Final Score (FS) from the four apparatus to correlate with jump evaluation data.

It was showed a significant correlation between SJ and CMJ Peak Power with the DV (SJ: r= 0.49, p<0.05, CMJ: r= 0.59, p<0.01) and FS (SJ: r= 0.49, p<0.05, CMJ: r= 0.58, p<0.01) of horse vaulting exercise. It revealed the importance of achieve a high muscle power of lower extremities to improve the performance of this exercise.

We also found significant relation between CMJ Peak and DV (r= 0.67, p<0.01) and CV (r= 0.63, p<0.01) at uneven bars exercise. The relation between CMJ and SJ Peak Force at balance beam was also significant. Although it's difficult to establish a relation between the uneven bars and balance beam performance and the jump evaluation results the analysis revealed that gymnasts who achieved high muscle power level had better scores.

At floor exercise we found significant relation between SJ Peak Power and DV (r= 0.56, p<0.05), CV (r= 0.49, p<0.05) and FS (r= 0.58, p<0.05). The CMJ Peak Power was also significant correlated with the DV (r= 0.57, p<0.05) and FS (r= 0.55, p<0.05).

This study showed the significant relation between muscle power measured by jump tests and performance of high level female gymnasts. Jump test results were revealed as an important tool that can be used for the control of the performance level of our gymnasts during the season.

ANALYSIS OF THE SWING HUB OF THE GOLF SHOT

Nesbit, S.

Lafayette College, United States

An analysis and functional description of the golf swing hub path is presented. The swing hub is defined as the path of the hand/club connection point or interface between the golfer and the club. Here the golfer controls the club kinematics and energy transfers from the body. An analysis of the swing hub was performed using a combined full-body golfer model with a parametric club model. This modeling approach removed the constant radius hub path constraint of traditional double-pendulum models.

The swing hub and associated parameters during the downswing were compared for four diverse amateur subjects (male-0 hdcp, male-5 hdcp, male-13 hdcp, fem-18 hdcp. data is presented in this order). While the hub paths of all subjects were unique and deviated considerably from a constant radius path, a three phase pattern emerged. During phase I the radius of the swing hub was max and nearly constant from the initiation of the downswing to the point were the club was vertical. The large initial hub radius reduced the initial centrifugal acceleration which in turn diminished the tendency of the club to move outward. During phase II the hub path radius decreased at a constant rate by a redirection of the linear force until the club reached the horizontal position where the radius obtained its min value. The result was a rapid increase in the centrifugal acceleration which caused the club to move outward. From this position the radius remained constant then increased slightly near impact (phase III). During this phase the golfer primarily controlled the path of the club as its momentum carried it through impact. The slight upward movement of the hub path near impact appeared to transfer additional energy to the club. There was considerable horizontal movement of the hub path center of rotation from the golfer’s left to right counter to the horizontal movement of the golfer CG. Vertical movement was relatively minimal.

Among the subjects, the max hub linear velocities (and profiles) were nearly identical (11.7, 11.6, 11.4, 11.2 m/s) though the max club head velocities were quite different (52.0, 49.7, 46.3, 42.1 m/s). The ratio of the max to min hub radius was related to skill level (1.39, 1.25, 1.19, 1.13). The better players had lower min path radii, and reached their min values later in the downswing. The overall linear distance of the hub path was related to skill level (2.42, 2.20, 1.96, 1.70m). The better players applied greater max linear forces (512, 453, 390, 304 N) over the hub path which resulted in a greater amount of energy (linear work) being transferred to the club (355, 289, 288, 235 N-m). The delay in achieving the min path radii coincided with achieving max power (3875, 3005, 2310, 1720 m/s). The data supports the opinion that linear work is more important than angular work (function of wrist torque) in transferring energy from the golfer to the club thus highlighting an important action of the hub path.

CHARACTERISTIC CURVE PATTERNS OF 3D BOAT MOTION IN INTERNATIONAL ROWING RACES IN ALL BOAT CATEGORIES

Draper, C., Rice, T., Buckley, R., Mattes, K.

University of Hamburg, Australian Institute of Sport, Germany

Introduction.
For success in international rowing, athletes must use their technical skills and entire performance capability (e.g., physical, condition, coordination) to achieve and retain a high average boat velocity throughout the 2000m race. For Rowing - a cyclical motion - a consistently high technical skill level under various velocity conditions and stroke rates is a necessary prerequisite for an efficient race. However, rowers are not perfectly symmetrical in applying forces on the pin, handle and footstretcher and must correct for intra-stroke boat balance and external perturbations. Measuring multi-dimensional boat-related aspects of rowing performance during racing, is seen as an area of opportunity to extend our knowledge of the 3D boat motion characteristics in all boat categories, which could in turn contribute to rowing superiority.

Methods

In the last two World Championships all Australian boats (n=31; 13 (2006); 18 (2007); 18 boat categories) were equipped with the Mini-maxX tracking device (Catapult Innovations, Australia, sample rate 100Hz, datalogger) during racing. Propulsive, transverse and vertical boat acceleration were directly measured. Yaw, roll, pitch of the boat and boat velocity were derived. The data were analysed and the stroke by stroke data detected using proprietary software. Every boat was analysed twice (e.g. semi final/ final). Graphical displays and statistical analysis were performed for each variable, and compared between categories. The coefficient of variation (CV) of the intra-stroke curve patterns (separately for drive/ recovery phases) was defined to assess the stroke consistency and the particular curve pattern.

Results

Characteristic curve patterns were found for each crew for all variables throughout all boat categories and ratings. All variables revealed a high consistency in the drive phase, high variations were found in the recovery phase and between different boat crews, except for the propulsive boat acceleration (aiprop), boat velocity (vb/boat) and pitch - they revealed a particular curve pattern for all boat classes. Transverse boat acceleration (latrans), roll and yaw showed a crew-related, however highly consistent curve pattern.

Discussion/Conclusion

Characteristic curve patterns were found for each crew for all variables throughout all boat categories and ratings. All variables revealed a high consistency in the drive phase, high variations were found in the recovery phase and between different boat crews, except for the propulsive boat acceleration (aiprop), boat velocity (vb/boat) and pitch - they revealed a particular curve pattern for all boat classes. Transverse boat acceleration (latrans), roll and yaw showed a crew-related, however highly consistent curve pattern.

STEPWISE MULTIPLE REGRESSION MODEL OF THE HAMMER THROW

Mercadante, L., Martini, T., Lara, J., Trabanco, J., Barros, R.
1 Campinas State University 2 Mogi das Cruzes University, Brazil

Previous studies had shown that the reached distance of the hammer throw depends mainly on the three release variables, the angle in relation to the horizontal plane, the height and the velocity of the hammer and the forces exerted by the air resistance on the hammer during the flight. A well known theoretical model to predict the thrown distance was proposed by de Mestre (2000). The present paper proposes and compares with de Mestre model an empirical model of stepwise multiple linear regression for hammer throw distance, in function of the release variables. The empirical model was built starting from 33 throws analyzed in two Brazilian high level competitions in 2006, being 21 male and 12 female. The DiVideo System was used for the 3D kinematical analysis. All statistical analysis used the level of significance of P<0.05. The averages of the release variables of the 33 Brazilian throws were 37.2° for the angles, 22.8m/s for the velocity, 113m for the heights, and 48.24m for the reached distances. The stepwise regression allows each variable can be separately included in the model, and the order of importance and inclusion is suggested in function of statistical parameters. The model was defined as y = -3.78v0 + 0.39a0 + 52.6 where y is the predicted distance, v0 the release velocity and a0 the release angle. The R² value of the model was of 0.96. In order to compare the predictions provided by the theoretical and empirical models, an independent data collection was used. The data set consisted of 6 throws and was acquired in the 1999 Athletics World Championship by Gutiérrez et al. (2002). The regression analysis of the predicted against measured values using this empirical proposed model showed a linear coefficient of -31.80 with the confidence interval [-137.56, 73.96], an angular coefficient of 1.46 with [0.02; 2.91] and the percent of explained variability equal to R²=0.66. A regression analysis using the de Mestre model showed a linear coefficient of -4.73 with the confidence interval [-36.54, 76.87], an angular coefficient of 0.97 with [1.02; 1.91] and the percent of explained variability equal to R²=0.65. The average difference between predicted and measured value was -2.01 m to the empirical model and 6.97 m to the de Mestre model. These results show that both models provide similar results for predicting hammer throw distance from release variables. However, it is important to emphasize that just a small number of truthful analyzed hammer throws were found in the literature for validating the models.

COMPARISON OF MOMENT-ANGLE PROFILE OF ELBOW FLEXORS - EXTENSORS IN ELITE YOUNG OVERHEAD ATHLETES

Nikolaidou, M., Noutsos, K., Barzouka, K., Boudolos, K.
National & Kapodistrian University of Athens, Greece

In in-vivo conditions, the moment vs. joint angle curve (M-A profile) is typically used to examine the force-length characteristics of muscles. During attack in volleyball (VB) and water-polo (WP), the elbow moves through an arc of 60°-70° joint flexion suggesting that the flexors and extensors operate in similar joint configurations, therefore muscle lengths. Previous studies (Herzog et al., 1991) have shown different extensor moment-knee angle relations between different athletes that were attributed to adaptation of muscle function to different functional requirements. The purpose of this study was to compare the moment-elbow angle profile between elite young overhead athletes.

Sample consisted of 10 VB and 10 WP athletes with body mass, height and age values being 80.0±8.0 kg, 185.7±5.1 cm and 17.2±1.0 years, and 76.1±5.0 kg, 174.8±8.0 cm and 15.2±0.9 years, respectively. Subjects executed 0.0 sec maximum dominant elbow flexion-extension contractions on a Cybex II+ at angles of 45-60-75-90-105-120° of joint flexion (0°=full extension), being in a supine position with

Saturday, July 12th, 2008
10:15 - 11:45
the shoulder joint at 45° of horizontal abduction and the forearm in neutral position. Maximal isometric flexor–extensor moment (Nm) was calculated. Data collection (Fs=1000 Hz) and data analysis used the AcqKnowledge software. A 2nd-order polynomial curve fitting approach was used to predict the M-A profile and the optimal elbow joint angle (Aopt). Possible differences in Aopt of the M-A profile and in the flexors-extensors moment magnitude across tested elbow joint angles between groups were examined with 1-test for independent samples and univariate analyses, respectively (p < 0.05).

In both groups, results showed that the flexor moment was stronger on positions of greater elbow joint extension and was reduced as the joint became more flexed, while the extensors showed a relatively constant moment-generating capacity across the tested elbow angles. The predicted Aopt of the flexors M-A profile was at 72° and 70° and the corresponding one for the extensors M-A profile at 74° and 70° of elbow flexion in VB and WP athletes, respectively, however no significant differences were observed between groups. VB athletes generated higher elbow extensor moment than WP athletes at 45° of elbow flexion, whereas no significant differences were found for the flexor moment.

The identical shape of the elbow flexor – extensor M-A profile in VB and WP athletes suggests similar adaptations of the elbow muscles to similar functional requirements. However, the observed difference at a joint configuration (greater elbow extension), which is more frequently seen in volleyball, provides evidence for adaptations of muscle function that may either relate with different competition conditions or may result from existing differences in muscle volume between groups, which become more pronounced in critical elbow joint angles for these sports.

AUTOMATIC DETECTION OF KEY EVENTS DURING THE TAKEOFF PHASE OF SKI JUMPS USING BODY FIXED INERTIAL SENSORS

Le Callenec, B., Jolles, B.M., Gremion, G., Cuendet, F., Aminian, K.
Ecole Polytechnique Federale de Lausanne, Switzerland

INTRODUCTION: Takeoff is one of the most important phases of ski jumping. It is then of particular interest to study meaningful kinematics parameters relating the takeoff movements to the overall performance. This requires to precisely identify key events such as when the takeoff movement is initiated (TS), when the toe leaves the ground (TO) or when the ski jumper achieved his final flight posture (TE). Unfortunately, this proved to be impractical using common equipment (i.e. video cameras). In this paper, we propose an ambulatory system that records the accelerations and the angular velocities of ski jumpers’ segments during jumps. Based on these signals, we then automatically extract three key events during takeoff: TS, TO and TE. We use these instants to derive timing information during takeoff in hill jumps.

METHODOLOGY: We first carried out in-lab measurements on 5 ski jumpers using a wheeled board on a 5m platform with an inclination of 5deg. Each jump was recorded using an optical motion capture system (VICON, 200Hz) considered as the reference. The key events TS_ref, TO_ref and TE_ref were then manually labeled using both the 3D reconstructions of the simulation jumps and the angle curves. In parallel, the athletes were equipped with 3D inertial modules placed on the thighs and the shanks. Each module was composed of one triaxial gyroscope, one triaxial accelerometer and an embedded datalogger recording the signals at 200Hz. The X-axis was defined as pointing towards the left, Y-axis as pointing upward and Z-axis as pointing forward. TS events were automatically identified by detecting peaks on the thighs angular velocities around the X-axis (pitch). TO events by detecting peaks on the shanks accelerations along the Y-axis and TE by detecting peaks in the shanks angular velocities around the Y-axis (roll). Finally, we applied our ambulatory system in real conditions on the Einsiedeln (Switzerland) medium jumping hill (hs-77 m) and determined takeoff duration (TO-TS) and spring movement duration (TE-TS).

RESULTS AND DISCUSSION: A total of 40 simulation jumps and 3 hill jumps were obtained. We compared our results to the reference (VICON + manual labeling). The standard deviation (SD) between TO and TO_ref was 15ms with a mean error (ME) of -12ms. The SD between TE and TE_ref was 29ms with a ME of 20ms. Finally, the SD between TS and TS_ref was 63ms with a ME of -6ms. This larger latter error may be explained by the fact that it is difficult to precisely determine when the thighs start to rotate even using angles curves. We finally applied our system in real conditions measuring 3 hill jumps. The average takeoff duration was 330ms. The average spring duration was 377ms.

CONCLUSION: we have proposed a new method using inertial sensors to automatically determine key events during takeoff. We validated our system in-lab and applied it on hill jumps to derive important timing information during takeoff.

PHYSICAL ACTIVITY STATUS IN MIDDLE-AGED MEN: CONFUSION AND CONFLICT BETWEEN VARIOUS PUBLIC HEALTH RECOMMENDATIONS

Thompson, D., Batterham, A., Markovitch, D., Dixon, N., Lund, A.
University of Bath & University of Teeside, United Kingdom

Introduction: Physical activity recommendations prescribe the minimum dose of physical activity required for general health in order to identify those people who are not sufficiently active. We do not know whether the various recommendations that are available unambiguously prescribe a similar amount of physical activity and therefore we sought to determine whether ten commonly-used physical activity recommendations similarly classify activity status in middle-aged men.

Methods: Following ethics approval, ninety men aged 45-64 years volunteered for the present investigation. We determined habitual minute-by-minute free-living physical activity energy expenditure in kcal/min over a full seven-day period of observation using synchronised accelerometry and heart rate with branched equation-modelling (Actiheart, Cambridge Neurotechnology Ltd., Cambridge, UK) as validated previously by our group (Thompson et al., 2006, J Nutr. 136: 1037-1042). We then examined individual attainment of ten permutations of commonly-used physical activity recommendations that originate from ACSM (US), CDC (US), Institute of Medicine (US), and Department of Health (UK).

Results: There was very poor absolute agreement between the recommendations, with an intraclass correlation coefficient (A,1) of 0.21 (95% CI, 0.12 to 0.31). The proportion of men defined as active ranged from to 11% to 98% for individual recommendations (mean 59%, SD 32%). Only 8% of men (n=7) met all 10 recommendations and would therefore be unanimously classified as active and only one man

THE EFFECT OF RESISTED PHYSICAL EXERCISE PERFORMED AT DIFFERENT HOURS OF THE DAY IN THE SLEEP PATTERN OF SEDENTARY INDIVIDUALS

De Mello, M., Faria, A., Rossi, M., Cavagnolli, D., Bittencourt, L., Tufik, S.
Federal University of São Paulo, Brazil

The past decades have seen a great variety of studies conducted in an attempt to assess the effects of physical exercise upon sleep. But because of the differences in methodologies and the fact existing studies have assessed the effects of aerobic exercise (AE) over sleep only, those of resisted exercise (RE) as well as how the time when exercise is performed affects the sleep pattern remains unknown.

Objective: The aim of the current investigation was to verify the effect of a session of RE performed at different times of the day (morning - 7:00 to 9:00, afternoon - 13:00 to 15:00, and evening - 18:00 to 20:00) in the sleep pattern of sedentary individuals who have good sleep quality.

Methods: 92 volunteers part took in this investigation, 34 of whom were men and 58 women, aged 30 ± 9 years of age, sedentary and with good sleep quality. The experimental protocol consisted of a session of RE composed by 3 series of 15 repetitions each, with a load equivalent to 50% of the 1-RM, after 130” intervals. The delta parameters of the polysonographies at the different hours of exercise were carried out by means of one way ANOVA, p <0,05.

Results: No significant differences were found in the sleep parameters when RE was performed at different hours of the day: sleep latency (p = 0,86); REM sleep latency (p = 0,85); total sleep time (p = 0,08); sleep efficiency (p = 0,13); stage 1 (p = 0,96); stage 2 (p = 0,80); slow wave sleep (p = 0,74); REM sleep (p = 0,60); vgl (p = 0,37).

Conclusion: Sedentary individuals with good sleep quality did not present any significant alterations in the sleep parameters when they performed a session of RE with a load equivalent to 50% of 1-RM.

Acknowledgments
The authors are greatly thankful to AEP, CEPI/FAESP (process 98/14303-3), CNPQ, CEPE and FADA/UNIFESP for the financial support granted to this study and are also thankful to Prof. Dr. Benedeto Sérgio Denadai for his important contribution.

INDIVIDUALILITIES EFFECTS OF RESISTANCE TRAINING UPON RESTING METABOLIC RATE IN OVERWEIGHT FEMALE 39-49 YEARS OLD

Kuehne, T., Mishchenko, V.
Academy of Fitness, Germany

It is known, that a rise of energy consumption by aerobic endurance training and energy restricted diet may results in decrease of resting metabolic rate (RMR) in healthy man (Donnelly, 2000; Ross, 2000). Therefore have to be assessed the effects of other exercise training programs. Recent studies have reported that strength training represents an adequate alternative to aerobic exercise in women obesity (Moos, 2004). We reasoned that an increase of muscle mass contribute a rise of RMR and has positive effects on energy balance in overweight female 39-49 years old. The aim of the study was to compare the effect of high intensity resistance training in middle age women with relatively decreased RMR versus others without a concomitant diet upon RMR.

17 untrained overweight female (BMI 33,2±2,5 kg/m2) were matched for RMR and assigned to relatively decreased RMR (D, n=8, BMI 33.5±2.4 kg/m2) and others (O), n=10. BMI 33,0±2,3 kg/m2, p<0.05) training groups. The subjects’ rest (supine) oxygen uptake measured in the morning for 10 min 3-4 hours after a light meal. The subjects of D and O group participated in the same resistance training program 2 day per week for 3 months with slow-speed isokinetic strength exercises of lower and upper body at 75-85% and 60-70% 1RM (8-10/12-15 repetitions per set, 3-5 sets). The determining of fat folds and oxygen uptake was performed before (week 0) and on week 12. The results showed that after 12 weeks training resting oxygen uptake significantly increase in D group only from 103.1± 5.6 on week 0 to 124.4± 6.5 ml/min/m2 on week 12 (p<0,05). The whole increase of lower and upper body maximal strength in D and O group were 20.1± 3.4 and 16.7± 3.9%, respectively (p<0,1). Post-trained decrease of body fat in D group was significantly more (-8.7±1.3%) than in group A (-5.4±0.9%). Resting oxygen uptake related to fat-free body mass showed a significant more increase in D group (from 4.02± 0.06 to 5.03± 0.07 ml.kg-1.min-1) than in group O. BMI decreasing was significantly more in D group (-11.9 ± 1,9%) than in group O (-8.1 ± 1,2%). This decreasing was related to changes of RMR (r=-0,62; p<0,05).

We concluded that two sessions per week of high intensity resistance training for 12 weeks improve resting metabolic rate in women with relatively decreased RMR only. BMI decreasing was significantly related to changes of RMR The results support the supposition, that strength training represents an adequate alternative to aerobic endurance training in women rehabilitation training programs. We supposed that long-term maintenance positive effect of weight loss programs of overweight middle age women may be provide by increasing of resting metabolic rate in persons with relatively decrease RMR.

"THE SLEEP OF A LABOURING MAN IS SWEET": THE EFFECTS OF PRIOR EXERCISE ON THE ARCHITECTURE AND QUALITY OF DAYTIME SLEEP

Atkinson, G., Fullick, S., George, K., Harrison, Y., Morris, C., Zaregarizi, M.
Liverpool John Moores University, United Kingdom

As illustrated by the Biblical maxim in the title of this abstract, relationships between sleep and exercise have been of interest for thousands of years (Atkinson and Devenne, 2007). Although the acute and chronic effects of exercise on nocturnal sleep quality have been studied previously, most researchers have employed subjective or activity-based indices of sleep quality rather than gold-standard polysomnography for formal definition of sleep architecture. Moreover, no previous researcher has considered how a bout of exercise influences the architecture of subsequent daytime sleep, which is important for the growing European population of shift-workers. Therefore, we hypothesised that quality and architecture of daytime sleep are improved by prior exercise.
Following a night of restricted (~4 h) sleep, 9 normative adults, aged: 34±6 y, either exercised at 70% VO2max or remained sedentary between 09:30-10:00. At 14:00, subjects were allowed to nap for up to 1 h in our sleep laboratory. After a 10-min period of relaxed wakefulness before lights-out, polysomnographic data were analysed to describe sleep latency (the time between lights-out and onset of stage 1 sleep) and the duration of stage 2 sleep. Wrist accelerometers were worn throughout the daytime sleep as a global measure of "restlessness". Subjective sleep quality (1-4 Likert scale) was also recorded. Data are described as means±SE and 90% confidence intervals (CI).

Wrist activity gradually decreased during the 10-min before lights-out in both trials. Nevertheless, the mean activity during this period was 11.5±0.6 units following exercise compared to 16.0±0.7 units without prior exercise (CI for difference = 0.5 to 8.5, P=0.029}. Sleep quality was perceived to be 1.2±0.2 units better in the exercise trial (P<0.0005). Daytime sleep latency reduced, although not significantly, from 421±100 s without prior exercise to 257±57 s following exercise (CI for difference = -368 to 41 s, P=0.085). Prior exercise did not affect the duration of stage 2 sleep (P=0.24).

These data suggest that prior exercise decreases restlessness during the preparation phase for daytime sleep and improves subjective sleep quality. There is some evidence that daytime sleep latency is also shorter following exercise. Therefore, we conclude that exercise could be beneficial to the shift-worker who has disrupted nocturnal sleep and is required to sleep during the daytime hours.

PROTECTIVE EFFECT CONFERRED BY SLOW VELOCITY LENGTHENING CONTRACTIONS AGAINST MUSCLE DAMAGE INDUCED BY FAST VELOCITY LENGTHENING CONTRACTIONS

Nosaka, K., Chapman, D., Newton, M., McGuigan, M.
Edith Cowan University, Australia

A bout of eccentric exercise confers protection to subsequent bouts of the same or similar eccentric exercise, and this adaptation is known as the "repeated bout effect". Previous studies have identified factors influencing the repeated bout effect, but no previous study has investigated the effect of lengthening contraction velocity. This study tested the hypothesis that slow velocity lengthening contractions would not provide protection against muscle damage induced by a subsequent bout of fast velocity lengthening contractions. Eighteen men (26.3 ± 4.2 yrs) were randomly placed into two groups: repeated bout group (n=10) and control group (n=8). The repeated bout group performed two bouts of exercise consisting of 210º·s⁻¹ for the first bout and 210º·s⁻¹ for the second bout. The control group performed the fast velocity bout only. Changes in maximal isometric strength, range of motion (ROM), upper arm circumference, muscle thickness, muscle soreness, serum creatine kinase (CK) and lactate dehydrogenase (LDH) activities were measured before, immediately after, and 24, 48, 72, and 96 hours after exercise. Changes in the measures over time after the fast velocity exercise were compared between groups by a two-way repeated measure ANOVA. For the repeated bout group, changes in the measures were compared between bouts by the two-way ANOVA. Comparison was also made between the first bout of the repeated routine exercise and control group (fast velocity exercise) by the two-way ANOVA. All criterion measures except muscle soreness indicated less muscle damage for the slow than fast velocity eccentric exercise, which supports the findings of our previous study (Int J Sports Med 27: 591-598, 2006). No significant differences between the first (slow velocity eccentric exercise) and second (fast velocity eccentric exercise) bouts were evident for changes in all criterion measures except ROM. The recovery of muscle strength and ROM was enhanced, and increases in upper arm circumference, muscle thickness, and blood markers of muscle damage (CK, LDH) were attenuated when the fast velocity eccentric exercise was preceded by the slow velocity eccentric exercise bout. Thus, the results of the present study suggest that the slow velocity eccentric exercise that results in less damage than the fast velocity eccentric exercise conferred some protection for a subsequent bout of the fast velocity eccentric exercise. The findings of the present study are in line with previous studies showing that an initial bout of eccentric exercise resulting in less damage can still confer protection against a more demanding eccentric exercise; however, the magnitude of protection is affected by the magnitude of muscle damage induced by the initial bout.

EFFECT OF HIGH-INTENSITY INTERMITTENT PRIMING EXERCISE ON 3KM CYCLING PERFORMANCE

Kilding, A., McIntyre, J.
AUIT University, New Zealand

Background: Priming exercise, or the ‘warm-up’ (WU), is an accepted practice prior to sporting competition. Previous research suggests that a high-intensity intermittent WU may be required to optimise performance (Bishop et al. 2001). The aim of this study was to determine the effects of three high-intensity intermittent WUs strategies on 3km laboratory time-trial (TT) cycling performance.

Method: Ten endurance-trained male cyclists (mean ± SD: age, 28.3 ± 8.4 yr, body mass, 81.8 ± 11.6 kg, stature, 1.8 ± 0.1 m, VO2peak, 4.6 ± 0.5 L.min⁻¹) participated. After an initial incremental exercise test to exhaustion, participants completed four 3km TTs on four separate occasions and in random order, each preceded by a different WU strategy of fixed duration. These included: a ‘self-selected’ (control) WU, and three different high-intensity intermittent WUs strategies of varying intensity (100% and 150% of the power at VO2peak, and all-out). Mean power during the subsequent 3km TT (Wmean) was determined for each trial. Measures of heart rate, oxygen uptake and blood lactate were also measured throughout each WU and 3km TT.

Results: The self-chosen WU resulted in a Wmean (379 ± 44 W) that was slightly, but not significantly, greater than both the 100% WU (376 ± 45 W, 0.7%, p = 0.570) and 150% WU (374 ± 48 W, 1.5%, p = 0.301), and was significantly greater than the ‘all-out’ WU condition (357 ± 45 W, 5.8%, p = 0.003). Similar differences were observed for 3km TT time.

EUSTORI/PORTUGAL, 09-12 JULY 2008 553
Conclusion: A priming strategy that is overly intense is detrimental to subsequent 3km cycling performance. Other intermittent WU strategies did not improve 3km-TT performance above that of a self-chosen WU. That a self-chosen WU resulted in a comparable performance to prescribed high-intensity intermittent priming, suggests that athletes are able to self-select (consciously or sub-consciously) a WU that is of an appropriate intensity/duration to optimise performance.

PACING STRATEGY USED DURING THE RUNNING LEG OF ELITE OLYMPIC DISTANCE TRIATHLON: EFFECTIVE, BUT NOT OPTIMAL?
Green, D., Jenkins, D.
Australian Institute of Sport, Australia

Introduction
The selection of an optimal pacing strategy allows an athlete to exercise to their physiological potential. For endurance events greater than 4 minutes the optimal pacing strategy is an even-paced strategy [1]. The aims of the present study were to compare: (i) pacing strategies during the running leg (10km) of elite Olympic distance triathletes with 10,000m athletic running performances; and (ii) pacing strategies of Successful (top 50% of observations) and Unsuccessful (bottom 50%) triathletes.

Methods
Data were collected at 8 major draft-legal Olympic distance triathlons between 2005-06. These events included the Commonwealth Games, ITU World Cups, and ITU World Championships. Timing data were collected at 3-4 points during the run with the first collection point positioned close to the 1km mark. The distance to each collection point was measured with a Rolson Tools 13-inch measuring wheel. Data collected ranged from 48-100% of triathletes finishing within 10% of the winning time in each race and consisted of 179 female and 326 male performances. Data for 10,000m run performance consisted of km splits for 10 male and 10,000m World Records (set since 1988) and km splits from 4 male and 4 female World Championship 10,000m finals between 2001-07. Data was provided courtesy of Ross Tucker and the IAAF website.

RESULTS
Elite triathletes exhibited a different pacing strategy during the running leg of their event compared with athletes competing in 10,000m running races. Triathletes adopted a ‘fast-start’ strategy, which resulted in the athletes slowing during the middle and latter stages of the run. In contrast to triathletes, the pacing strategy adopted by runners in 10,000m running races was either ‘even-paced’ for male World Record performances or ‘fast-finishing’ for World Championship races. Male triathletes typically adopted a more aggressive ‘fast-start’ strategy compared to their female counterparts, although regression analysis showed both started 6-8% faster than their average running speed for the 1st km of the 10km run. The pacing strategy adopted by the Successful was not consistently different from the Unsuccessful triathletes. On average, the winners (both male and female) of each triathlon ran the first kilometre approximately 5% faster than their average pace for the 10km run.

CONCLUSIONS
The structure of a triathlon means each triathlete does not necessarily commence the running leg of the event at the same time as their competitors, which may result in attempts to capitalise or minimise differences within the early stages of the run. However, the race comparison with world-class distance runners suggests that elite triathletes are not optimally pacing the running leg of their event, and that overall performance during a triathlon may be improved by adopting a more even-paced running strategy.

MUSCLE OXYGENATION AFTER DOWNHILL WALKING-INDUCED MUSCLE DAMAGE
Davis, G., Ahmadi, S., Sinclair, P.
The University of Sydney, Australia

It has been well documented that exhaustive downhill walking (DW) exercise, which involves repetitive eccentric contractions, may result in delayed onset muscle soreness and/or muscle damage. Some of the known consequences of repetitive and uncustomised eccentric exercise include long-lasting decreases in force generation, loss of flexibility and decreased range of motion. Increased muscular pain, tenderness, oedema and an efflux of intramuscular proteins into the blood stream are also secondary outcomes after eccentric exercise. The purpose of this study was to investigate changes in muscle oxygenation and other markers of DW-induced muscle damage within vastus lateralis, over five days following the exhaustive exercise.

Nine healthy males performed 40-min DW on a treadmill at walking velocity of 6.4 km/h and gradient of -25%. To increase the likelihood that DW would induce muscle damage, subjects were loaded with 5% of their body weight carried in a back pack. Maximum voluntary torque (MVT), subjects’ perception of muscle soreness (SOR), plasma creatine kinase (CK) activity and myoglobin (Mb) concentration were assessed before and after DW exercise on the first day, and then again on days 2, 3, 4 and 5. To determine if markers of muscle damage were associated with changes of muscle oxygenation, near infrared spectroscopy (NIRS) of vastus lateralis was employed at rest and during isometric exercise at 50% and 80% MVT on the days following DW. Repeated-measures ANOVA revealed that MVT decreased while SOR and Mb concentration significantly increased after DW (p<0.05). Up to a 25% decrement in MVT was observed after DW. The significant changes in MVT and CK activity along with significant increments in Mb concentration and SOR demonstrated the effectiveness of our experimental protocol to evoke muscle damage. Resting muscle oxygenation increased immediately after DW, but recovered within 24 hours. Other NIRS-derived variables at rest varied little from pre-DW values, suggesting either these were either insensitive to exercise-induced muscle damage or that muscle oxygenation is little changed in the days following DW. In contrast, the volume of muscle oxygen desaturation during 80% isometric MVT ranged from 4% to 28% greater after DW, and was still elevated by 11% four days later. Muscle oxygen desaturation immediately after 80% MVT was significantly higher after DW, and remained elevated by 11% over pre-DW values on day 5. Similarly, NIRS-derived muscle oxygen desaturation and re-saturation kinetics were significantly faster than pre-DW values.

Collectively, the findings of our study supported the hypothesis that DW-induced muscle damage may affect muscle oxygenation kinetics, as evidenced by the changes in resting and exercise muscle oxygenation. The possible mechanism responsible for these changes might be increased resting muscle oxygen utilization after muscle damage due to an increased requirement for aerobic energy-demanding repair p
THE EFFECT OF GRADED COMPRESSION SOCKS ON EXERCISE CAPACITY AND POST-EXERCISE RECOVERY

Terblanche, E., Welman, K.
Stellenbosch University, South Africa

Due to intense training programmes and competition schedules, athletes are keen to explore any strategy which may enhance their post-exercise recovery. Various methods have been investigated, including active recovery, hydrotherapy and compression garments. It has been suggested that compression socks may improve venous return during and after exercise and therefore facilitate the clearance of waste products. Manufacturers of compression garments further claim that it will enhance exercise performance. The aim of this study was to compare the effects of graded compression socks on the exercise capacity and lactate recovery profiles of athletes during short maximal exercise and prolonged submaximal exercise.

In experiment 1 (maximal exercise), ten trained athletes completed two incremental running exercise tests to exhaustion separated by at least 7 days, in random order, with and without socks. In experiment 2 (prolonged submaximal exercise), 7 trained athletes completed two submaximal treadmill tests at 70% VO2max, separated by at least 7 days, in random order, with and without socks. The latter protocol lasted two hours and simulated a hilly route, including level, uphill and downhill sections. During the ‘with socks’ trials, athletes wore the compression socks during the exercise and up to 30 min into recovery. In all cases, subjects sat passively on a chair for 30 min after exercise. Cardio-respiratory parameters were measured with the Cosmed Quark b2 metabolic system and blood lactate concentrations were measured using the Lactate Pro analyzer.

Wearing compression socks did not result in higher maximal exercise capacities or better performances during the prolonged exercise test. Directly after the maximal exercise test, there were no differences in blood lactate concentrations. However, trials with the compression socks resulted in significantly lower blood lactate concentrations after 30 min recovery (4.4 ± 1.9 mmol/L vs 5.8 ± 2.0 mmol/L; P = 0.008). After the prolonged exercise tests, the blood lactate concentrations directly after exercise were significantly higher without the compression socks (1.9 ± 0.8 mmol/L vs 2.3 ± 0.9 mmol/L; P = 0.041), despite no differences in distances completed (18.9 ± 1.1 km vs 19.0 ± 1.2 km). After 30 min recovery, the blood lactate concentrations were significantly lower in the tests with socks (1.6 ± 0.5 mmol/L vs 2.4 ± 0.4; P = 0.008).

Our results show that exercise capacity and performance are not enhanced by wearing compression socks during exercise. Our study supports previous findings that compression socks aid post-exercise lactate recovery during both short- and long-term exercise. However, the effects were more pronounced after prolonged exercise where lactate recovery was significantly faster with compression socks. Our results therefore suggest that endurance athletes may benefit most through this strategy during exercise of longer duration.

EXERCISE-INDUCED PEAK FAT OXIDATION IS INCREASED BY ENDURANCE TRAINING AND DIET

University of Copenhagen, Denmark

Aim: To investigate if exercise-induced peak fat oxidation is increased by 12 weeks of endurance training with or without weight loss or by an energy-reduced diet.

Methods: Forty young, overweight male volunteers (age: 32±5 [mean±SEM] years, BMI: 28.1±1.1 kg.m-2) were randomized to 4 intervention groups: Training (T), Training without weight loss (Ttwl), Diet (D) and Control (C). An energy deficit of 600 KCal day-1 was induced by either endurance training or diet in T and D. Ttwl had an identical training regime of 600 KCal day-1, but had to increase dietary energy intake by 600 KCal day-1. C maintained their habitual lifestyle during the 12-week intervention period. Before and after the intervention, maximal oxygen consumption (VO2max) was measured and peak whole body fat oxidation (FATmax) estimated by indirect calorimetry using bicycle ergometer exercise protocols with an initial warm-up followed by work load increments of 25 watt min-1 and 30 watt 13 min-1, respectively. Body Mass (BMI), Fat Mass (FM) and Lean Body Mass (LBM) were determined by DXA scanning.

Results: After the intervention BM was reduced 5.0±2.7 and 5.0±1.6 kg in T and D, respectively, and decreased in D by 1.1±0.9 kg (P<0.01). No change in BM was observed in C. VO2max increased in T and Ttwl by 0.5±0.3 and 0.5±0.1 L.min-1 (P<0.01), respectively. VO2max was not changed in D and C. FATmax was increased in T, Ttwl and D by 0.17±0.14 (P<0.05), 0.13±0.08 (P<0.05) and 0.10±0.06 gfat.min-1 (P<0.05), respectively, and remained unchanged in C. The relative workload (%VO2max) at which FATmax occurred was increased in T and Ttwl by 8.2±6.0 (P<0.01) and 9.9±7.3 (P<0.05) %VO2max, respectively, and was unchanged in D and C. The change in FATmax was related to the change in FM and VO2max (r=0.53, P<0.001 and r=0.49, P<0.005, respectively). The change in %VO2max at which FATmax occurred was associated to the change in FM and VO2max (r=0.36, P<0.05 and r=0.40, P<0.01, respectively).

Conclusion: FATmax (gfat.min-1) was increased both by endurance training and dietary-induced weight loss, whereas the relative workload at which FATmax occurred was increased only by training. Endurance training regardless of weight loss is hence the most beneficial way to increase FATmax. The association between co-occurring changes in FATmax and FM suggests that the increase in FATmax by endurance training or energy-reduced diet is coupled to the activation of mechanisms involving both mobilization and utilization of fat.

DOES LOW-INTENSITY RESISTANCE EXERCISE WITH VASCULAR OCLUSION FOR LOWER-LIMBS ENHANCE TRAINING EFFECTS OF HIGH-INTENSITY RESISTANCE EXERCISE FOR UPPER-LIMBS?

Madarame, H., Ochi, E., Nakazato, K., Ishii, N.
The University of Tokyo, Japan

Our previous study has shown that a low-intensity resistance exercise with vascular occlusion for leg muscles causes increases in the size and strength of arm muscles subjected to normal resistance exercise, the intensity of which was lower than that can induce muscular hypertrophy (Madarame et al. 2008). We assume that any systemic factor released after the occlusive exercise are involved in this...
remote effect. However, the remote effect of the occlusive exercise on other muscles subjected to normal high-intensity resistance exercise has not been studied.

PURPOSE: The purpose of this study was to see whether low-intensity resistance exercise with vascular occlusion for lower-limbs enhances training effects of high-intensity resistance exercise for upper-limbs.

METHODS: Sixteen men volunteered to participate in a resistance exercise regimen consisted of bench-press (BP) and squat (SQ) exercises, twice a week for 10-wk. They were assigned into either an occlusive training group (OCC, N=8) or a normal training group (NOR, N=8). Both groups performed the BP exercise at an intensity of three-repetition maximum IRM without occlusion (3 sets x 3 reps). After the BP exercise, the OCC performed the SQ exercise (30-40% of IRM, 3-4 sets x 15-30 reps) with restricted venous blood flow (200-250 mmHg), whereas the NOR performed the same SQ exercise without occlusion. Before and after the 10-wk training period, the IRM strength and the cross-sectional area (CSA) of muscles with MRI were measured. The data were analyzed with a two-way ANOVA (group x time) with repeated measures.

RESULTS: There was a significant main time effect for the SQ IRM (P<0.001), and the SQ IRM increased in both OCC and NOR. In addition, there was no significant time x group interaction for the SQ IRM (P<0.05), and the relative increase of the SQ IRM in the OCC (12.9%) was larger than in NOR (9.7%). The BP IRM increased in a similar manner in both OCC and NOR. Although there was a significant main time effect for the BP IRM (P<0.001), there was no time x group interaction. Similarly, CSA of triceps brachii increased in a similar manner in both OCC and NOR. There was a significant main time effect for the CSA of triceps brachii (P<0.001), but no time x group interaction. CONCLUSION: These results indicate that low-intensity resistance exercise with vascular occlusion for lower-limbs does not enhance training effects of high-intensity resistance exercise for upper-limbs.

THE EFFECT OF HIGH FAT DIET AND TRAINING ON MITOCHONDRIAL FUNCTION IN HEALTHY SUBJECTS

Skovbro, M., Boushel, R., Dela, F.
University of Copenhagen, The Copenhagen Muscle Research Centre, Denmark

The effect of combined high fat diet and training on mitochondrial function has not previously been investigated. Also, a link between mitochondrial function and insulin sensitivity and VO2 max accompanying these interventions is not defined. Twenty healthy untrained male subjects were randomized to a high fat diet (55-60% fat, 25-30% carbohydrate and 15% protein) HFD, n=10) or normal diet (25-35% fat, 55-60% carbohydrate and 10-15% protein, ND, n=10) initially for 21 wk, followed by addition of exercise training (exT) for 21 wk (cycle ergometry, 45 min per day, alternating between continuous (65% VO2 max) and interval training (75% VO2 max). Frequent registration of diet, body weight and resting energy expenditure ensured matching of caloric intake to energy expenditure. Insulin sensitivity was measured by isoglycaemic hyperinsulinaemic clamp (40MU/m2/min) and expressed per lean body mass (LBM). Mitochondrial function was determined in permeabilized muscle from vastus lateralis by high resolution respirometry (Oroboros Oxygraph-2k). VO2max, but not insulin sensitivity did not change in either group after the intervention. State 3 mitochondrial respiration with substrates for complex I +II (malate+glutamate+ADP + succinate) increased (from 59±5 to 73±5 pmol.sec-1.mg-1, P=0.05) with training in ND but not in HFD. Changes in mitochondrial function were unrelated to VO2 max and insulin sensitivity. Respiration upon stimulation with lipids (octanoyl carnitine) tended to be increased by training only in ND (6.3±1 to 8.2±1 pmol.sec-1.mg-1, P=0.08). Both groups showed an increase in state 4 respiration HFD =7±2, ND =10±3 pmol.sec-1.mg-1 increase, P=0.05) in the presence of oligomycin indicating a potentially higher membrane leak. However, no effect of diet or diet + training was found on the regulation of coupled and uncoupled respiration expressed by the respiratory control ratio (RCR= state3/state4a) and uncoupling control ratio, (UCR= state3u/state3). The results of this study indicate that a HF diet can suppress the normal increase in muscle mitochondrial state 3 respiration with exercise training, including the potential to oxidize lipids.

SKIN SURFACE MENTHOL APPLICATION ON SWEATING RATE DURING EXERCISE

Kounalakis, S., Botonis, P., Geladas, N., Koskolou, M.
University of Athens, Greece

At rest, application of menthol on the skin stimulates cold-sensitive afferent pathways, which may activate norepinephrine release and thus probably lead to local cutaneous vasoconstriction and body heat conservation. On the other hand, sustained exercise initiates sweating for heat dissipating purposes. It is not known, whether application of menthol, a widespread ingredient of various cosmetic and therapeutic skin creams could affect sweating rate during exercise. The purpose of the present study was to investigate the effect of the skin surface menthol application on sweating rate response during steady state exercise.

For this purpose eight subjects cycled at 50% of their maximum heart rate (HR, 220-age), so long as to reach 38 oC in rectal temperature (Trel) on two separate conditions (control-C, menthol-M) administered at random order. In M condition, a 5-min resting period was followed by application of 4.6 gr menthol per 100 ml of water on the skin all over the body. At rest and during exercise, HR, Trel, sweating rate (SwR), forearm skin temperature (Tskforearm), the proximal-distal skin temperature gradient (Tskdiff) and oxygen consumption (VO2) were measured.

Throughout exercise, power output and HR were similar between the conditions (power output: 139.5±8.8 Watt and 150.6±9 Watt, HR: 132.5±10.3 bpm and 133.8±10.8 bpm in M and C, respectively). Trel was similar between the two conditions at rest and during the first 15 min of cycling, but during the last 10 min of exercise the rate of rise in Trel was higher in M (0.24 vs. 0.14 oC/min for M and C, respectively, p<0.03). The average sweat rate during exercise was lower in M 0.97±0.16 g cm-2.min-1 vs. 3.32±0.22 g cm-2.min-1 for M and C, respectively; p<0.01), while the initiation of sweating was observed 4.4 min later in that condition (7.63±0.48 vs. 3.25±0.21 min for M and C, respectively, p<0.01). However, once sweating had started, the increase was similar between conditions (regression slope 10.23±0.66 vs. 10.00±1.28 for M and C, respectively). Tskdiff and VO2 were higher in menthol condition only in the first 12 min of exercise (Tskdiff: 2.8±0.1 oC vs. 1.0±0.1 oC and VO2: 1.89±0.3 l vs. 1.75±0.3 l for M and C, respectively, p<0.05) without being different from this time and onwards. Overall, Tskforearm was not different between experimental conditions. At the first stages of exercise, menthol application on the skin seems to induce vasoconstriction, thermogenesis and inhibition of sweating, responses, which are released at later stages due to the accumulated amount of heat.
EFFECTS OF GROWTH HORMONE RECEPTOR ANTAGONIST TREATMENT ON FAT METABOLISM DURING ENDURANCE EXERCISE

Goto, K., Doessing, S., Nielsen, R., Kjaer, M.
Department of Life Sciences, Japan

Backgrounds: Growth hormone (GH) administration has become a prevalent doping technique used in athletics II. It has been generally shown that acute exposure to GH during exercise exaggerates lipolysis during exercise (2, 3, 4). However, the effect of GH blockade on metabolic and substrate responses remains unclear. The present study was designed to determine effects of GH receptor (GHR) antagonist treatment on fat metabolism before, during, and after prolonged exercise.

Methods: Twenty healthy young men were assigned to either GHR antagonist treatment (N=10, 25 ±1 yrs, 184 ± 2 cm, 80 ± 5 kg) or placebo group (N=10, 23 ±1 yrs, 182 ± 2 cm, 81 ± 5 kg). The subjects received either GHR antagonist (somavert, 10 mg daily by sc injection) or placebo for 16 days (every second day). After the treatment period, they performed 60 min of submaximal bicycling (30 min of exercise at 55 % of VO2max followed by 30 min of exercise at 70 % of VO2max) followed by all-out exercise at 90 % of VO2max. Blood and respiratory gas were collected, before exercise and post-exercise. Muscle sample of leg was taken after exhaustion to measure muscle lactate content.

Results: The treatment group showed higher concentration of serum GH before the exercise (Treatment, 18.5 ± 1.43 µg/l; Placebo, 0.1 ± 0.04 µg/l, P < 0.001). During the 60 min of exercise, GH concentration was consistently higher in the treatment group than in the placebo group (P < 0.001). However, no significant observation was observed in responses of serum glycerol, free fatty acids, glucose, insulin, plasma epinephrine and norepinephrine during the exercise between the groups. Oxygen uptake and respiratory exchange ratio showed no significant difference between the groups. In addition, muscle lactate content after exhaustion showed no significant difference between treatment (30.0 ± 4.7 mmol/kg dw) and placebo group (23.3 ± 3.7 mmol/kg dw).

Conclusions: GHR antagonist increased markedly baseline level of GH, possibly by negative feedback mechanism. However, the treatment did not affect significantly lipolysis and substrate oxidation pattern during exercise. These results suggest that GH is not a crucial factor for enhancements of lipolysis and fat oxidation during prolonged exercise in healthy men.

ENERGY EXPENDITURE AND EXERCISE INTENSITY ESTIMATED BY HR-VO2 RELATIONSHIP DURING TRIATHLON COMPETITION

Chukyo University, Japan

Triathlon is a triple-event endurant sport in which athletes compete sequentially in swimming, cycling and running. In order to determine the energy expenditure and exercise intensity of triathlon, we recorded heart rate (HR) during triathlon competitions. Ten college-level male triathletes, 18-21 years old, volunteered in this study. HR was recorded with HR monitor (ITZ-MAX50, Acumen and Team System, Polar) during triathlon competitions in which wetsuits were used during swimming and drafting was not allowed during cycling. Three incremental exercise tests until exhaustion in swimming, cycling and running were carried out in the laboratory and oxygen consumption (VO2) and HR were monitored. Using the individual correlating equation between HR and VO2, energy expenditure during triathlon race was estimated. Mean competition time (± SD) for Olympic distance (1.5 km swimming, 40 km cycling and 10 km running) was 2h24m(0's ± 14m45s). Time for swimming, cycling and running was 26m27s ± 3m50s, 1h12m12s ± 3m50s, and 45m23s ± 8m47s, respectively. Total heart beats and heart beats for swimming, cycling and running were 25,273 ± 2342, 4,641 ± 539, 12,663 ± 536 and 7,968 ± 1,565 beats, respectively. Mean HR for race and HR for swimming, cycling and running were 174 ± 7.2, 174 ± 8.3, 175 ± 7.3 and 175 ± 8.0 bpm, respectively. Total energy expenditure for Olympic distance triathlon race was estimated to be 2,196.4 ± 286.9 kcal (n=10). Mean exercise intensity during Olympic distance triathlon race was 0.252 ± 0.026 kcal/kg/min and 14.3 ± 1.5 METs, which is compatible to bicycling at >32 km/h without drafting (16 METs), running at 14 km/h (14 METs), speed skating (15 METs) and cross country skiing at >13 km/h (14 METs) and is more intense than the most competitive sports such as handball, boxing and squash (12 METs), rugby, soccer, American football and judo (9-10 METs), tennis, badminton, volleyball, basketball, and ultimate (7-8 METs), or baseball (5 METs)*. In conclusion, 1) HR monitoring revealed that Olympic distance triathlon is not only endurant but also intense sport with the HR as high as 175 bpm and with the exercise intensity as high as 0.252 ± 0.026 kcal/kg/min and 14.3 ± 1.5 METs. 2) Total energy expenditure to complete Olympic distance race was estimated to be about 2200 kcal.

INFLUENCE OF CREATINE LOADING ON MUSCLE PHOSPHOCREATINe KINETICS DURING HIGH-INTENSITY KNEE-EXTENSOR EXERCISE

Jones, A., Wilkerson, D., Fulford, J.
University of Exeter, United Kingdom

Following the onset of exercise, muscle phosphocreatine concentration (PCr) and oxygen uptake (VO2) change with similar kinetic profiles until a new steady-state is attained. Meyer's 'electrical analogue' model of respiratory control posits that the time constant for the exponential rise in VO2 (and the exponential fall of PCr) is the product of the mitochondrial resistance and the metabolic capacitance (Meyer, 1988). The latter is determined predominantly by the total muscle creatine content. We therefore hypothesised that increasing the muscle metabolic capacitance through creatine loading would result in slower muscle PCr kinetics (as determined using 31phosphomagnetic resonance spectroscopy, 31P-MRS) following the onset of exercise.
Seven male subjects completed 'step' tests to heavy-intensity exercise (80% of peak work-rate) from a resting baseline using a single-leg knee-extensor ergometer situated inside the bore of a 1.5 T magnetic resonance scanner (Intera, Philips, Netherlands). Four-like transitions were performed both before and after a 7-day intervention in which subjects supplemented their diet with 20 g per day of creatine monohydrate to increase total muscle creatine content. Muscle [PCr], inorganic phosphate concentration and pH were determined every 6 s during 2 minutes of rest and 6 minutes of exercise, and the muscle [PCr] kinetics were described using standard non-linear regression techniques. The resting muscle [PCr]/ATP ratio increased – 8% from 4.66 ± 0.27 to 5.04 ± 0.22 (P<0.05), consistent with a significant increase in muscle total creatine content caused by the dietary creatine supplementation. The relative fall in [PCr] from rest to end-exercise was not significantly different between the control and creatine-loaded conditions ([PCr], Con: 55 ± 16 % vs. Cr: 51 ± 17 %; P>0.05). However, the [PCr] kinetics were significantly slower in the creatine-loaded condition (mean response time, Con: 75 ± 17 vs. Cr: 98 ± 27 s; P<0.05).

The principal finding of this study was that increasing muscle total creatine content through dietary creatine supplementation resulted in significantly slower muscle [PCr] (and presumably VO2) kinetics across the transition from rest to exercise. These data are consistent with Meyer’s electrical analogue model of respiratory control. The muscle metabolic capacitance is therefore an important mediator of the oxidative metabolic ‘inertia’ that is evident at the transition to an augmented energetic demand, with PCr hydrolysis temporarily buffering the stimulus i.e., ADP concentration, phosphorylation potential, etc.

OP-RE03 Rehabilitation 3 - General

QUANTIFIED WALKING BEHAVIOR AND ITS RELATION TO FEAR OF FALLING IN OLDER PERSONS
De Bruin, E., Schweizer, C., Murer, K.
Institute of Human Movement Sciences and Sport, ETH Zurich, Switzerland

Background.
The most common reason for losses in functional capabilities in the aged is inactivity or immobility. Physical activity may, amongst other factors, also be associated with fear of falling. A recent study reported that people with a high fear of falling were more often low active or moderately active compared with people who had no such fears and were more often very active (1). Because data on the reliability of self-reports are limited in older individuals (2) alternative methods are needed for long-term monitoring of daily physical activity and the assessment of motor functioning under real-life conditions. New possibilities for research in prevention and rehabilitation are offered by measurements that quantify physical activity with ambulatory monitoring systems (3). This study aimed at determining the association between quantified walking behavior and fear of falling in older Swiss persons.

Methods.
This was a cross sectional study with a convenience sample of older persons with different living status (independent living, residential settings). Physical activity was measured continuously with a StepWatch Activity Monitor (SAM) during one week. The Falls Efficacy Scale-International (FES-II) was used to determine a person’s fear of falling while performing physical and social activities (4). Sixty-two persons (39 female), aged 82.4 ± 7.1 years, participated in this study.

Results.
The older persons took on average 8678 ± 3928 steps per day (range 2318 – 20308) and had a mean of 20.5 ± 6.2 points on the FES-I (range 16 – 50). Pearson’s Correlation revealed a strong negative relationship between the average total daily steps taken and fear of falling (Pearson’s r = -0.459, p < 0.01). People with high fear of falling were all showing low quantities of daily steps compared with people who had no such fears who were exhibiting a broader range of daily step quantities.

Discussions.
Older persons with high fear of falling possibly restrict their walking activity which is expressed in the the quantity of steps taken. These findings suggest that the quantity of walking activity in older persons should be taken into account in studies that investigate the amount of falls in older populations. Although the relationship between fear of falls and the quantity of walking activity was based on cross-sectional data and, thus, does not imply a causal relationship, we know from previous studies (cf [5]) that people restrict their mobility because of fear of falling. The association between falls efficacy and walking quantity found in this study suggests that clinical rehabilitation programs should also focus on confidence.

LOWERED AEROBIC EXERCISE CAPACITY IS ASSOCIATED WITH IMPAIRED SKELETAL MUSCLE METABOLISM IN PATIENTS WITH METABOLIC SYNDROME
Hokkoaido University, Japan

Background. Low aerobic exercise capacity is an independent, strong predictor for mortality in patients with type 2 diabetes (1). In patients with type 2 diabetes, impaired exercise capacity is related to downregulation of mitochondrial oxidative phosphorylation in skeletal muscle (2). Moreover, insulin resistance is associated with intramyocellular lipid accumulation (3). We thus hypothesized that there might be an intimate link between aerobic exercise capacity and the skeletal muscle proper (mitochondrial oxidative phosphorylation and fatty acid metabolism) in patients with metabolic syndrome (MetS). Methods: The incremental exercise tests with a cycle ergometer were
performed in 11 patients with MetS (age 52 ± 11 years), and 11 age- and sex-matched control subjects. Using 31P magnetic resonance spectroscopy (1H-MRS), phosphomonoesters (P), inorganic phosphorus (Pi), and intracellular pH were measured at rest and during a unilateral plantar flexion (40 times/min for 4 min) with a constant load of 20\% one-repetition-maximum (1RM) in the right calf. Using 1H MRS, intramyocellular lipid (IMCL), an index of the balance between uptake and oxidation of fatty acid) was measured in resting tibialis anterior muscle. Results: Body weight, percent body fat, waist circumference, fasting plasma glucose, insulin, and triglyceride were significantly increased in MetS as compared with controls. HDL-cholesterol was also significantly decreased in MetS. Lean-adjusted anaerobic threshold (ATlean) was significantly decreased (18.0 ± 2.4 vs 22.5 ± 4.3 ml/kg/min, p < 0.01) and maximal phosphomonoesters (P) loss during plantar flexion (denaturing impaired mitochondrial oxidative phosphorylation) was exceeded in MetS (33.5 ± 14.0 vs 21.5 ± 10.5, p < 0.05) without the change of intracellular pH. IMCL was significantly elevated in MetS (IMCL: 4.8 ± 1.4 vs 2.0 ± 1.6 mmol/kg wet weight, p < 0.01). ATlean correlated negatively with maximal PCR loss (r = −0.47, p < 0.05) and IMCL (r = −0.45, p < 0.05), indicating that lowered aerobic exercise capacity was associated with impaired skeletal muscle metabolic properties. There was also a correlation between IMCL and maximal PCR loss (r = 0.50, p < 0.05). Conclusions: Lowered aerobic exercise capacity might be associated with impaired skeletal muscle oxidative phosphorylation and dysregulation of intramyocellular fatty acid metabolism in patients with MetS.

AMBULATORY PERFORMANCE AND COGNITIVE STATUS IN GERIATRIC REHABILITATION

Vogt, L., Wieland, K., Himmelreich, H., Bach, M., Banzer, W.
J.W.Goethe-University Frankfurt/Main, Germany

Introduction: Cognitive impairment could be viewed as one possible obstacle in motor rehabilitation. Due to the significant number of rehabilitation inpatients with cognitive deficits, this study was designed to further explore the effect of the admission cognitive status on gait and stair climbing rehabilitation outcome in geriatric patients. Methods: One hundred seventy nine geriatric patients (female 139; male 40; age: 67-97 years) consecutively admitted to a geriatric inpatient rehabilitation regimen (mean length of stay 28.7±13.9 days) participated in the study. Admission cognitive status was assessed by the Mini-Mental-State Examination (MMSE) and the population stratified in 3 groups: severe (0-17, 34 patients) and mild dementia (18-24, 43 patients) and unimpaired group (25-30, 102 patients). Ambulatory status and stair climbing ability were determined before and after rehabilitation by the Performance-Oriented Mobility Assessment (POMA) and standardized judgments. A POMA score of 19 or less was used for predicting a high risk of falling. An intervention effect of at least 5 points at the individual level of the POMA was defined as the minimum functional gain to emphasize the difference between severely cognitively impaired patients to the cognitively intact patients. The stair test required the subjects to ascend and descend a flight of steps one leg after another as fast and comfortably as possible. Performance was rated on a four-point ordinal scale scoring system based on the subject’s difficulty performing the task and the use of the handrail for support and balance. Results: Approximately 2/3 of all patients demonstrated functional ability improvements of at least 5 points (POMA scale) at the individual level during rehabilitation. The 95%-CI of the overall differences between the POMA admission and discharge scores ranged from 6.1 to 7.5 points (cognitive impairment: 5.4-7.3 severe, 5.8-9.2 mild, 5.6-8.7 unimpaired). However, at rehabilitation discharge cognitively impaired still demonstrated a 3.4 times (95%-CI = 1.4-8.6) higher chance for increased fall risk and only 24% of the cohort was able to negotiate stairs with slight or no limitations. Conclusion: Although cognitively impaired patients demonstrated an functional overall intervention response comparable with cognitively intact patients the present study evidenced that the geriatric cohort with reduced mental status (MMSE < 18) are at greater risk of falling and have a greater need for supervision, both in the hospital and at discharge. Herewith the study further elucidated the relationship between cognitive impairment and functional gain achieved during geriatric rehabilitation. Beside the enhancement of treatment strategies to restore and maintain function in the cognitively impaired longitudinal studies should quantify the number of falls and accident events.

AN ADAPTED ECCENTRIC TRAINING IN THE MANAGEMENT OF CHRONIC LATERAL EPICONDYLAR TENDINOPATHY

Croisier, JL., Foidart, M., Crielvoard, JM., Forthomme, B.
University of LIEGE and CHU Sart Tilman, Belgium

Introduction: Lateral epicondylar tendinopathy represents a frequent overuse injury. In spite of many conservative treatment procedures, that injury frequently entails prolonged symptoms and relapse when returning to offending activities. Aim: To compare the outcome of patients performing an isokinetic eccentric training with that of age-, gender-, activity- matched patients receiving a non strengthening classical rehabilitation. Patients and Methods: 92 patients with unilateral chronic lateral epicondylar tendinopathy (mean duration of symptoms 8 +/- 3 months) were assigned either to a control group (n = 46) or to an eccentrically trained group (n = 46). The control group underwent from a passive standardized rehabilitation excluding strengthening exercises. In addition to this program, the trained group performed eccentric exercises based on the repetitive lengthening of the active musculo-tendinous unit. That program started with submaximal contraction intensity and slow speed movement. Modalities were progressively intensified in intensity contraction and speed movement over a long-lasting treatment. Program effectiveness was assessed through pain score evaluation, disability questionnaire, muscle strength measurement and ultrasonographic examination. Results: Compared to the non-strengthening control group, the eccentric training permitted to observe: (1) a significantly more marked reduction of pain intensity, mainly after one month of treatment, (2) the absence of strength deficit on the involved side through bilateral comparison for the forearm supinator and wrist extensor muscles, (3) an improvement of the tendon image as demonstrated by a frequent decreased thickness and recovered homogenous tendon structure, (4) a more marked improvement of the disability status during occupational, spare time and sports activities. In conclusion, these results highlight the relevance of implementing an isokinetic adapted eccentric training in the management of chronic lateral epicondylar tendinopathy.
THE INFLUENCE OF PROPRIOCEPTION TRAINING ON PERONEAL LATENCY TIME

Dias, A., Esteves, J., Fernandes, O., Pezarat-Correia, P.
Faculty of Human Kinetics, Technical University of Lisbon, Portugal

BACKGROUND: Injuries of the ankle joint, commonly known as ankle sprain, are the most common in sports activities [1][2][3] as well as in everyday life [2]. As such, proprioceptive training is often employed as an effective therapeutic approach for these type of injuries. In addition, proprioceptive training has an important role in the prevention of new injuries. However, until now, the majority of the studies were focused on the prevention of a new injury, lacking results on primary prevention (occurrence of a first injury).

OBJECTIVES: To investigate the effects of proprioceptive training on the onset of peroneal muscle activity in subjects with no history of injuries to the lower extremities.

METHODOLOGY: 34 participants (age = 19.5±1.5), physically active, with no history of injuries in the lower extremities took part in this study and were divided in two groups: experimental (EG) and control (CG). The participants in the experimental group underwent a proprioceptive training programme, with two sessions per week, in a 4-week total, using a wobble board. Reaction time of peroneus longus (PL) and brevis (PB) muscles were measured using surface EMG and a trap-door that opened to a 30° angle of inversion. Measurements were made before and after the training programme.

RESULTS: The reaction time values (ms) were registered before and after the training protocol: for the CG, PL=69.2±11.6 and 67.2±11.1; PB=67.7±12.4 and 66.2±12.7; for the EG, PL= 70.0±14.3 and 66.1±13.4; PB= 69.6±13.5 and 67.6±16.4. Parametric and non-parametric tests showed no significant differences between the control group and the experimental group (p<0.05) before or after the training programme. Nonetheless, a small reduction of onset time occurred with the subjects of the experimental group by the end of the training protocol.

CONCLUSIONS: These findings indicate that the use of a proprioceptive training, two sessions per week for a 4-week period, on physically active subjects, with no history of injuries in the ankle joint, did not cause noteworthy changes on the onset of peroneal muscles activity. The lack of significant changes in the onset of peroneal muscles suggests two possible explanations. The first one is related to the insufficient amount of trainings sessions per week, which weren’t enough to cause a considerable change in peroneal latency time. The second may be due to the fact that the subjects were all physically active, and as such not as susceptible of having a considerable improvement in their peroneal latency time.

OP-TT11 Training and Testing 11 - General

EVALUATION OF GROSS MOTOR SKILLS IN CHILDREN: APPLICATION OF TGMD - 2 IN THE CZECH REPUBLIC

Cepicka, L.
University of West Bohemia, Czech Republic

Gross motor skills are defined as skills that involve the large, force-producing muscles of the trunk, arms, and legs and are used to achieve a movement task or goal such as throwing a ball to a friend or jumping over a puddle (Ultrich, 2000). The measurement of gross motor skills is widely used to identify children with developmental delay as well. The test of Gross Motor Development-2 (TGMD-2) is one of the most employed tools for the examination of developmental delay in motor behavior or disorder in coordination. The test consists of two subtests: locomotor and object control. The aim of the present study was to assess the qualitative gross motor skills performance of children in pre school age. Forty nine children with a mean age of 5.90 years (SD = 0.64) participated; twenty eight were boys (M age = 5.87 years, SD = 0.63), and twenty one were girls (M age = 5.94 years, SD = 0.64). They were recruited from mainstream urban kindergarten. The TGMD-2 was used to assess their gross motor skills. Results show that there are some differences between norm population (U.S. children) and the Czech population. The meaningfulness of the differences can be estimated in many ways. The effect size (ES) was used in this study. There is no difference between Czech and U.S. girls on object control subtest. The difference between Czech and U.S. girls on locomotor subtest has a moderate effect. The ES of differences between Czech and U.S. boys equals to 1.49. It means that the differences of boys’ subsamples have large effect. These results probably indicate that use of standardized American norms of the TGMD-2 cannot be generalized to the Czech population and an additional study is needed on larger sample of children.

THE EFFECT OF PAST PERFORMANCE ON THE PROBABILITY TO SCORE IN A HANDBALL MATCH

Volossovitsch, A., Dumangane, M., Rosati, N.
Faculty of Human Kinetics Technical University of Lisbon, Portugal

Introduction
Spectators and participants in many sports seem to believe that the outcome of sporting actions is related with previous events of the contest. This problem has been widely discussed in studies that focus on “hot hand” and streakiness phenomena, psychological momentum and critical moments. Most of these studies, which have been testing the hypothesis of independence and identical distribution of points scored in the match, were based only on the past performance of the player or team and paid no or little attention to the opponents’ behavior.
Therefore, the purpose of this study was to verify if the past offensive performance of the team and of its opponents influence the probability of scoring in Handball match. It was also tested if this influence is time-varying and if it changes with the match importance (round of championship) and "quality" (based on team's rankings).

**Methods**

The data from 17th, 18th, 19th Men’s Handball World Championship were pooled in a panel database that included information from 224 matches observed by ball possessions (32273 observations). It was assumed that matches were independent and in each match the two teams were modeled symmetrically. The data were used to estimate a dynamic linear probability model for the probability of scoring in a handball match as a function of the past offensive performance of both teams and point difference (dynamic regressors), as well as importance and "quality" of the match (nondynamic regressors). It was tested if the influence of past performance changes during the match. The model has been estimated for two groups of matches with different number of ball possessions (49-57 and 58-66).

**Results**

The results of model estimation suggest that the probability of scoring does not depend on the past offensive performance of the own team, but depends on the past offensive performance of the opponent (the own team defensive performance) and on the point difference in the last ball possession. It was found that the effects of the recent past performance of the opponent and of the point difference on the probability of scoring in Handball are time-varying and influenced by the "quality" and by the pace of the match.

**ANALYSIS OF TACTICAL PERFORMANCE IN TOP LEVEL HANDBALL SETTING THE RELATION BETWEEN TYPE, AREA OF BALL RECOVER AND PATH OF FIRST ATTACKING ACTION**

**Prudente, J., Garganta, J., Anguera, T.**

*University of Madeira, Portugal*

In team sports interactive dynamics team’s behavior and contextual changeability are important features of tactical performance. This study intends to set the relation between type, area of ball recover and path of first attacking action with the ball in top level Handball. The way of ball recovering seems to be an indicator of defensive success, making possible the fast defence/attack transition, increasing situations of numerical and/or spatial team’s advantage and facilitating goal shooting.

The initial stage of the attacking sequence, when a player, after ball recovering, decides to carry or to pass the ball, it is an instant that may constrain the offensive game method to be used, also conditioning the time of opponents to relocate themselves on the playing field, what affects their capacity to counteract. This fact led us to question if handball teams seek to optimize some tactical routines concerning the path of the players and the ball, or, on the contrary, if players performance in interaction with team mates and opponents, may hinder tactical patterns.

To carry out the study, sequential analysis technique was used, aiming to relate the way of ball recover, taking into account the actions of goalkeepers as well as the field players.

The sample includes 3170 offensive sequences, registered in twenty-five games of the final phases of the 2002 European Championship and the 2003 World Championship, involving, in both cases, only teams placed in the top eight positions. In view of the results it seems pertinent to highlight the following: (1) The goalkeeper’s saving of the ball presents a significant probability of inducing ball recover in the goal-area and a pass to the central and lateral areas, near the free-throw line; (2) The ball recover performed by the defenders after disarming or interception, presents a significant probability of occurring at the goal-area and inducing a pass to the central and lateral areas, near the free-throw line.

The analysis of the results makes possible to figure out the probability of ball recover type influencing both the area where this occurs as well as the area towards which the first action with the ball will take place.

**EFFECTS OF MOVEMENT COMPLEXITY ON RHYTHMIC ABILITY**

**Capranaica, L., Iannarilli, F., Losa, M., Vannonzi, G.**

*Istituto Universitario di Scienze Motorie, Italy*

**Introduction**

The evaluation of rhythmic ability, intended as the capability to translate an acoustic perception into a corresponding motor behaviour (Fraisse et al., 1949), focused mainly on tapping. Although artistic sports are based on exercises performed according to rhythmic constraints, there is no information on the relationship between the complexity of a motor behaviour and the individual’s rhythmic ability. Thus, this study aimed at evaluating the rhythmic ability of individuals while performing different motor tasks.

**Methods**

Sixteen (8 men, 8 women) subjects (age: 29±3yrs) with no previous formal rhythmic training were administered a computerized rhythmic test (Perschini & Capranaica, 2004), consisting of two rhythmic sequences (R1 and R2) of 4/4 signature played with a 60 beat/min tempo and one (R3) of 12/8 signature played with a 80 beat/min tempo, having 6, 9, and 8 beats respectively. Actually, R3 presented a more complex signature than R1 and R2, while the beat ratio of R2 was more elaborated than those of R1 and R3. Subjects were asked to reproduce the rhythmic patterns by means of finger tapping on a table (T), stepping with no locomotion (S), and walking (W). A 9-camera Vicon MX stereophotogrammetric system (Vicon®, UK, frequency=120 samples/s) was used to reconstruct the 3D position of 6 retroreflective spherical markers located on the skin. Three parameters were used to evaluate rhythmic performances (0=correct performance): 1) the number of beats (NB); 2) total duration (D); 3) rhythmic ratio among beats (RR).

**Results**

Twelve subjects correctly reproduced NB in the three tests. More frequently, failures were found for R2 (31%) than R1 and R3 (6%), with 19% errors in W and 12% in T and S. Main effects (p<.0001) for test and pattern emerged for D and RR, while the interaction between test and pattern was significant only for D. For patterns, post-hoc showed differences (p<.01) only between R2 (D=1.14 ± 0.69s, RR=0.14±0.10) and the other patterns (R1: D=0.05 ± 0.34s, RR=0.08 ± 0.07; R3: D=0.21 ± 0.46s, RR=0.11±0.11). For tests, post-hoc showed differences (p<.01)
only between W (D=0.78 ± 0.86s, RR=0.18±0.11) and the other tests (T: D=0.16 ± 0.46s, RR: 0.07±0.04; S: D=0.41 ± 0.57s, RR=0.09±0.09). A significant (p=0.048) correlation (r=.52) was observed only between T and S in R.

Conclusions
The results confirmed that rhythmic ability is affected more by the ratio among beats rather the complexity of time signature of the patterns (Persichini & Capranica, 2004). The differences emerging between walking and simpler tasks, and the low correlation between tests indicate that rhythmic ability is specific to the complexity of the movement.

INTERACTIONAL EFFECTS OF BALANCE AND SUCCESS ON THE CRITICAL MOMENTS FROM BASKETBALL GAMES
Ferreira, A., Sampaio, J., Ibañez, S., Volossovich, A.
1 Faculty of Human Kinetics – Technical University of Lisbon (Por); 2 Sport Department – Trás-os-Montes and Alto Douro University (Por); 3 Sport Sciences Faculty – Extremadura University (Spal, Portugal)

The influence of game balance and success on the Critical Moments (CM) from the basketball games seems to have different impacts. Game balance has shown a negligible effect on the quantitative occurrences of CM. However, winning and losing teams presented differences on the number of provoked CM’s particularity during the first three game periods (Ferreira, 2006). Taking account of this independent effect, the present study aims to identify the influence of this interactional effect.

The sequential casuistry of game final score differences (Ferreira et al. 2003, 2006) was used in order to determine and select the CM’s of eighty basketball games. According to expert coaches’ opinions, the games were divided in two main temporal blocks: the first three periods and the fourth period. The crossover of game balance and game success generated four team groups: the winning and losing teams for balanced and unbalanced games. The obtained CM’s for winners losers were studied according to the tempo they occurred per game. After a preliminary parametric exploration of the data, three categories were defined according to the general modal value.

The categories were called Presence of CM, At least 1 CM and More than 1 CM. The winning and losing teams were compared for each period. Despite the differences of 30% differences for the first three periods. The analysis of the adjusted residuals allows to specify the differences in the Absence of CM and the interactional effect of game balance and success is not reflected in the number of critical episodes of basketball balanced games.

Fatigue during intense exercise has been proposed to be a multifactorial phenomenon. Factors such as sarcotemmm depolarization, especially caused by accumulation of extracellular K+, as well as lowered muscle pH and creatine phosphate (CP) have been suggested to be contributing factors in the development of fatigue during repeated intense exercise. Thus, the muscle ion transport proteins are important when discussing fatigue development. The Na+, K+ pump is pivotal in maintaining the muscle membrane potential during exercise and it has in untrained been shown to be up-regulated by different types of exercise training, but little has been done with sprint training in well-trained subjects. In a study, endurance trained subjects replaced their normal training by 30-s sprint runs 3-4 times a week, and after 4 weeks the expression of the muscle Na+, K+ pump α1 subunit and Na+/H+-exchanger isoform 1 was 29 and 30% higher (P<0.05), respectively. Furthermore, plasma [K+] was reduced (P<0.05) during repeated intense running. Performance in a 30-s sprint test, Yo-Yo intermittent recovery test and two supra-maximal exhaustive runs was improved (P<0.05) by 7%, 19%, 27% and 19%, respectively, after the sprint training period, whereas maximum oxygen uptake and 10-K performance time were unchanged. Thus, it appears that the Na+, K+ pump plays a role in control of K+ homeostasis and in the development of fatigue during repeated high-intensity exercise. Furthermore, performance during intense exercise can be improved even with a reduction in training volume if the intensity of training is very high.
EXPLORING THE PSYCHOLOGICAL LIMITS TO HUMAN ACHIEVEMENT

Williams, M.
Liverpool John Moores University, United Kingdom

Many factors contribute to the development of expertise in sport. The contribution of hereditary characteristics and the importance of practice, instruction, and the mentorship of significant others are often debated. The common or lay opinion is that elite performers are born rather than made, creating the perception that less ‘gifted’ athletes may continually strive to reach excellence without making the necessary gains needed to compete at the highest level. However, recent research employing the deliberate practice theoretical framework has indicated that athletes achieve excellence in sport through many hours of deliberate, purposeful practice with the specific intention of improving performance. Typically, performers have to devote in excess of 10,000 hours of practice to achieve excellence, regardless of sport. This commitment and continual engagement in practice is the most important determining factor on the path to excellence. Hereditary factors may also be important in helping elite athletes develop the necessary ‘rage to master’ (i.e., the commitment and motivation to persist in practice over many years). The proposal is that expertise develops as a result of specific adaptations to the movement, and the signal should be filtered individually in each phase, by different filtering techniques. We tested the applicability of these new approximants, by comparing both usual and alternative filtering and smoothing techniques, in 2D kinematics, in order to increase the accuracy of the inverse dynamic approach in the calculations of intra-articular moments and forces. We tested the applicability of these new approximants, by comparing both usual and alternative filtering and smoothing techniques, in 2D kinematic signals collected with a high-speed video camera, during the performance of very demanding jumps from classical ballet. Three professional high level ballet dancers from The National Ballet Company, of Portugal, participated voluntarily in the study. The results show that the uniform treatment of the kinematical signal is not a reasonable strategy. The data must be cut in several phases, according to the movement, and the signal should be filtered individually in each phase, by different filtering techniques.

EFFECT OF SWING VELOCITY ON BALL KICKING PERFORMANCES IN YOUNG MALE SOCCER PLAYERS

Teshima, T., Hosoda, M., Matsuzaki, Y., Tsunoda, N.
Kokushikan University, Japan

The purpose of this study was to investigate an effect of swing velocity on ball kicking performances in Japanese young male soccer players. Two hundred eighty-seven Japanese male soccer players aged from 9 to 22 years old were participated as subject. The subjects were classified four groups (EG: Elementary school students group, n=56; JG: Junior high school students group, n=141; HG: High school students group, n=53; UG: University students group, n=37) based on chronological age. The anthropometric parameters for body height (BH), body weight (BW) and Fat-free mass (FFM) were measured in all subjects. All subjects were performed maximal ball kicking to measure maximal kicked ball distance (BD) by tape measure method. Kicked ball velocity (BV) was measured by Rader Gun IMizuho, Japan in distance of 5m with the three trials. Maximal swing velocity (SV) of the lower limb during ball kicking movement was measured by using a custom made measurement system of movement velocity connected to Speed Meter (VINE, Japan). Ratio of BV to SV (BV/SV ratio) was calculated in each subject.

BH, BW and FFM were significantly increased in each group. However, there was not significant difference between HG and UG in BH. Ball kicking performances were showed higher value in UG than the other groups. BD and BV were significantly differences between
DOES MUSCLE FATIGUE INFLUENCE VERTICAL JUMP LANDING BIOMECHANICS? EFFECTS OF REPETITIVE VERTICAL JUMPING TASK

Mourão, P., Gabriel, R.
(1) Maia Higher Education Institution, Maia, Portugal (l) University of Trás-os-Montes and Alto Douro, Vila Real, Portugal

Successfully practice in any sport requires the domain of many abilities. One of these abilities, present in many sports, is the vertical jump (Tillman et al., 2004). A natural consequence of this ability is the return to the ground knowing as landing which has as objective to absorb the load created during the preceding aerial and propelling phase (Dufek & Bates, 1990). However, despite the many strategies that allow doing it efficiently, the jump landing offers injury risk factors optimal development instances, exposing the subjects to high loads (Madigan & Pidcoe, 2003). This potential is even higher when the structures are affected by fatigue (Gribble et al., 2004; Madigan & Pidcoe, 2003). Hence, our purpose was to assess muscle fatigue influence in jump landing external load.

Twelve healthy subjects (21.33±2.15 years, 61.67±100.68N weight, 168.33±7.86cm height) performed continuous cycles of ten repetitive jumping (starting from a squat position) at a 40 jumps per minute pace, followed by a unilateral dominant lower limb drop-landing (40cm) in a force platform. The subjects were considered fatigue if after failing to maintain jumping rate over three consecutive jumps. For the accomplishment of this study to determine the behaviour differences of the ground reaction forces in the antero-posterior, medio-lateral and vertical components, with and without fatigue influence in jump landing, a Kistler 9281B platform of forces was used and the results were analysed by the computer program Acqknowledge 3.2.6 of BIOPAC Systems.

Our results indicated that our suggested fatigue protocol only influence the posterior component of GRF (maximum value before fatigue: -12.31±9.49%BW, maximum value after fatigue: -23.81±13.65%BW, p<0.013).

Hence, we concluded that fatigue, affecting the peak value of the posterior component of GRF, also challenge antero-posterior joint stability, increasing injury risk.

ENERGY COST, WALKING PATTERN AND WEIGHT LOSS IN OBESE CHILDREN

Peyrot, N., Belli, A., Thivel, D., Isacco, L., Taillardat, M., Duchê, P.
UR Physiologie et Physiopathologie de l’Exercice et Handicap, Université de Saint-Etienne, Médecine du sport et Myologie - CHU Bellevue, 42055 Saint-Etienne Cedex 02, France

During walking, an excessive body mass increases load and inertia of body segments and thus mechanical energy needed to maintain a given speed. As a consequence the energy cost of walking (Cr, respectively in J/m) is higher in obese compared to non obese, in both adults (Foster et al., 1994) and children (Maffeis et al., 1993). However, after weight loss in former obese adults, the relative decrease is higher for Cr than for body weight (Foster et al., 1994). More than a decrease in fat mass, it has been suggested that changes in mechanical gait pattern could be responsible for the additional reduction in energy expenditure (Foster et al. 1994) observed after weight loss. In line with this hypothesis, mechanical differences were observed during walking in obese adults (Browning and Kram, 2007) and children (McGraw et al., 2000, Nantel et al., 2006).

We aimed to further investigate both the metabolic and mechanical changes and their possible relationships, occurring after weight loss in obese children.

Ten obese children (body weight > 95th percentile aged between 13 and 17 were explored before and after a significant body weight loss of 7% due to 4 month dieting. Fat mass (FM, in %) and fat free mass (FFM, in kg) were measured by dual-energy x-ray absorptiometry (DXA, QDR 4000, Hologic inc., Bedford, MA USA). Body mass index (BMI, in kg.m-2) was also calculated. Metabolic and mechanical parameters were measured during walking at 1.25 m/s. Cr was calculated from expired gas measured using a breath-by-breath portable gas analyser (K4b2, COSMED s.r.l., Italy). Tri-axial accelerometer and gyroscope (MTx, Xsens, the Netherlands) fixed at the sacro-lumbar junction was used to asses external mechanical work (Wext, in J/m) and medio-lateral displacement (MLd, in m) of the centre of mass according to Meichtry et al. (2007).

After dieting, significant (Wilcoxon tests, P<0.05) decrease of FM (-22%) and BMI (7%) and increase of FFM (7%) were evidenced. Decrease in Cr (11%), Wext (15%) and MLd (4%) were also observed. Moreover, Cr and Wext were positively correlated (P<0.05) both before and after dieting.

These results show that like in adults, the relative decrease is higher for Cr than for body weight. The 15% decrease in Wext, as well as the Cr and Wext link, further support the possibility that changes in mechanical gait pattern could be responsible for the additional reduction in energy expenditure observed here during walking at 1.25 m/s.

13th ANNUAL CONGRESS OF THE EUROPEAN COLLEGE OF SPORT SCIENCE
THREE-DIMENSIONAL ANALYSIS OF CASCADE JUGGLING: EFFECT OF EXPERIENCE

Romanazzi, M., Galante, D., Paganoni, S., Lovecchio, N., Sforza, C.
Università degli Studi di Milano, Italy

Introduction - Executing a cascade juggling is a complex task, demanding high levels of concentration, attention, and coordination. Motion complexity develops as number of implemented balls grows. Juggling is a cyclic activity, where jugglers move their hands along two nearly elliptical trajectories, one clockwise, the other counter clockwise, at an average phase difference of 180°. The ball is released inside the ellipse, and caught outside. The ball is thrown toward the contralateral hand along a parabolic path subjected to gravity laws. This movement has to be repeated cyclically how as long as possible. Therefore, it is necessary to gain a perfect movement control and a sufficient plasticity for corrections or recoveries, which can only be acquired by practicing (1).

Methods - In the current study, the 3D motion patterns of two groups of jugglers with different levels of experience and ability (6 skilled experts, aged 14-30 y, who could juggle with 7 or more balls, 7 unskilled jugglers aged 17-26 y, who could juggle with 6 or less balls) were compared. Symmetry, repeatability and frequency of execution were analyzed, following the ellipses drawn by the middle fingers of jugglers. Three juggling exercises (basic plays) with 3, 4 or 5 balls were recorded by an optoelectronic motion analyzer working at 120 Hz (2).

Results - More skilled jugglers showed lower execution frequencies than less skilled jugglers (Mann-Whitney's test, p<0.01 in the 3-ball scheme, p<0.05 in the 5-ball scheme). In all juggling exercises, significant differences (p<0.05) were found in the anterior-posterior symmetry of movement (skilled jugglers were less symmetric than less skilled jugglers), while no differences were found in the other directions. Ability significantly influenced movement repeatability in the 4-ball scheme during vertical (p<0.01) and right-left (p<0.05) movements, both in dominant and non-dominant sides, with a larger repeatability in the more skilled jugglers. In the 5-ball cascade, ability influenced more the dominant hand repeatability than the non-dominant one. In contrast, no effects of experience were found for the 3-ball exercise.

Conclusions - Specializing on a highly complicated scheme, like a 7-ball cascade, did not provide any improvement for simpler plays, like a 3-ball scheme. More experienced jugglers can better manage higher throws, gaining time to move balls and to face higher levels of movement imperfections, than less experienced jugglers. They also use higher throws and slower movements for simpler exercises. As predictable, more difficult exercises highlight differences between dominant and non-dominant upper limbs, a factor that has a minor role in low-difficulty exercises.

CHARACTERISTICS OF TRUNK MUSCLES SIZE AND AXIAL ROTATION TORQUE ON DIFFERENT ROTATED POSITIONS IN BASEBALL PLAYERS

Takahashi, Y., Tanaka, S., Kumagawa, D., Tsunoda, N.
Kokushikan University, Japan

Trunk movements are examined in many athletic activities. Above all, it is an important factor for pitching and hitting movements in baseball players. Therefore, this study investigated that the characteristics of trunk muscles size and axial rotation torque on different rotated positions in baseball players.

Twenty male collegiate baseball players (BP, age: 19.6±1.2 yrs, height: 175.1±4.6 cm, body weight: 72.4±7.3 kg) and 10 untrained male students (CON, age: 20.9±1.1 yrs, height: 174.3±7.3 cm, body weight: 64.8±4.3 kg) were served as subjects. The trunk axial rotation torque was measured by isokinetic dynamometer (Biodex system 3, torso rotation test). All the subjects performed trunk axial rotation movement for dominant (DR) and non-dominant (NDR) hand side directions with maximal effort. The position in turn to front of trunk was defined 0 and the position inside the ellipse, and caught outside. The ball is thrown toward the contralateral hand along a parabolic path subjected to gravity laws.

Results - More skilled jugglers showed lower execution frequencies than less skilled jugglers (Mann-Whitney's test, p<0.01 in the 3-ball scheme, p<0.05 in the 5-ball scheme). In all juggling exercises, significant differences (p<0.05) were found in the anterior-posterior symmetry of movement (skilled jugglers were less symmetric than less skilled jugglers), while no differences were found in the other directions. Ability significantly influenced movement repeatability in the 4-ball scheme during vertical (p<0.01) and right-left (p<0.05) movements, both in dominant and non-dominant sides, with a larger repeatability in the more skilled jugglers. In the 5-ball cascade, ability influenced more the dominant hand repeatability than the non-dominant one. In contrast, no effects of experience were found for the 3-ball exercise.

Conclusions - Specializing on a highly complicated scheme, like a 7-ball cascade, did not provide any improvement for simpler plays, like a 3-ball scheme. More experienced jugglers can better manage higher throws, gaining time to move balls and to face higher levels of movement imperfections, than less experienced jugglers. They also use higher throws and slower movements for simpler exercises. As predictable, more difficult exercises highlight differences between dominant and non-dominant upper limbs, a factor that has a minor role in low-difficulty exercises.

MUSCLE STRUCTURAL CHANGES DUE TO ONE YEAR TRAINING IN JAPANESE JUNIOR SPEED SKATERS

Kumagawa, D., Tsunoda, N.
Kokushikan University, Japan

The purpose of this study was to clarify the characteristics of muscle structure and athletic performance due to one year training in Japanese male junior speed skaters. Forty male speed skaters aged from 12 to 17 years old were served as subjects. Subjects were divided in six age groups. All subjects had belonged to speed skating clubs and they performed training of the speed skating all through the year. In this study, muscle thicknesses of the thigh anterior (MTTal), thigh lateral (MTTll), thigh posterior (MTTp), leg anterior (MTLa) and posterior (MTLp) as muscle structural parameter were measured by B-mode ultrasonic method. The mean 500m skating velocity (SV), calculated from the individual best records recently attained, was used as athletic performance.
The significant increases were seen of body height in 12 to 15 yr groups. The skating performances were significant improved in all ages skaters. The significant differences in MTLa and MTtI were observed between before and after training in each group of 12 to 15 yr. However, no significant differences were observed in 16 and 17 yr groups. The MTtI in 16 and 17 yr skaters increased significantly from before to after training. In leg muscles, significant changes in MTLa and MTtI were observed only in 13 and 14 yr. Comparisons of increment ratio in anterior and posterior of the lower limbs muscle thicknesses, the increment ratio of MTtI showed significantly higher values than MTLa in after 15 yr. However, increment ratio of MTtI showed significantly lower values than MTLa in 13yr and 14yr.

The increment ratio of thigh muscle thicknesses and mean skating velocity were significantly correlated in all age groups. However, no significant correlation coefficients were observed between increment ratio of leg muscle thicknesses and mean skating velocity. These results indicated that the effects of speed skate training on lower limbs muscles were differ by each region and developmental stage in junior speed skaters. Moreover, it is considered that the improvement of athletic performance is affect by the structural development of thigh muscles.

KINETICS ADAPTATIONS TO SHORT-TERM SLED TOWING AND SPRINT TRAINING

Alcaraz, P., Elvira, J., Palao, J.
Universidad Católica San Antonio de Murcia, Spain

INTRODUCTION. The use of resisted sprinting techniques is common in athletics and in a variety of sports. However, previous research has focused on studying the kinematics when applying these methods on untrained subjects. As neural adaptations in the neuromuscular system in elite athletes may differ from those adaptations reported for untrained athletes, the results from these studies may not be representative of experienced athletes. The aim of this study was to examine the effects of resisted and unloaded sprint training programs on stride length, frequency, and contact time of the maximum velocity phase on experienced athletes. METHOD: Five female and 12 male national-level athletes with 8-9 years of training experience participated. All athletes participated in a standardized three-week program (sprint, jump, resisted, and resistance training five days per week). Following the standardized program, participants took part in one of two 4-week programs: a) resisted sprint training (RS) (n = 8) with a load of 8% body mass or b) Traditional sprint training (TS) (n = 9). 50-m run pre- and post-tests from the starting blocks were done. A 2D photogrammetric analysis of the run was carried out A high-speed video camera was used operating at 250 Hz. The optical axis of the camera was perpendicular to the direction of running, and the field of view of the camera was zoomed so that the athlete was visible in a 10-m wide region at the 45-m mark of the 50-m run. The trials were digitised using a 22 points model. T-tests for dependent and independent samples were used. RESULTS. The RS group significantly improved the stride length (2.7 ± 2.5%), while the TS group decreased stride contact time (3.5 ± 3.2%) in the maximum velocity phase. In addition, there were between-group significant differences in stride contact time (RS = 2.4 ± 5.4 vs. TS = -3.5 ± 3.2%). CONCLUSION: Resisted sprint training with 8% body mass sled towing for four weeks improves stride length without causing a significant reduction in stride frequency. Traditional sprint training improves stride contact time and maintains the stride length. Caution and supervision must be used for stride contact time in resisted sprint training.

PREDICTING ADDED MASS IN HUMAN SWIMMERS FROM BODY SIZE MEASUREMENTS

Kjendilie, P., Berthelsen, P., Caspersen, C., Eik, M., Pøkøzdi, C.
Norwegian School of Sport Sciences, Norway

Introduction: Added mass is the mass of water a swimmer has to accelerate in addition to his body during changes in velocity. It is an important concept in determining the total energy expenditure of human swimmers during unsteady motion. It is also important to know the added mass when using indirect methods to find a swimmer’s passive drag. As added mass determination is dependent on specific measurement methods often unavailable to the common sports scientist, it would be worth exploring the possibility to estimate AM from body size measurements. The aim of our study was thus to find the added mass for human swimmers and its relationship with body size measures, and to construct predictive linear regression statistics.

Methods: Eleven male adults aged 25.2±4.9 years, 10 females (22.7±3.6 years) and 10 boys (13.7±0.8 years) were included in this study. The subjects were connected to a 2.8m long bar with handles, attached with springs (stiffness k=318N/m) and a force cell. By oscillating this system vertically and registering the time period of oscillations it is possible to find the added mass of the swimmer, given the known distance of the swimmer at the oscillating bar may vary, affecting the added mass to a small degree. It is concluded that a reasonable variation in added mass other variables must be investigated, or is due to measurement errors. The human factor must not be forgotten, including other body size measures such as body width and depth improved the accuracy of this prediction to an r2=0.85. For the rest of the variation in added mass other variables must be investigated, or is due to measurement errors. The human factor must not be forgotten, the position of the swimmer at the oscillating bar may vary, affecting the added mass to a small degree. It is concluded that a reasonable prediction of added mass needs only body mass as input, and is further enhanced by including body with and depth, but not for the females.

Results: A mean added mass of 17.0±3.8kg, corresponding to 26.3±2.9% of body mass was found for the whole group, and 21.4±2.5, 15.0±1.2 and 14.5±3.1kg for the men, women and boys respectively. For the whole group of subjects, an r2 value of 0.79 was reached for linear regression with body mass (BM). Including frontal surface area, reaching height (representing the underwater characteristic length) and fineness ratio did not enhance the r2. Including body width (BW) and body depth (BD) to the regression increased the r2 to 0.85. Added mass (AM) can thus be predicted by: AM=0.22*BM+0.25*BW+0.17*BD-2.4 Looking at males and females separately, r2 was 0.90 for males (including BM, BW and BD) and r2=0.56 for females (including only BMI).

Conclusions: By including body mass in the regression we could explain 79% of the variations in added mass for the whole group. Adding other body size measures such as body width and depth improved the accuracy of this prediction to a r2=0.85. For the rest of the variation in added mass other variables must be investigated, or is due to measurement errors. The human factor must not be forgotten, the position of the swimmer at the oscillating bar may vary, affecting the added mass to a small degree. It is concluded that a reasonable prediction of added mass needs only body mass as input, and is further enhanced by including body with and depth, but not for the females.

ANAEROBIC POWER PRODUCTION CHARACTERISTICS DURING CYCLING EXERCISE WITH DIFFERENT WORK LOAD IN MALE VARSITY ATHLETES
Tanaka, S., Tsunoda, N.
Kokushikan University, Japan

Anaerobic power production capacity is an important factor in any athletic activities. Its power output capacity affected by athletic training mode was reported previously. The purpose of this study was to investigate the anaerobic power production characteristics during cycling exercise on athletes of various events. The subjects were consisted of 11 throwers, 17 sprinters, 34 baseball players, 29 soccer players, 36 kendo players, 29 judo players, and 16 long distance runners and 22 controls. All the athletes were performed muscle training and technical drills of each sports performance throughout the year. Fat free mass (FFM) was measured by body fat analyzer in all the subjects. The maximal anaerobic power (MAP) was obtained by bicycle ergometer (Power max V, Combi co. Japan). Subjects were performed ten seconds with the maximal efforts intermitted of three steps work load, and requested to have warm-up and two minutes rest. Relative maximal anaerobic power to fat free mass (MAP/FFM) was calculated in all the subjects. And also, the relative load and pedalling rate of 2nd and 3rd sets to 1st set were calculated. In addition, times to peak power on each exercise were measured in all the subjects. Throwers showed highest values in MAP among other groups. Lower values in MAP were found in long distance runners whose values were not significantly different from that of controls. On the other hand, MAP/FFM in baseball players and sprinters were showed highest values that of among other groups. MAP/FFM in judo and long distance runners were observed lower values compared with other athletes groups and control. In all the groups, the highest power was obtained the load of the 2nd set. In work load of MAP, throwers was showed highest value that of other groups. And also, pedalling rate of MAP in sprinters was observed highest value. Relative load and pedalling rate of 2nd and 3rd set to 1st set were observed differed by athletic event. Significant differences were observed time to peak power of MAP among the athlete groups. In all the groups, times to peak power of 1st set was faster than that of 2nd and 3rd set. From these results, it was cleared that anaerobic power production capacity on bicycle exercise was differed by the athletic event. Therefore, athletic training mode may affect to the maximal anaerobic power production time and capacity in male athletes.

ALLOMETRICAL ANALYSIS ON THE DEVELOPMENT OF THROWING AND KICKING PERFORMANCES DUE TO PHYSICAL GROWTH IN JAPANESE MALES
Tsunoda, N., Teshima, T., Kumagawa, D., Tanaka, S.
Kokushikan University, Japan

It is well known that development of athletic performance effected by physical growth. However, it was no reported development of differences for athletic performances such as throwing and kicking of the ball to physical growth during Japanese teenage males. Therefore, the purpose of this study was to compare the development of throwing and kicking performances to growth of body height in Japanese males.

The ninety-five baseball players and 99 soccer players aged from 10 to 19 years of old were served as subjects. They trained technical drills of each athletic performance throughout the year. These subjects were devided in five groups according to body height every 10cm. Body height, body weight and fat free mass were measured in all the subjects. Throwing velocity (TV) in the distance of 5m as a throwing performance was measured by radar gun (Mizuno, Japan) in baseball players. And also, kicked ball velocity (KV) as a kicking performance was measured by radar gun in soccer players. These parameters were used allometrical analysis methods to relative development on throwing and kicking performances due to physical growth. The throwing and kicking performances (y) corresponding to body height (x) were plotted on double logarithmic graph to obtain allometric equation y=bx^a, where a is a developmental index and b is constant. The developmental index of TV and KV were higher than 1 for growth index of body height. And also, developmental index of TV was higher value than that of KV. The one sharp bend in the graph showing the relationship between TV and body height. In addition, the one sharp bend in the graph showing the relationship between KV and body height. Accelerated development of TV begins earlier than that of KV in teenage males.

From these results, it was clarified that development of throwing and kicking performances were observed faster than compared with growth of body height. And, these developmental velocities were differed between upper limb and lower limb during teenage males.

INCREMENTAL TREADMILL RUNNING: AN ELECTROMYOGRAPHIC AND METABOLIC ANALYSIS
Gonçalves, M., Silva, S., Silva, P., Fraga, C.
Biomechanics Laboratory – São Paulo State University / LINESP – Rio Claro – São Paulo – Brasil, Brazil

For the muscular fatigue analysis during incremental protocol, the electromyographic (EMG) signal amplitude breakpoint has been analyzed in function of exercise intensities (HUG et al., 2006) or in function of the significant increase on the EMG signal amplitude between the beginning and the end of each stage (HANON et al., 1998). Another methodology using surface EMG called electromyographic fatique threshold (EMGFT) has been used (MATSUMOTO et al., 1991; OLIVEIRA, GONÇALVES, in press). Considering the evident development of protocols aimed at analyzing the surface EMG signal as a non-invasive methodology to analyze the muscular fatigue and also due to the lack of use of incremental treadmill running protocols, the purpose of the present study was to determine the EMGFT of vastus lateralis (VL), vastus medialis (VM), biceps femoris caput longum (BFCL) and gastrocnemius lateralis (GL) muscles and to correlate it with the lactate threshold (LT) and anaerobic threshold (AT). Eighteen male and healthy subjects, physically active, ran to volitional exhaustion on a treadmill during incremental test. The EMG signals were recorded continuously, blood samples were collected from the ear lobe and the heart rate (HR) was directly monitored using a heart rate monitor. The RMs (Root Mean Square) values of each muscle were obtained in each stage for determination of the EMGFT. EMGFT velocities of VL, VM, BFCL and GL muscles correspond to 60%, 54%, 56% and 58% of
the maximum velocity (Vmax), respectively, being similar to LT (60% Vmax), and EMGFT and LT values were significantly lower than AT (77% Vmax). No significant correlation was found between EMGFT and LT / EMGFT and AT values. The present data demonstrate that EMGFT determined through incremental treadmill running test is presented as an aerobic index, being an alternative for the muscular fatigue analysis, however, further studies should be conducted in order to analyze whether it could be used for evaluate performance, prescribe exercise intensities and evaluate training effects, as achieved by the LT and AT.

BIOMECHANICAL ANALYSES AND PREDICTORS OF DIAGONAL STRIDE PERFORMANCE IN ELITE CROSS-COUNTRY SKIERS 

Holmberg, HC., Goejpert, C., Stöggl, T., Müeller, E., Lindinger, S. 

Mid Sweden University, Östersund, Sweden 

Introduction: In cross-country (XC) skiing classical style was the only racing style until the mid 1980s and the main focus of early biomechanical studies was on the diagonal technique (DIAG). With the introduction of the new free style, research became more oriented toward this although both styles have gone through substantial development during the last decade (Smith, 2002). Recently, modern double poling technique has been thoroughly analyzed as regards its biomechanical characteristics and factors related to performance (Holmberg et al., 2005; 2006). However, there is still a lack of biomechanical data describing modern DIAG. Therefore, the aims of the present study were 1) to perform a basic biomechanical description of modern DIAG, and 2) to detect decisive factors related to DIAG performance. Methods: Twelve Swedish elite XC skiers (VO2max-DIAG: 72.3 ± 3.8 ml·kg⁻¹·min⁻¹) performed DIAG roller skiing at a treadmill inclination of 5° at 11 km·h⁻¹ for biomechanical analyses. DIAG performance was defined by time to exhaustion (TIEDIAG) during a DIAG incremental pre-test (4°-11° [1°/min]; with a constant velocity of 11 km·h⁻¹). Leg and arm joint angles (goniometers), pole forces (strain gauge transducers; 2000 Hz) and plantar forces (Pedar Mobile, 100 Hz) were recorded continuously. Correlations between DIAG performance (TIEDIAG) and biomechanical variables was examined using Pearson product-moment correlation coefficient tests (P<0.05). Results: Correlations were found for cycle time and cycle length (r=0.668; P<0.01), cycle rate (r=-0.731; P<0.01), relative foot ground contact time (r=0.658; P<0.05), absolute and relative leg swing time (r=0.756; P<0.01; r=0.638, P<0.05), amplitude and angular velocity of hip angle during leg swing (r=-0.634; r=-0.652; P<0.05), hip angle at ski plant (r=-0.616; P<0.03), absolute and relative hip extension time (gliding phase) (r=0.689; P<0.01; r=0.592, P<0.05), absolute peak foot force (r=0.606, P<0.05), duration and amplitude of the knee angle extension after ski in, e. g. when the skis came in contact with the ground, to the knee angle maximum (r=0.743; r=0.710, P<0.01), rear foot force at minimal hip angle before push-off (r=-0.634; P<0.05), relative (%BW) peak pole force (r=-0.706, P<0.01), pole force at start of forward swing of the opposite leg (r=-0.681; P<0.01), amplitude of elbow extension during poling (r=0.741; P<0.01) and duration of elbow extension after pole out (r=-0.615; P<0.01). Discussion: It can be concluded that better DIAG skiers have 1) a longer and more distinct forward swing in their legs, 2) shorter ground contact, characterised by a lower body position when the skis come into contact with the ground, 3) a more distinct hip and knee angle extension (preparation) just before push-off, 4) a higher absolute production of leg force during push-off and 5) arm work characterised by longer and later peak pole forces (late accentuation). 

THE KINETIC CHAIN OF TENNIS STROKES 

Psalmian, V. 

Comenius University, Slovakia 

INTRODUCTION The kinetic chain is coordinated activation of the body segments which starts with legs, trunk and back, then follows to shoulders, elbows, wrists and ends with the acceleration of the racket. Technique of ground tennis strokes plays a key role in sport performance. PURPOSE The purpose of this study was to obtain new and precise knowledge which can be applied in sport praxis. METHODS Six tennis players in age from 17 to 21 were recorded by 2 synchronized video cameras in two ground tennis strokes (forhand, backhand). This 3D space is real and good enough for understanding of each tennis stroke. 3D biomechanical analysis with the help of software Simi motion allows to find exact values of kinematic parameters RESULTS Hitting technique represented by kinetic chain is stable at our group and strokes of one player have very common characteristics. The interesting differences appeared among tested tennis players but we could find some basic phases which have to be done in same or similar way. We obtained following average results for velocities in contact time (racket and ball): front racket=20,2 m/s, lower racket=10,2 m/s, right wrist=6,6 m/s, right elbow=4,9 m/s, right shoulder=2,3 m/s All this values of playing hand confirm the theory about increasing velocity and acceleration during the stroke. The other hand is also useful and achieves even higher velocities: left wrist=7,2 m/s, left elbow=5,3 m/s and left shoulder=3,1 m/s Excellent kinetic chain has to be connected with very stable body position. This represents very low velocity of forehead (1,3 m/s). The lower part of body must be also very quiet and average velocity of left and right hip, left and right knee, left and right ankle-bone is 1,4 m/s All pre-hitting phase has to be very accelerated but smooth and top level players are able to do some movements corrections in time 0.1 s before contact phase (velocity decrease) with the aim of better timing. Precise and fast footwork during preparing phase is visible at all tennis players but better stabilisation work in contact time brings lower velocities. Very interesting are high acceleration peaks in time about 0,05s before hitting the ball but quite big differences exist in deceleration after this moment. The reason for doing this is accuracy of prepared shot CONCLUSIONS Correct kinetic chain represent optimal tennis technique. Based on our achieved results, we can confirm that 3D biomechanical analysis is an excellent mean for diagnostics of tennis strokes which leads to improvement of personal styles.

A METHOD TO CAPTURE AND MODEL THE GEOMORPHOLOGY OF SNOW SURFACES FOR USE IN BIOMECHANICAL INVESTIGATIONS IN SNOW SPORTS

Gilgien, M., Reid, R., Haugen, P., Smith, G.
Norwegian School of Sport Sciences, Norway

Introduction:
This paper presents a method with which the geomorphology of a snow surface can be measured and modelled in such a way that allows the derivation of local gradients at any location on the captured slope. This methodological description is part of a technique analysis project in which kinematic and kinetic characteristics of alpine skiers were derived from multiple camera views.

Method:
The geomorphology of a 40 m long, 8 m wide and 18.6° inclined investigation area was captured by terrestrial surveillance with a theodolite. Since the snow surface was quite uniform, the distance between the captured points (Pc) was chosen to be approximately 1.5 m. These measured points on the surface (Pc) were triangulated by the method of Delaunay [1] to a preliminary, triangulated surface ('Striangulated'). Since the first derivative of such a surface is discontinuous, we computed a cubic interpolation which was based on and passed through the measured surface points (Pc). For the interpolated surface ('Sinterpolated'), derivatives are continuous [2] and allow the derivation of local gradients area-wide. The interpolated surface was determined with an evenly spaced grid interval of 30 cm. The local gradient at any point Ps on the interpolated surface was derived from the orientation of the plane spanned by the three closest grid points to Ps.

An alternative to 'Sinterpolated' would be the computation of a least-squares plane ('Sleast-square') through the measured points, however it is expected that considerable detail would be lost despite the slope's uniform nature.

Results:
Both 'Sinterpolated' and 'Sleast-square' were determined for the 40 x 8 m area and compared. The mean difference (rms) between the interpolated surface and the least-squares plane was 5.7 cm but was as large as 27 cm. The relatively smooth snow surface had local variability of about 7.6 cm above and below the mean surface level.

We chose to use 'Sinterpolated' for our subsequent analysis as we wished to derive the local gravitational gradient and decompose it into the component that accelerates the skier along the trajectory. Using the interpolated surface points, kinetic analysis was carried out for 2 slalom turns which were part of a longer course.

Discussion:
Determining local characteristics of a snow surface is challenging but can provide detailed information concerning forces acting on the skier during turns across the surface. Surface gradients can be used to better understand the kinetics of ski turning.

KNEE JOINT KINEMATICS AND MODERN ALPINE SKI RACING TECHNIQUE

Haugen, P., Reid, R., Gilgien, M., Brack, A., Smith, G.
Norwegian School of Sport Sciences, Norway

INTRODUCTION: In 1999, Berg et al. [1] reported a range of motion in the knee joint angle of 98 ±11 deg for the outside leg and an average angular velocity of 69 deg/sec in slalom. They observed two periods of knee extension over the turn cycle. Equipment and technique have evolved considerably since the 1990's. In 2005, Kugovnik et al. [2] described the development of technique from the double-motion technique - similar to that observed by Berg et al. - to a single-motion technique which they were able to relate to improved performance.

The purpose of this paper is to describe the knee angle kinematics of a highly-skilled group of skiers using modern equipment and technique.

METHODS: The kinematics of 6 male members of the Norwegian national team were analyzed through 2 turns during a slalom race simulation. The gates were set at a 10 m distance with a 3 m offset on a slope inclination of 18.6 deg. Hip, knee and ankle joint center 3-D positions were determined from 4 panning cameras and calibration control points distributed near the course [3]. The knee angle of the outside leg was calculated using the dot product between the thigh and shank segment vectors. Knee angle data were time-normalized as a percentage of turn cycle. Descriptive statistics and ensemble averages were calculated using all 12 of the analyzed turns.

RESULTS & DISCUSSION: In examining the knee angle ensemble average, a cyclic pattern of knee extension and flexion is apparent, resembling the single-motion technique described by Kugovnik et al. [2]. In the turn initiation phase, knee angles increased from an average (+SD) of 93 ±10 deg at turn-start to reach an initial peak angle of 124 ±10 deg by 35.7 ±6.1% of the turn cycle. Knee angular velocities in this phase varied substantially with an average of 108 ±49 deg/sec. Throughout the main loading phase of the turn, knee angles decreased slowly in an eccentric or quasi-isometric movement for the knee extensors. In some turns, a secondary knee extension was observed in the latter part of this phase, similar to the double-motion technique. During turn completion, knee flexion predominated with an average angular velocity of -120 ±36 deg/sec. By turn-end, the skiers had reached an average angle of 88 ±9 deg.

CONCLUSIONS: When compared to the Berg et al. data [1], the results of this study show a somewhat increased knee joint range of motion as well as increased angular velocities. On average, the pattern of motion resembled the single-motion technique [2], although there were exceptions.

COMPARISON OF THE GROUND REACTION FORCE BETWEEN GAIT WITH DIFFERENT UNIFORMS AND MILITARY MARCH PERFORMED BY OFFICERS

Corrêa, S., Romano, R., Ladeira, A.
University Presbiterian Mackenzie, Brazil

One of the main goals of the current research on military march is to minimize injuries. Boots and the additional weight used by the police officers, due to their uniforms, can lead to an increase of the overload at the joints and modify the normal gait pattern. This study derived from a problem brought out by the Municipal guard guards who during their daily work suffer consequences from the use of all the equipment (uniform, weapon, tonfa, ballistic vest, garrison belt and boots) which adds 6 to 9 kg to body weight. The present study aimed to compare ground reaction force during military march and gait with different uniforms and overloads, analyzing in the vertical axis the peak force in touch down and toe-off phases and the minimum force during the single support phase. The sample was composed by 35 officers of the Municipal Guard being in average 34.3 years old. For the data acquisition an AMTI Platform was used connected to a PC/AT, with acquisition’s software and signals’ processing executed at Windows platform. The subjects walked by the force platform at their natural speed for the three first conditions wearing: physical education uniform, military uniform and boots, complete uniform. In the fourth condition they performed the military march, in the rhythm demanded for taking part in a parade and wearing complete uniform. In order to compare the differences between the trials it was used the statistics ANOVA with Post-hoc of Tukey with significance level of 0.05. The results showed significant differences in peak force at touch down between military march and the other gait trials and in minimum force at single support between military march and complete uniform trial and between this last one and physical education uniform trial, with the complete uniform trial showing a greater value. No differences were found between the trials in peak force at toe-off phase. In relation to the differences in single support we suppose that with the use of tennis and without an additional load the gait is natural what generates a good acceleration during the weight transfer of the contrary leg, what also happens in the military march but with an additional muscular force demanded by the greater rhythm. The difference in peak force at touch down is dependent on the greater velocity imposed by the military march and also due to the knee angle, that must be kept straight during a longer time than in the other trials, what does not allow the natural damping phase. We can conclude that the military march in relation to the other trials has a greater possibility of causing injuries because of the greater peak force at touch down. The other trials that represent the daily movements performed by the officers do not show any significant difference in the gait pattern, only the trial with complete uniform leads to a stride with a greater demand from the leg muscles due to a lower decrease from the vertical force during single support.

COMPARISON OF MUSCULAR ACTIVITY AND GROUND REACTION FORCE BETWEEN LAND BASED AND AQUATIC PLYOMETRIC TRAINING: A PRELIMINARY STUDY

Corrêa, S., Massetto, S., Oliveira, B., Holanda, F., Bonini, F.

University Presbiterian Mackenzie, Brazil

The benefits of jump-specific plyometric exercises have been studied in athletes and non-athletes. This training method has been associated with factors such as increased power output and maximum rate of force development as well as increased muscle fiber size, characteristics likely attributed to the stretch reflex, high eccentric loading, and explosive nature of plyometric exercises. In the last years some authors have described the use of aquatic jumping training as aquatic plyometric training. This training should reduce the impact forces and increase the resistance to the movement. The results suggest that in comparison to the land-based training, the aquatic plyometric training could provide comparable training gains while providing a therapeutic modality for reducing muscle soreness and pain. On water the stress is considerably reduced because of its buoyancy that thus reduces stretch reflex, exercise velocity and the eccentric load over athletes’ joints which seems to generate a different stimulus, with different characteristics from the land-based plyometric training. The aim of this study was to describe and analyze the ground reaction force and the muscular activity of the muscles: rectus femoris, biceps femoris, biceps femoris, tibialis anterior and gastrocnemius during the landing on two different ground conditions, land or swimming pool, after jumping from two different heights (54,7 cm and 73,2 cm). Three Physical Education students took part in this study and were asked to perform three jumps for each condition and height, landing in the force platform and jumping out as quickly and forceful as possible. For the acquisition of the registers a platform and a electromyography of 8 channels (EMG System of Brazil), water resistant and of 12 bits resolution were used, with acquisition’s software and signals’ processing executed at Windows platform. Surface electrodes of bipolar type were used on active EMG interface with amplification of 20 times and were located as the protocol suggested by Delagi (1981). The analyzed values were RMS for each muscle during the contact with the force platform and the peak force during contact after landing from the different conditions and heights. In order to compare the differences between the trials it was used the statistics ANOVA with Post-hoc of Tukey with significance level of 0.05. The results showed significant differences in muscular activity of rectus femoris, biceps femoris and gastrocnemius and also in peak force for the two conditions. Specifically the differences between the two heights, in both conditions, were only found in rectus femoris activity and in peak force. In general the muscular activity was greater in landing in swimming pool while the contrary was found for peak force. Both findings seem to support the studies that propose the use of aquatic plyometric training, but due to the small sample size, the results may not be considered as strong evidence.

ADVANCES IN ELITE FEMALE TRIPLE JUMPING: TIME MANAGEMENT AND VELOCITY PROFILES

Niessen, M., Jürgens, A., Hartmann, U.
University Leipzig, Germany

The progression of female triple jumping (TJ) took place rapidly within the last few years. Since 2000 international championships tenner crosscut TJ results were >14.5m. Achieved distances in TJ depend upon ideal kinetic energy production and conversion into height and distance through approach speed in every take off (TOI) (e.g. Hay 1992). Aim of the study is to describe behaviour and influence of selected approach characteristics of time management (TMI) and horizontal velocity (v (m/s)) profiles in elite female TJ. Numerous competition-velocity profiles were compiled among several elite female TJ during outdoor-seasons between 2002 and 2007 (Niessen et al. 2004): Velocity was registered by a laser distance device (LDM 300CL), placed in approach direction and focussed on lower back of the athlete. Speed curves were edit and filtered by 67p1 moving average of distance & speed (Sport 3.9, LoveDrei). Additional 2D-kinematic video-analysis of side movement was performed (Niessen et al. 2003). Descriptive and group-specific parametric statistics were applied.

Elite female TJ (n=52): performance: 14.3±0.4m achieved maximum velocities (vmax) of 9.0±0.2m/s around 0.6s or 5.5m prior to board. No statistically relevant relationship was noticed between vmax and effective distance (Deff: official plus toe-to-board distance).
FIELD MEASUREMENT OF EMG PATTERNS IN POLE VAULT: A PILOT STUDY

Petrone, N., Marcolin, G.

University of Padova, Italy

The pole vault is a complex spectacular discipline [1,2] involving several types of athlete's skills and a great number of muscle groups whose activation pattern is characteristic during the different stages of the vault. Elite athletes can reach highest results after a proper refinement of their vaulting technique and parallel optimization of their physical performance levels. The activation pattern of a skilled athlete and its timing at the different instants of the pole vaulting event can be seen as an optimized motion pattern to be studied for physical interpretation and training purposes. The high number of muscles involved all over the body requires possibly a portable acquisition device with several channels: the final athlete's back impact on the mat also involves the use of a compact minimally invasive system to avoid disturbs or injuries to the athlete.

The surface EMG activity of 16 muscles (arms [4], shoulders (2), chest (2), quadriceps (2), back (5), and abdomen (1)) was recorded by means of a PDA PockeEMG (BTS-Italy) at a sampling frequency of 1Khz synchronously to video recording from 2 commercial cameras. Three subjects performed a set of indoor vaults aiming to their personal best. Video images were analysed by Dartfish® SW and synchronized to EMG signals. EMG signals were integrated, filtered and plotted against time with corresponding video frames to reveal the coordination patterns of the vaults. The EMG results of this pilot study are the first set of data collected. In the following acquisitions muscle signals will be recorded synchronously with strain data from the pole (2) and the planting box and with 3D motion capture from inertial sensors of the limbs.

DEVELOPMENTAL FACTORS TO THE THROWING AND HITTING PERFORMANCES IN JAPANESE MALE teenager BASEBALL PLAYERS

Miyazaki, M., Izutsu, T., Nakatoh, D., Tanaka, S., Tsunoda, N.

Obirin University, Japan

The aimed of this study was to clarify the developmental factors to the throwing and hitting performance in teenager baseball players. Forty-three male baseball players aged from 12 to 17 years old were requested in this study. These subjects were classified by three groups for every two years (G1: 12-13 years, n=17, G2: 14-15 years, n=15, G3: 16-17 years, n=11). The body height (Bh), body weight (Bw) and fat free mass (FFM) as a body size parameters were measured in all the subjects. The maximal ball velocity of overarm pitched in a exposure time of 1/2000s. The phase of hitting motion analyzed from stride foot contact to ball impact in all the subjects. Hitting ball velocity (Hv) was increased with age groups. Significantly higher value was showed in G3 (33.2±2.3 m/s) compared to other two groups(G1: 26.8±2.3 m/s, G2: 30.0±1.8 m/s). Significant partial correlation coefficient was obtained between Hv and Bh (rxy.z= 0.610, p<0.01). And also, Hv was closely related with FFM (rxy.z= 0.536, p<0.01) in all the subjects.

TO H & S and time management is necessary to individually adjust training and finally TO performance.

COMPARATIVE ANALYSIS OF VERTICAL GROUND REACTION FORCES IN TAP DANCING

Richter, A., Schwameder, H.

University Karlsruhe, Germany

Introduction: Sports floors in general and dance floors in particular are constructed to reduce the impact of heavy loads on the lower extremities in order to prevent injuries (Bowling, 1989; Macintyre & Joy, 2000; Werter, 1985). At this point in time, despite the large variety of different floor constructions, there is a lack of detailed recommendations on how to construct sprung dance floors that decrease the strength of the impact in tap dancing. Vertical ground reaction forces can indicate information on joint loading in general, however it is very difficult to provide accurate force plate data from sprung floors in tap dancing. Therefore, the aim of this study was to investigate if plantar pressure soles (pedar-X, Novel, Munich) can be accurately applied to measure vertical ground reaction forces in tapping on sprung floors.

Methods: 9 tap dancers (19.4 ± 4.2 yrs) performed two different step sequences (flaps and shuffle hop steps). The ground reaction forces were measured simultaneously with pedar-X insoles (100Hz) and two AMTI force plates (1000Hz). The step cadence was given by music (106 bpm). For comparative analysis the average of the peak forces out of 10 steps from each system was calculated for both the left and the right foot per person. Paired t-test and Pearson’s correlation were used for statistical analysis.

Results: The force-time course for both steps (left and right) coincide well for the two systems in the lower and middle range, however, regarding the peak forces, a good correlation can be observed. Looking at the mean differences between the two systems, the pedar peak forces of the two systems were 16.1% (±5.0%) for the flaps and 13.8% (±4.8%) for the shuffle hop steps.

Discussion and conclusion: Due to the technical conditions of the pedar and the AMTI systems, the measured differences in force data was expected. This corresponds with previously reported results (e.g. Barnett et al., 2000). Although the two systems differ significantly regarding the peak forces, a good correlation can be observed. Looking at the mean differences between the two systems, the pedar may not be suitable to measure the absolute forces accurately, however, it supports its use to measure the discrepancy in vertical ground reaction forces of tapping on different sprung floors.

HIGH PRECISION INERTIAL MEASUREMENT FOR TRACKING THE TRAJECTORIES OF SKI JUMPERS; SMART BOOT PROJECT

Virmavirta, M., Nieminen, T., Tarhassaaari, T., Kettunen, L.

*University of Jyväskylä, **Tampere University of Technology, Finland

Measurements of ski jumpers’ trajectory are almost exclusively based on the traditional motion analysis techniques using one or more high speed cameras. Motion analysis studies provide very useful data from ski jumping performance and they have certainly improved the understanding of the factors affecting final result in ski jumping (for review, see Schwameder 2008). However, great number of cameras needed to record the entire ski jumping performance makes the measuring set-up very difficult to accomplish and often limits the area of interest to certain part of the performance only. Synchronization of the cameras and especially calibration of the image space of long distance can not always be done reliably. For example a good pan and tilt high speed camera set-up allows the distance of ~ 40 meters of the flight phase to be recorded accurately (Virmavirta et. al. 2005). Digitizing of ski jumpers in the motion analysis process is very time consuming and the feedback from the analysis is usually available so late that this method can not be considered very helpful in the coaching of the athletes. Therefore a new method for tracking the trajectories of ski jumpers was developed in this smart boot project.

The accuracy of the different measurement devices attached to the jumper (e.g. accelerometers) has been fairly poor as compared to the above mentioned motion analysis techniques and they have had, at least some psychological effects on jumping. However, in this project the development of the high technology devices has provided the package of the measurement system so that ski jumpers do not perceive at all the existence of the measuring system installed in their jumping boots. Cooperation with the ski jumping boot factory Jalas, Finland made it possible that this in-baked system consists of its own computer with memory, accelerometers and gyroscopes. The high accuracy of the accelerometers is based on the special modelling of the sensors and the positions, orientations, and parameters of the sensor box were determined by placing the box in three orthogonal positions on the special calibration table with maximum rotating speed of 6000 rpm. The data collection of the system is automatically started when ski jumpers secure their ski bindings before the jump. Since the trajectory of ski jumping boots coincides exactly with the inrun tracks of the jumping hill, the GPS real time kinematic (RTK) measurement of the inrun profile provides a good reference for the measured data.

Preliminary results showed that smart boot measures the information from the ski jumping performance very accurately and independently without disturbing the performance of ski jumpers. Ski jumpers’ position can be measured with the accuracy of the RTK measurement, i.e., in the level of centimetres.

THE CHANGES OF BALL VELOCITY AND MOTION WITH WINDMILL PITCH TRAINING FOR SOFTBALL

Kitagawa, Y., Kumagawa, D., Tanaka, S., Tsunoda, N.

Kokushikan University, Japan

Windmill pitching performance such as ball velocity and accuracy are important factors in the softball game. There were no reports of windmill pitch training for softball. The purpose of this study was to clarify the role of training the windmill pitching performance in Japanese male.
The subjects were 6 males (age: 25.5±1.0 yrs, height: 173.7±1.3cm, body weight: 85.1±1.9 kg). The training program consisted of 18 training days to two or three days in a week with two months. Subjects were trained windmill pitch for 50 pitching. Pitching motion on before and after training recorded by two high-speed cameras, and analyzed by computer with 3-D analysis software. The phase on pitching motion analyzed from leg takeoff to ball release, and pitching motion phase analyzed start to top (ST) and top to release (TR) in all the subjects. The maximal ball velocity was measured in the distances of 13.1m both before and after training. The all subjects were performed to 3 fastballs pitch with maximal effort. The velocities of elbow and wrist joints on pitching motion were analyzed on before and after training. And also, mean accelerations of the pitched ball and pitching motion time were calculated in ST and TR respectively.

The maximum ball velocity in after training (21.0±0.9 m/sec) was significantly higher than that of before training (18.9±1.2 m/sec). And also, significant difference on elbow joint velocity was observed between before and after training.

In TR, mean accelerations of the pitched ball in after training (82.5±7.8 m2/sec) was clearly changed compared to the before training (62.0±9.1 m2/sec). In addition, the motion time of after training (0.190±0.012 sec) was significantly shorter than that of before training (0.245±0.026 sec). However, these parameters in ST were not significant difference.

From these results, it was considered that the velocity of ball and motion time were dependent on pitching training times. There for more long terms training was necessary to improvement of windmill throwing performance.

THE EFFECTS OF EXTERNAL LOADING ON THE HEIGHT AND MAXIMAL VELOCITY IN-WATER AND DRY-LAND VERTICAL JUMPS BY WATER POLO GOAL KEEPERS: PRELIMINARY RESULTS
Masseto, S., Corrêa, S., Teixeira, S., Romano, R., Guimarães, G.
Universidade Presbíteriana Mackenzie, Brazil

Platanou (2005) described that the performance of the water polo athletes in the water vertical jump correlates poorly with the height assessed in the dry-land vertical jump. However, for goal keepers this can be an important variable because these athletes need to jump high greats and train with heavier loads than the others players. Thus, many coaches have applied external loading during jump training, performed in dry-land and in water. This paper described preliminary results of the effects of external loading on the height and maximal velocity attained by water polo goal keepers in vertical jumps performed in land and in water. Three goal keepers (1 female; 2 male) from the national team volunteered to take part in this study. In dry-land the maximal height was assessed by the use of a jump test platform that automatically calculated this variable from the time spent in the air and was placed over the force platform. The acceleration of the body was calculated using vertical force and body mass. Vertical velocity was subsequently determined by integrating the acceleration. The jumps were performed from a squat position with the heels on the platform and the thighs in a horizontal position. Lower limb counter-movement and swinging of the arms were not allowed; the participants grasped the collar of their shirts with their hands. In water the subjects performed the jump in the middle of the goal bars, without support, and with flexed arms, raised out of the water. They were filmed by two digital cameras (60 Hz) after receiving a reflective mark at the forehead. The difference between the heights of the mark at the initial position of the jump and the highest point achieved was calculated after using an automatic tracking system of this mark and the maximal velocity was obtained from a derivative of this mark. The participants jumped with no load (0%), or an external load corresponding to 5%, 10% or 15% of their relevant body weight. The loads were distributed on the trunk in accordance with previous standardization (Driss et al., 2001). They performed three vertical jumps at each load with at least 90s between jumps in random order. The results showed a high correlation between water and dry-land conditions for the four different loads (r=0.64), with the values between the subjects varying from r=0.86 (female) to r=0.73, r=0.67 for males. However, the correlation values between the maximum velocity developed by the athletes in both conditions varied a lot between the subjects, showing a correlation for the female (r=0.58) and no correlation for the males (r=0.22, r=0.11). We know that the movements in water are dependent from active drag and buoyancy forces, both are influenced by body density, body shape and drag is related to the squared velocity. All these parameters together have influence on the velocity and the height achieved, but it seems that the technique used can somehow interfere in the performance.

BIOMECHANICS OF GAIT ANALYSIS IN OBSESE AND NON OBSESE DOWN SYNDROME YOUNG ADULTS - KINEMATIC ANALYSIS
Pinho, JP., Oliveira, G., Fonseca, M., Sousa, F.
Faculdade de Desporto da Universidade do Porto, Portugal

Down syndrome (DS) is one of the most common chromosomal disorders and it is estimated that it affects one in 550 born babies. The most common characteristics that this population has are a variety of musculoskeletal and neuromuscular disorders such as hypotonia, ligament laxity, insufficient muscular stability and strength that influence the quality of gait¹. Overweight and obesity are other common characteristics that can influence their gait pattern² but only a few studies seem to have considered this factor as one that influences quality of DS population. The purpose of this study was to analyze gait characteristics of adults with Down syndrome and understand how obesity can influence their gait pattern. Four groups of 4 participants of both genders were formed and matched by the Body Mass Index (BMI) and age. Down Syndrome group (DS) mean age 27.8 ± 5.7 and BMI of 22.1 ± 2.5; Obese Down Syndrome group (ODS) mean age 34 ± 1.4 and BMI of 32.5 ± 2.6, Normal Control group (NC) mean age 24 ± 2 ± 2.2 and BMI of 23.4 ± 1.6; Obese Control group (OC) mean age 29 ± 2 ± 3.1 and BMI of 34.5 ± 1. Twenty-two spherical passive reflective markers were secure over standard anatomical landmarks and Kinematic data were obtained from two 50Hz digital video cameras. All participants walked with self-selected speeds for 5 times on 5-meter walkway and the 3 best trials of each participant were analyzed. APAS (Ariel Performance Analyzing System) software was used to analyze the kinematical data. Time spent in stance phase (percentage) was: ODS 70.6±14; DS 62.8±15; OC 62.5±2; NC 62.1±6 and the time spent in swing phase (percentage) was: ODS 29.4±4; DS 37.2±8; OC 37.5±3; NC 37.9±2. The mean cadence (strides per minute) was: ODS 144.1±7.8; DS 145.7±9.4; OC 149.5±1.7; NC 148.2±1.2. The mean stride length (m) was: ODS 0.71 ±0.2; DS 0.89±0.1; OC 1.25±0.2; NC 1.26±0.1. The vertical displacement of the Centre of Gravity (m) was: ODS 0.029±0.006; DS 0.037±0.009; OC 0.057±0.017; NC 0.04±0.006. The calcaneus elevation (m) was: ODS 0.099±0.021; DS 0.125±0.02; OC 0.194±0.023; NC 0.215±0.019. In persons with DS, where the syndrome itself may stigmatize the person, obesity can further limit the capacity to participate in social, recreational, and athletic activities that are so important for physical and emotional development. The main results of this study suggest that people with Down Syndrome reveals abnormalities in their gait patterns that are even
more constrained by increasing BMI, assuming harmful motor consequences. It is of fundamental importance a greater awareness so that DS population avoids obesity in order to improve their quality of life.

SOLEUS MOTOR UNIT FIRING BEHAVIOR DURING RAMP AND CONSTANT FORCE CONDITIONS
Kallio, J., Holmes, M., Sogarda, K., Avela, J., Komi, P., Linnamo, V.
Neuromuscular Research Center, Finland

Muscle force can be increased by recruiting inactive motor units or by increasing the firing rate of active units. The strategy to control muscle force varies according to activation level and contraction type. In small hand muscles with constant force levels there are fluctuations in force and also in motor unit firing rate (Lippold et al. 1957, Stephens and Taylor 1974, Taylor et al. 2003). The purpose of the study was to investigate whether these fluctuations would be observed also in Soleus motor unit firing behavior during varying and constant force contractions.

Six subjects performed isometric plantar flexions while seated in an ankle ergometer. Motor unit activity was recorded with wire electrodes and decomposed using Daisy-software (Olsen et al. 2001). The tasks consisted of ramp (RFI) and constant force (CFI) contractions of 10 and 20% MVC.

The mean firing rate of 12 motor units during CFI was 7.03pps and 8.74 pps at 10% and 20% of MVC, respectively. For the RFI the corresponding mean FR were higher with 7.22 (P<0.001) and 9.46 (P=0.02) pps. In addition, more MUs were active and there were more fluctuations during ramp contractions when compared to the same target force level in CFI. There were no differences in RMS values calculated from the antagonist (TA) and synergist (MG) surface EMG between contraction modes.

Several studies have found a derecruitment and decrease in firing rate during the initial stage of CF contractions (e.g. De Luca et al. 1996), which was supported by the present findings. As there was no difference in antagonist/synergist muscle activity, it can be concluded that differences in firing rates between the two contraction types are due to the use of different neural strategies employed by the CNS specific to the Soleus, a muscle that plays an important role in movement and balance control. This is further supported by the higher number of MUs recruited during a RFI contraction relative to a CFI and the differences in firing rate variability of the same motor units in the two tasks.

COMPARISON OF NEUROMUSCULAR ACTIVATION TO MAINTAIN POSTURAL STABILITY DURING DOUBLE LEG AND SINGLE LEG STANCE BETWEEN GENDERS
Fernandes, O., Lucio, E., Carromeu, C., Jerónimo, T., Cortes, N.
Universidade de Evora, Portugal

Introduction: Postural control can be defined as the ability to maintain equilibrium in a quiet-standing position. This control is kept by the sensor-motor system, which integrates visual, vestibular, and somato-sensory information. The resultant oscillation is normally performed in a smooth and controlled way. The purpose of this study is to assess neuromuscular activation differences between male and female of the tibialis anterior (TA) and soleus (SOL) and center of pressure (COP) oscillation during quiet-standing positions, and to assess whether these fluctuations would be observed also in Soleus motor unit firing behavior during varying and constant force contractions.

The mean firing rate of 12 motor units during CFI was 7.03pps and 8.74 pps at 10% and 20% of MVC, respectively. For the RFI the corresponding mean FR were higher with 7.22 (P<0.001) and 9.46 (P=0.02) pps. In addition, more MUs were active and there were more fluctuations during ramp contractions when compared to the same target force level in CFI. There were no differences in RMS values calculated from the antagonist (TA) and synergist (MG) surface EMG between contraction modes.

Several studies have found a derecruitment and decrease in firing rate during the initial stage of CF contractions (e.g. De Luca et al. 1996), which was supported by the present findings. As there was no difference in antagonist/synergist muscle activity, it can be concluded that differences in firing rates between the two contraction types are due to the use of different neural strategies employed by the CNS specific to the Soleus, a muscle that plays an important role in movement and balance control. This is further supported by the higher number of MUs recruited during a RFI contraction relative to a CFI and the differences in firing rate variability of the same motor units in the two tasks.

BILATERAL DEFICIT IN MUSCULAR POWER AND EMG DURING MULTI-JOINT ISOKINETIC LEG EXTENSION MOVEMENTS UNDER DIFFERENT CONSTANT SPEEDS
Ryo, Y., Kazuo, F.
Graduate school, Japan

Purpose

13TH ANNUAL CONGRESS OF THE EUROPEAN COLLEGE OF SPORT SCIENCE
Bilateral deficit (BLD) is known as a decrease in maximum contraction muscle force during both limbs acting simultaneously (bilateral contractions) compared with the sum of the forces produced during each limb separately (unilateral contractions). The purpose of this study was to examine the characteristics of BLD in muscular power and muscle activation during multi-joint isokinetic leg extension movements.

**Methods**

BLD was measured using leg extension power (LEGPOWER, Takei co., Ltd., Japan) under following two protocols: 1) 46 males (20.7±1.9 years) at the velocity of 0.2 and 1.0 m/s. 2) 9 males (20.7±1.3 years) at the velocity of 0.2, 0.6 and 1.0 m/s along with EMG recordings. EMG recorded from 6 muscles such as GM, RF, VL, BF, BF1, LG. EMG data were integrated (iEMG) after full wave rectified. In these two experiments, bilateral index (BLI) was calculated by mean power and iEMG to define for BLD in a following equation. BLI%=[100×(bilateral/unilateral)-100 (Haward and Enoka, 1991)]. When BLI showed a negative value, it reflects a BLD.

**Results**

In protocol 1, BLI of mean power were 65293;9.2±6.7% in 0.2m/s, 65293;19.5±9.3% in 1.0m/s. BLI was significantly greater in 1.0m/s than 0.2m/s;65293;56.8±6.3% in 0.2m/s;65293;14.6±7.5% in 0.6m/s;65293;10.5±7.4% in 1.0m/s;1478±236% were smaller than unilateral contractions (0.2m/s;530±88W, 0.6m/s;1246±197W, 1.0m/s;1826±232W) at each velocities (p<0.001). BLI were 65293;3.9±2.2% in 0.2m/s,65293;10.5±6.1% in 0.6m/s,65293;19.1±8.0% in 1.0m/s. There is significantly different between 0.2m/s and 1.0m/s;65293;1.0±6.3% in 1.0m/s;19.1±8.0% in 1.0m/s. There is significantly different between 0.2m/s and 1.0m/s;65293;46.8±6.3% in 0.2m/s;65293;15.0±6.1% in 0.6m/s;65293;19.1±8.0% in 1.0m/s. when significantly different between 0.2m/s and 1.0m/s;65293;14.6±7.5% in 0.6m/s;65293;10.5±7.4% in 1.0m/s;1478±236% were smaller than unilateral contractions (0.2m/s;530±88W, 0.6m/s;1246±197W, 1.0m/s;1826±232W) at each velocities (p<0.001).

**Conclusions**

The main findings of this study were 1) BLD was existed during multi-joint isokinetic contractions, and BLD depend on velocity of movement. 2) Muscle activations were smaller in bilateral contractions than unilateral contractions.

**LOWER LIMB SYMMETRY DURING RHYTHMIC LATERAL STEPPING**

Rousanoglou, E., Tampaki, A., Boudalos, K.

National & Kapodistrian University of Athens, Greece

Lower limb symmetry is usually assumed for simplicity of data collection and analysis, however few studies have actually reported this symmetry using quantitative biomechanical data, where both limbs were evaluated (Sadeghi, et al., 2000). The purpose of this study was to investigate the lower limb symmetry during rhythmic lateral stepping. Twelve participants (18.7±0.3 yrs, 66.3±9.0 kg, 167.5±7.8 cm) performed series of lateral steps with the leading foot contacting a forceplate (Kistler 9881, 250 Hz). One cycle of movement included one step to the right (RS) followed by one step to the left (LS) (leading foot right). Trials were performed with the RF leading as well with the LF leading (randomized order of the leading foot). All trials were recorded with a camera (Panasonic HK-600) for kinematic analysis of the step length (Lstep). Trials were performed in preferred stepping frequency (PSF) and in two frequencies set by an external rhythmic stimulus (as lower (LFS:82 beats/minute) and higher (HFS:144 beats/minute) than the PFS, respectively (Rousanoglou & Boudalos, 2006). The kinetic parameters determined were the duration of the cycle of movement (tcycle), duration of contact (tccontact), the vertical impulse (Fzimpulse). All parameters were determined for the leading foot, for a series of 14 cycles of movement. The individual mean value, standard deviation (SD) and coefficient of variation (CV%) during the 14 cycles were calculated. Finally the group means (average of individual values) were estimated for each parameter and inserted for statistical analysis. Student paired t-tests were applied for the differences between LF and RF, separately in each stepping frequency (ps<0.05). The significant kinetic differences were found for mean tcycle in LPS (RF:3.979±0.008s, LF:3.972±0.009s, p=0.009), SD and CV% of Fzimpulse in PSF (RF:20.4±7.5s, LF:22.5±7s, p=0.042 and RF:2.9±0.3%, LF:3.4±0.7%, p=0.026, respectively) and mean tcycle in HPS (RF:62.8±12N.s, LF:60.4±7.2N.s, p=0.005). No significant difference was found for Lstep (ps>0.05). These results show that although there was a consistent spatial symmetry, as shown by the same Lstep in both limbs, in all three stepping frequencies, kinetic performance was not always symmetrical. Moreover, stepping frequency appears to alter the kinetic symmetry. Thus for a global apprehension of lower limb symmetry, a combination of parameters that reflect the cause (force), timing of force, the effect (step length) as well as the frequency of the movement should probably be used.

**PP-HF04 Health and Fitness 4**

**THE DISEASES OF THE MUSCULOSKELETAL SYSTEM AND CONSCRIPTS’ PHYSICAL READINESS RELATED TO THIS IN THE UNIT OF THE ESTONIAN ARMY**

Antson, H., Märks, H.

The Estonian Defence Forces, University of Tallinn, Estonia

All soldiers in the Estonian Defence Forces must take the Army Physical Fitness Test (APFT) regardless of their age. The APFT is a three-event (push-ups, sit-ups, 2-mile run) physical performance test used to assess muscular endurance and cardio respiratory (CR) fitness. Individuals’ disabilities and health related problems are detected during medical examination carried out before entering into service. The aim of the current paper is to elicit the relationship between the findings of the medical examination of conscripts before entering into service and the results of their first and second physical test at their Military Post in 2007. 613 male conscripts, aged 18 to 22 participated in the survey. Soldiers are divided on the basis of their health condition into two groups: healthy, and healthy with restrictions. The medical records of the freshmen and their APFT results in the beginning (the first test) and at the end (the second test) of the basic training course, as well as their physical progress, were analysed. Diseases of the musculoskeletal system and its connective tissues are considered to be a rather common health problem (49% of all diseases) among freshmen. The occurrence of musculoskeletal problems among conscripts was highest among the following: other acquired deformities of limbs 35%, scoliosis 17%, dorsalgia 12%, kyphosis and lordosis 4%, spinal osteochondrosis 3%, other juvenile osteochondrosis 3%. The correlation analysis revealed some significant relations. There was a connection between the health group of the soldiers and the results of their physical tests. It appeared that 50% of the healthy soldiers did not participate in the APFT.
not perform positively in their first APFT in the beginning of the soldier’ basic course whereas this indicator for the conscripts within the category healthy with restrictions was 65%. 5% of the healthy soldiers and 20% of the soldiers within the group healthy with restrictions did not pass the second APFT. The physical test development dynamics of the soldier group healthy with restriction has weekly correlated with the average physical test development dynamics of the last five years (r= 0.18 , p<0.05). The soldiers’ group healthy does not deviate significantly from normal average dynamics (r=0.87, p<0.05).

BONE-MUSCLE BALANCE AND BONE DIMENSION IN ATHLETES AND NON-ATHLETES OF BOTH GENDERS

Belfort, D., Baptista, F.
Faculty of Human Movement, Technical University of Lisbon, Portugal

Previous works suggest that lean mass is an important determinant of bone mineral in both genders. Nevertheless there is lack of research respecting the balance between bone and lean mass and the influence of lean mass on bone dimensions. Purpose: To compare bone mineral content (BMC), bone area (BA), BMC and BA for lean mass (LM), and BMC and BA for body height, in athletes and non-athletes of both genders. Methods: Subjects were 262 athletics, 122 female (18 ±5.4 yrs; 21.8 ±2.2 kg/m²), and 140 males (18 ±5.9 yrs; 22.9 ±2.3 kg/m²), and 527 non-athletics, 290 female (17.7 ±5.9 yrs; 23.0 ±4.4 kg/m²), and 237 males (17.9 ±4.8 yrs; 23.0 ±4.2 kg/m²), with an age range from 10 to 33 years. BMC, BA and LM of total body were evaluated by dual x-ray absorptiometry. Standing height was measured on a stadiometer. Analysis of covariance (ANCOVA) was used to analyze the main and interaction effects of condition (athlete vs. non-athlete) and gender (male vs. female) on BMC, BA, BMC/LM, BA/LM, BMC/body height and BA/body height. Analysis of BMC and BA were adjusted for body weight and height, BMC/LM and BA/LM were adjusted for body height, and BMC/body height and BA/body height were adjusted for body weight. Results: It was observed a condition main effect with athletes presenting higher values than non-athletes on BMC (1.019 ±±17.1 vs. 1.233 ±9.3 ±2.2 g, p<0.001), BA (1.205 ±8.67 vs. 1.960 ±4.9 ±2cm, p<0.001), BMC/body height (15.9 ±0.1 vs. 14.1 ±0.7 cm/cm, p<0.001) and BA/body height (11.5 ±0.03 vs. 11.9 ±0.02 cm/cm, p<0.001). A gender main effect was also observed with males having higher values than females on BMC (2.561 ±15 vs. 2.390 ±16 g, p<0.001), BA (2.026 ±5 vs. 1.986 ±6 ±2cm, p<0.001), BMC/body height (15.5 ±0.1 vs. 14.5 ±0.1 cm/cm, p<0.001), and BA/body height (12.2 ±0.03 vs. 12.1 ±0.03 cm/cm, p<0.001), and females demonstrating higher values than males on BMC/LM (6.0 ±0.7 vs. 5.1 ±0.7 ±g/kg, p<0.001) and BA/LM (5.0 ±0. ±6 vs. 4.2 ±3.±6 ±cm²/kg, p<0.001). A significant or almost significant interaction effect was found on BA (p=0.004), and BA/body height (p=0.094), with athletic females revealing a proportionally higher bone width than other groups. Conclusion: Despite highest values of BMC, BA and LM in athletes than in non-athletes, and in males compared to females, muscle-bone balance, namely, BMC/LM and BA/LM ratios were similar between athletes and non-athletes and higher in males than in females. Regarding bone width, females benefited more than males from sports commitment. This study provides evidence for an important contribution of lean mass (a surrogate of muscle mass) and sport engagement on BMC and bone width, and particularly in women compared to men.

BODY IDEAL OF BRAZILIAN AND PORTUGUESE FEMALE RECREATIONAL BODYBUILDERS

Pedretti, A., Silva, R., Vasconcelos, O.
Porto University, Portugal

Physical appearance is very important for human development (Cash, 1990), because the body is the kernel of all human actions (Loy, 1991). Garganta (2000) highlight that our actual society idealizes ectomorph morphologies for women. Some studies have showed that women very often experience body dissatisfaction with a strict desire for leanness (Harrison, 2000). American women show up negatively in relation to body dissatisfaction and desire for extremely thinness, followed by the European and Asiatic women (Pedretti, 2008). The emergence of a more muscular woman ideal in 80’s, permit the practice of weight training and bodybuilding more acceptable for women very often experience body dissatisfaction with a strict desire for leanness (Harrison, 2000). American women show up negatively in relation to a more mesomorph or less endomorph body ideal, as well as other anthropometric variables, are discussed.

PERCEPTION OF CLIMACTERIC SYMPTOMS OF BRAZILIAN WOMEN OF A MUNICIPAL PHYSICAL ACTIVITY PROGRAM

Ramos, L., Domingos, P.
Foundation of Superior Education of Passos, University of the State of Minas Gerais, Passos, Brazil

Background: The climacteric is a process of physical and emotional changes for the woman, which receives the influence of many factors, such as personal and familiar history, environment, culture, customs and personal peculiarities, among others. Objective: To assess the menopausal symptoms of women members from a municipal program of physical activity. Methods: This study included 30 climac-
Mild and only 3.3% reported severe. Conclusion: Despite of the mild intensity of the physical activities offered in this municipal program, there was a benefit in climacteric symptoms, highlighting the social importance of exercise, which promotes social integration, improves quality of life and increases the welfare physical and mental. Efforts should be directed to develop researches involving the perception of climacteric symptoms in women and the influence of various factors on this perception and to promote a construction of public policies that highlight the importance of physical activity in promoting health through preventive measures and educational practice.

ASSESSMENT OF WOMEN'S SELECTED FUNCTIONAL PARAMETERS IN BMI CATEGORIES
Ignasiak, Z., Slawinska, T., Domaradzki, J., Rozek, K.
University School of Physical Education, Poland

Obesity is one of the most important factors of the risk of disasters especially in circulatory system and the reason of metabolic disease (Gibbons at all 1983, Morrow at all 1995, Ignasiak, Domaradzki 2003). Sedentary lifestyle and excessive food consumption characteristic for rich societies results in the growth of fat tissue. The aim of the work was the assessment of women's' selected functional parameters in BMI categories. The urban women were examined in our studies. They were divided into two groups on the basis of BMI level. The first group (n=40) consists of women with BMI in normal category (the mean BMI=22.4±4). The second group (n=32) consists of women with BMI in obesity category (the mean BMI=33.9±9). Hemodynamic parameters, functional parameters of the respiratory system and parameters of body posture were measured. Results show that differences between women with normal and higher BMI in body weight, BMI but also body height and normative BMI were statistically significance. Obese women have higher blood pressure, but parameters don't exceed the limit of the norm. Additionally women with lower BMI have better values of heart work index (HWI) as well as vital capacity (VC) and forced vital capacity (FVC).

Cervical spine lordosis and thoracic spine kyphosis were similar in both groups of women. The only body posture parameter discriminating women with normal and abnormal BMI is lumbar spine lordosis and the difference is statistically significant. We suppose that it can be related to more spine load by abdominal fat tissue. As the conclusion we can say the higher BMI the worse vital parameters of the organism.

MEASUREMENT OF OXYGEN CONSUMPTION OF INDOOR WALKING WITH A DOUBLE TREADLES TREADMILL VS TRADITIONAL TREADMILL
De Angelis, M., Benvenuti, P., Simonetta, S., Cecchinelli, F., Zanuso, S.
*Faculty of Human Movement and Sport Science, Univ of L’Aquila, **Faculty of Motor Science, Univ of Urbino, **Dept of Motor Science, Univ of Padova, *Medical Scientific Research Dept, Technogym Spa, Italy

Introduction:
Treadmill walking have been largely used for calories burning. In the last years several news devices have been introduced to give alternatives to the more traditional treadmill. Recently, a new equipment (TreadClimber®) for indoor walking has been produced. It consists in a doubled deck treadmill in which there is a dual action motion of the treadles due to the alternate supporting phase during walking. So far there is no evidence that this kind of exercise can determinate a different energy expenditure than traditional treadmill walking.

Aims
The aim of this study was to measure oxygen consumption (VO2) during walking on this new equipment and to compare the values with walking on a traditional treadmill, at the same speed and grade.

Methods
12 subjects, 6 males and 6 females (30.2 ± 5.7 yrs, 173.7 ± 9.4 cm, 72.2 ± 10.8 kg), after familiarization on both the devices, in 4 separate days walked for 6 minutes 8 times on a TreadClimber® (ITC916, Nautilus®, USA) and 6 times on a professional treadmill (Run 900 Exctile, Technogym Spa, Italy) at different speeds and grades. For both the devices 3 and 5 km-h-1 were used. For treadmill 8, 10 and 12 % of slope were used. For TreadClimber, in which a minimum and a maximum setting is possible to operate on the slope, the real slope was measured without the use on handlebars were studied. During the sessions VO2 (QuarkB2, Cosmed srl, Italy) was measured. Statistical analysis was performed with t-test to check the significance of regression coefficients.

Results
No statistical differences were found between the measured VO2 values on the two devices when walking was performed with and without holding on the handlebars, at 3 km-h-1. Similarly, no difference was found between the two devices at 5 km-h-1 without holding on the handlebars. A statistically very significant difference was found between walking at 5 km-h-1 on traditional treadmill and walking on TreadClimber using handlebars: In this case, energy expenditure on TreadClimber was lower than that on traditional treadmill.

Conclusion
The results of this study showed that walking on the new device determine the same VO2 than walking on a traditional treadmill if handlebars are not used to hold. Because of the stumbles that can occurred during walking on TreadClimber, holding on the handlebars reduces significantly the energy expenditure at the higher speeds.

COMPARATIVE STUDY OF THE QUALITY OF LIFE PERCEPTION AND CLINICAL CONDITIONS IN THE SUBJECTS WITH TYPE II DIABETES MELLITUS, PRACTICING AND NON-PRACTICING PHYSICAL EXERCISE
Neiva, C., Oliveira, T., Campos, P.
UNAERP, FC-UNESP, UNIFRAN, FESP-UEMG, Brazil

The present study about the comparison of perception of quality of life and clinical conditions on type II diabetics subjects that practice and do not practice physical exercises, had the objective to compare the possible differences on the perception between the two groups.
and thus to evaluate the existence or not of the differences about these aspects. The subjects answers were of 24 patients [16 - 66.7% are women and 8 - 33.3% are men and the average age was 60 ± 10 years] from the Diabetes Educative Center of the Nurse School - University of São Paulo (USP) - Brasill, where 13 were practicing physical exercise and 11 did not practice. To compare the quality of life perception, life habits and clinical conditions, the WHOQOL-Bref Instrument and an informative questionnaire were used. The T-test was employed to analyze the difference between two groups. In relation to the life habits and clinical conditions, the practicing physical exercise subjects presented values of glycemia, arterial pressure and weight below of the non-practicing physical exercise. For the domains (physical, psychological, environment and social of the WHOQOL-Bref, through of the frequency percentages given on the answers we can verify that the practicing physical exercise had better result in almost all domains. A no significant difference was perceived only in the physical domain. Despite of difference on the physical domain, is possible to observe that the quality of life is dependent of the physical exercise and others factors. Thus, we can concluded that type II diabetics subjects involved on physical activity program get a better clinical condition and perceptions of quality of life than the sedentary ones.

SEX DIFFERENCES IN VO2peak IN NINE-YEAR OLD RURAL NORWEGIAN CHILDREN

Resaland, G., Maren, A., Anderssen, A., Andersen, B.
Sogn og Fjordane University College, Norway

Introduction

Several studies have shown sex differences in children’ cardio respiratory fitness, defined as maximum oxygen uptake (VO2peak). However, there are few studies with accurate and high-quality measures of direct VO2peak on representative populations. Therefore, we wanted to investigate VO2peak sex differences in 256 (124 boys and 132 girls) fourth graders in two Norwegian rural towns.

Methods

Body weight was measured at the nearest 0.1 kg using a calibrated electronic scale with the children wearing light indoor clothing. Body height was measured with the children standing in an upright position. VO2peak was measured directly where the children ran on a treadmill until fatigue.

Results and conclusions

Boys had significantly higher VO2peak (p<0.001) than girls regardless of how it was expressed.

It is unlikely that the difference in VO2peak can be explained by lack of effort from the girls, because, subjectively the girls and boys put in equal effort. This was supported by no significant difference in RERpeak ([Boys, 1.05±0.04 vs girls, 1.06±0.05]) and that girls had a significantly higher HRpeak than boys [205.5±7.5 vs 203.1±6.8, respectively]. Other studies using VO2peak direct measurements have found that boys have a significantly higher VO2peak compared to girls. These studies have suggested that the difference in VO2peak relative to body mass can largely be attributed to variations in body composition, i.e., the larger percentage of body fat in girls. In the present study, half of the subjects performed DXA measurements. Girls had a significantly higher fat percentage (p<0.001) than boys, 25.8±7.9 vs 19.4±7.0, respectively. This supports that body composition is central when explaining gender differences in VO2peak. However, the fact that girls have a smaller stroke volume could also contribute to a lower VO2peak for girls. Stroke volume was not tested directly in the present study, but can be calculated from the absolute VO2peak in milliliters divided by the HRpeak. This indirect measurement of stroke volume is defined as O2pulse. In the present study, the boys have a significantly higher O2pulse than the girls (p<0.01), 8.7±1.1 vs 7±1.1, respectively. In addition, several studies using valid and reliable objective methods to measure children’s physical activity levels have shown that girls have significantly lower levels of habitual physical activity, both in respect to total physical activity and more vigorous activity. Therefore, an implication of the findings in this study and others is that one should encourage physical activity for girls, mainly on their own terms.

CHARACTERIZATION OF A SHORT ANAEROBIC PEAK USING AN INTERMITTENT AQUATIC EXERCISE PROTOCOL AND HEALTH RISK DETERMINATION

FADEUP, Portugal

According to ACSM (1998) strenuous physical exertion may trigger ischemic cardiac events, particularly among persons not accustomed to regular physical activity. Nevertheless, performers evolves in hydro classes are induced to raise his effort until very high intensities. This kind of efforts are apparently little studied and scarcely characterized. The aim of the present study was to characterize an intermittent short intensity exercise and detect possible health risk factors associated with it. Nine healthy women [39.4 +/- 9.3 years] experienced in hydrogymnast practice participate on the study. Exercise protocol consisted on 3min of warm up [level 11 in Borg's 6 to 20 Rate of Perceived Exertion (RPE) Scale], followed by 5min of aerobic exercise of low-mean intensity (13 to 15 in Borg's RPE scale) and by an intermittent exercise composed by 3x30s leg-kick, with 30s passive recovery. Rest HR values (POLAR Vantage NV) were obtained both on land and in water and during exercise. BP was evaluated at rest and after exercise by experienced health professionals using a sphygmomanometer and a stethoscope. Mean BP (MBP) was also calculated using systolic (SBP) and diastolic blood pressure (DBP) [(MBP=1/3(SBP-DBP)+DBP] and used as a health risk factor. [La-] was determined at rest and after exercise (LactatePRO). Due to the lower number of subjects studied, both non-parametric Wilcoxon test and parametric Paired Samples T-Test were applied to data. Level of significance was established on 5%. Differences obtained through both statistical procedures were the same. HR rest values were significantly lower on water (70.8±5.85 bpm) comparatively to (74.6±6.50 bpm) land. Peak and mean HR values of the intermittent anaerobic exercise were 177.2±10.16 and 167.5±10.25 bpm, respectively. After exercise systolic arterial blood pressure was significantly higher (mean difference of 27.5±6.90 mmHg) and diastolic arterial blood pressure was significantly lower (mean difference of 15.6±8.82 mmHg) than in rest. The same MBP was observed in rest (79.3±6.13 mmHg) and after exercise (78.1±9.81 mmHg), showing a lower cardiovascular risk associated to short intermittent anaerobic exercises. [La-] values were significantly higher after exercise (110.7±2.65 mmol.L-1) comparatively to rest (10.9±0.10 mmol.L-1) and showed the high level of participation of the anaerobic metabolic pathway. BP and [La-] results combined lead to the conclusion that anaerobic intermittent exercise could be safely used in hydrogymnastic classes with healthy subjects.

HEALTH INDICATORS OF THE ADULTS SEVILLIAN POPULATION

Ries, F., Chacón, F., Romero, S.
University of Seville, Spain

Objective: To assess the habits in relation with physical activity of the adult sevillian population and also the autoperception of their health status. Methods. 1002 adults (n= 470 males, n= 531 women, older than 18 years old)in Seville were asked with a 69 questions survey about health and wellbeing indicators and also topics in relation with a healthy lifestyle. Results. 50.6% of the subjects were done any physical activity. Among them the 56.7% were males and the 45.6% women, lowering this percentage (38.5%) in adults older than 64 years old. At least the 33.47% of the women could walk for more than 10 minutes. Alasought the 36% of the males and the 27.7% of the women thought they have a good health, among the elderly the 29.3% thought their health it was bad. In this sense, just the adults between 18-24 and 25-44 feel their health as good. Conclusion. The showed results describe the characteristics of the adult population in Seville in terms of the physical features and psychological health, taking into account differences in age and sex. It was seen how half of the population was practicing any activity and mostly among the women the activity it was to walk. With regard to the health indicators the sevillian adults have a good concept of their health however the perception is bad in adults older than 64 years old. Keywords: Physical activity and sports, health, lifestyle.

GROWTH, BODY COMPOSITION AND MOTOR PERFORMANCE IN BRAZILIAN ADOLESCENTS OF DIFFERENT SOCIOECONOMIC LEVELS

Serassuelo Jr., H., Ronque, E., Reichert, F., Simões, A.
North Paraná University (UNIPAR) - Londrina State University (UEL) - Physical Education and Sport School (EEFEUSP), Brazil

INTRODUCTION. The health-related physical fitness components are important factors in the context of public health. Several studies have demonstrated that high physical exercise and low sedentary behaviors are associated with beneficial health outcomes in children and adolescents. In addition, socioeconomic level is associated with a broad range of outcomes and it may also play an important role on the health components of fitness in adolescents. OBJECTIVE. To explore the association between growth, body composition, performance in motor tests and socioeconomic level in Brazilian adolescents. METHODS. The sample comprised 512 adolescents (45.5% boys) aged 11 and 12 years living in Cambé, PR, Brazil. Socioeconomic level was investigated through a standardized questionnaire, which classified individuals into either high (HSEL) or low (LSLE) socioeconomic level. Height, body mass, and tricipital and subescapular skinfold thickness were measured. In addition, the following motor tests were performed: sit-and-reach, standing long jump, modified pull-up, modified sit-up, 50 meter run, and nine or 12 minutes run/walk test. For a comparative analysis between groups in the quantitative variable the t test was applied. The level of significance adopted for all the analyses was p<0.05. RESULTS. HSEL girls presented higher values of height, body mass and sum of tricipital and subescapular skinfolds than girls in HSEL. No association between socioeconomic level and performance in the motor tests was observed in girls. Nonetheless, boys of HSEL performed better in the sit-and-reach, standing long jump, modified sit-up, and 50 meter-run tests. Finally, the analyses of both anthropometric and motor variables suggested that girls from LSEL are more maturated than girls in HSEL. Such a result was not evident among boys. CONCLUSION. Although socioeconomic level is associated with a wide range of health outcomes, it associated only moderately with the health-related components of physical fitness investigated in this sample of Brazilian adolescents. Further studies shall address possible interactions between socioeconomic level and maturational status on the level of physical fitness of children and adolescents.

CHANGES IN BODY COMPOSITION OF UNIVERSITY STUDENTS DURING FOUR YEARS OF FOLLOW-UP

Alegre, L., Lara, A., Abídián-Vicén, J., Aguado, X.
University of Castilla-La Mancha. Camilo José Cela University, Spain

INTRODUCTION
Overweight and obesity are one of the major health problems in developed countries. The beginning of a university degree has been identified as a "critical period" that could determine whether an individual will develop a healthy lifestyle, without overweight and following the recommendations of physical activity. Besides, greater body fat has been related to lower physical fitness in young individuals (1). Therefore, the present study aimed to evaluate the changes in body composition and jump performance in a group of young men and women during their entire university studies.

METHODS
Eight men and 10 women, students from the first course of a Sports Sciences degree in Spain, started as volunteers the present study. All subjects were physically active on a recreational basis, but none was engaged in any structured physical activity during the study. Results. 50.6% of the subjects were done any physical activity. Among them the 56.7% were males and the 45.6% women, lowering this percentage (38.5%) in adults older than 64 years old. At least the 33.47% of the women could walk for more than 10 minutes. Alasought the 36% of the males and the 27.7% of the women thought they have a good health, among the elderly the 29.3% thought their health it was bad. In this sense, just the adults between 18-24 and 25-44 feel their health as good. Conclusion. The showed results describe the characteristics of the adult population in Seville in terms of the physical features and psychological health, taking into account differences in age and sex. It was seen how half of the population was practicing any activity and mostly among the women the activity it was to walk. With regard to the health indicators the sevillian adults have a good concept of their health however the perception is bad in adults older than 64 years old. Keywords: Physical activity and sports, health, lifestyle.

MUSCLE STRENGTH DECREASE WITH AGE IN INSTITUTIONALIZED ELDERLY

Dolenec, A., Strojnik, V.
University of Ljubljana, Faculty of Sport, Slovenia

Aging is accompanied with loss of muscle mass and strength, a phenomenon called sarcopenia. Observational studies indicate that approximately 1% of muscle mass is lost per year after 40 years of life (Janssen et al. 2000) and 12-14% of muscle strength is lost per decade after 50 years of life (Asmussen and Heeboll-Nielsen, 1962). Appropriate strength training may stop or at least slow down these processes (Frontera et al. 1988). The purpose of our study was to determine the relationship between age and measured parameters in Slovenian elderly people living in homes for elderly people.

Forty-nine men (age 77.9±6.9 yrs, mass 75.4±12 kg, and height 170±4.4 cm) and 103 women (age 80.1±7.7 yrs, mass 71.2±13 kg, and height 161±4.6 cm) participated in this research. All participants were from six Slovenian homes for elderly people. We measured torque during maximal isometric voluntary plantar and dorsal flexion (90 deg in ankle and knee respectively), left and right knee extension (90 deg position), forward, backward, left and right side body lean, all in standing position. Pearson’s correlation coefficient was used to determine the relationship between age and measured parameters.

The results showed that all the measured parameters in women were significantly correlated with age. In men, only the strength of knee extensors of both legs and forward body lean were significantly correlating with age. The correlations between torque in plantar and dorsal flexion and age were close to statistical significance (plantar flexion, p=0.084; dorsal flexion, p=0.071). Women’s results were in agreement with others (Lynch et al. 1999). However, in men the expected trend was observed only in two parameters.

One of possible reasons for non-systematical strength decline in elderly men could be their different activity levels regarding age. In this case we could expect systematical strength decline only in muscles that are included or excluded from most of daily activities. If we speculate that muscles responsible for forward body lean are excluded from most of daily activities and legs are involved in many daily activities the results became close to expectations.

LIKELIHOOD OF METABOLIC DISORDERS AND PHARMACOLOGIC THERAPY USE ACCORDING TO BMI LEVEL, IN OLIVEIRA DE FRADAS MEDICAL CENTRE

Pimenta, N., Almeida, A.
Sport Science School of Rio Maior, Portugal

Introduction: Obesity is associated with other metabolic disorders, increasing the risk of mortality and disability (Pi-Sunyer, 2004; Peeters et al., 2004). The aim of this study was to estimate the likelihood of Oliveira de Frades Medical centre (OFMC) users, in different levels of Body Mass Index (BMI), having other metabolic disorders and using pharmacologic therapy.

Methods: We observed the anthropometric, biochemical and homodynamic variables for the diagnosis of metabolic disorders (obesity, dyslipidemia, hypertension and hyperglycaemia) in 200 OFMC users (75 men and 125 women, with mean ages of 48±13 and 46±14 years, respectively, ranging 18 to 69 in both genders), in Portugal. We also used a data sheet to register medication in use for metabolic disorders. All subjects gave their informed consent to participate in this study. We used odds ratio (OR) to estimate the risk of overweight (OW) and obese (OB) subjects having metabolic disorders and using pharmacologic therapy as compared with normal weight (NW) subjects, according to WHO BMI classification (WHO, 1998). The level of significance was set at P<0.05.

Results: Obesity and overweight was present in 28.0 and 40.5% of the subjects, respectively. OB subjects showed higher odds of having other metabolic disorders as compared with NW (hypertension: OR 5.3, confidence interval [CI] 2.2, 12.5), dyslipidemia: OR 2.3, CI [1.1, 4.9] and hyperglycaemia: OR 3.3, CI [1.4, 7.9] and OW (hypertension: OR 2.2, CI [1.2, 4.7]). OB subjects also showed higher odds of using pharmacologic therapy as compared with NW (blood pressure lowering medicine: OR 3.8, CI [1.2, 12.9], glycaemia control medicine: OR 6.4, CI [1.3, 30.7], Cardiac medicine: OR 4.2, CI [1.1, 16.2] and OW (glycaemia control medicine: OR 5.6, CI [1.5, 21.6]). OW subjects only showed higher odds of having hyperglycaemia (OR 2.7, CI [1.2, 6.1]) as compared with NW. The odds of using pharmacologic therapy weren’t significantly higher in OW as compared with NW.

Conclusion: These results show that the OW and OB OFMC users are more likely to have metabolic disorders and use of pharmacologic therapy than NW. Considering the high prevalence of OW and Ob and high prevalence of pharmacologic therapy use identified in our sample, as well as the known potential metabolic benefits associated with weight loss, in our understanding a weight loss program should be considered as a cost effective measure to impact these subjects health.

METABOLIC SYNDROME AND RISK OF CARDIOVASCULAR DISEASES AS DETERMINED BY RISK FACTORS IN OLIVEIRA DE FRADAS MEDICAL CENTRE USERS

Pimenta, N., Almeida, A.
Sport Sciences School of Rio Maior, Portugal

Introduction: Cardiovascular diseases (CVD) are the leading cause of death in the world (Yach, 2004). Several factors have been identified as part of it’s complex cause (Grundy, 1999). The aim of this study was: (1) to identify the prevalence of CVD risk factors and of metabolic processes (Frontera et al. 1988). The purpose of our study was to determine the relationship between age and measured parameters.
syndrome (MS) in Oliveira de Frades Medical centre (OFMC) users, (III) to identify the risk level for Coronary Heart Disease (CHD) of OFMC users, (IV) to observe the differences in the level of risk between OFMC users with and without MS.

Methods: We observed the anthropometric, biochemical, homodynamic, behavioural and familial variables that constitutes risk for CVD, including those for the diagnosis of MS (obesity, dyslipidemia, hypertension and insulin resistance) in 189 OFMC users (69 men and 120 women, with mean ages of 48±13 and 46±14 years, respectively, ranging 18 to 69 in both genders), in Portugal. We used the definition of MS from the World Health Organization (WHO) (Grundy, 2004). We also estimated the level of risk for CHD according to American Heart Association/ American College of Cardiology (Grundy, 1999). Descriptive statistics were used and Mann-Whitney test to compare results between groups was performed. The level of significance was set at P<0.05.

Results: The prevalence of obesity (28,0%), hypertension (31,5%), dyslipidemia (49,0%), Hyperglycemia (30,5%), diabetes (7,5%), tobacco use (8,5%) and family history of CVD (43,0%) was identified. 20% of subjects were diagnosed with MS. 81,9% of the subjects were considered low risk, 14,8% were average risk and 2,7% were high risk of CHD. Considering subjects groups with and without MS, respectively, 87,9% and 59,4 were low risk, 9,5% and 34,4 were moderate risk, 1,7% and 6,3 % were High risk. Average risk was only found in the group of subjects with MS (8,9%). There were significant differences between subjects with and without MS concerning the level of risk (P=0.000).

Conclusion: These results show that there is high prevalence of metabolic risk factors such as obesity, hypertension and dyslipidemia. Considering the sample origin it could be expected a higher prevalence of MS. The majority of subjects are considered low risk. The diagnosis of MS may be a simple and useful tool in identifying higher risk subjects.

PREVALENCE OF CHILDHOOD OVERWEIGHT AND OBESITY IN CHILDREN FROM RIO MAIOR, PORTUGAL

Costa, S., Pimenta, N., Seabra, A., Fragoso, I., Varela-Silva, M.
Sports Sciences School of Rio Maior, Portugal

Introduction. Childhood obesity has been increasing in many countries worldwide, being considered by the World Health Organization - WHO (1998) as a global epidemic. Its aetiology is complex, and influenced by the dynamics between biological and environmental factors.

Aim. The aim of this study is: (1) to document the prevalence of overweight and obesity among children from the kindergartens (KG) of the Rio Maior County; (2) to quantify the prevalence of sports participation among children from the KG of the Rio Maior County; (3) to assess the association between children's Body Mass Index (BMI) and sports participation; the association between children's Body Mass Index (BMI) status and sports participation; (4) to document the intergenerational effects on BMI.

Methods. We assessed 253 children (128 girls and 125 boys), ages from 3 to 5 years old, from the KG of the Rio Maior county's public and semi-public school network. Height and weight were taken (ISAK, 2006), and questionnaires to parents were used for biosocial data. We also estimated the level of risk for CHD according to American Heart Association/ American College of Cardiology. Circulation, vol. 100: 1481-92.

Results. The prevalence of overweight and obesity was 13.8% and 7.1%, respectively. Almost twenty five percent (24.6%) of the children participated in some sort of sport activities. No associations were found between children's BMI status and sports participation, or parents' characteristics. Low correlations were found between parents' and children's BMI (r=0.17 to 0.49, p=0.001 to 0.033). Statistical differences were found in the prevalence of childhood overweight and obesity, when considering the group of fathers with basic education versus the group of fathers with higher education (p = 0.036). Prevalence of overweight and obesity also differed between girls who did and did not participate in sports (p = 0.031).

Conclusion: Considering in our sample the prevalence of childhood overweight and obesity is similar to those found in other European countries, and the percentage of sports participation is similar to the national estimate for the adult population. Girls were more involved in sports than boys, although with higher prevalence of overweight and obesity. Fathers' educational level seems to influence the prevalence of childhood overweight and obesity prevalence.

BODY IMAGE AND ITS RELATIONSHIP WITH ANTOPROMETRICS AND PSICOMETRICS MEASUREMENTS IN OLDER WOMEN

Barros, J., Lope, K., Oliveira, R., Castro, M., Souza, A., Lima, R., Bezerra, L.
Universidade de Brasilia, Brazil

Introduction. Aging is associated to several alterations that can have among other consequences a distortion of body image (BI). Purpose: (1) Identify the ideal body image (IBI) characteristics desired by the volunteers, (2) establish the dissatisfaction grade (DIG) and the distortion in relation to the real body image (RBI), and (3) Examine the relationship between the DIG with RBI as well as with anthropometric (AV) and psychometric (PV) variables, in older women. Methods. 47 physically active women (66±3 4 years, VO2 max 20,3 ml kg-1 min-1), with preserved cognitive function, were submitted to a maximal cardiopulmonary exercise test after rest physician evaluation. The measured AV were body mass index (BMI), waist circumference (WC) and the waist to hip ratio (WHR). In addition, body fat percentage was evaluated by dual energy x-ray absorptiometry. The evaluated PV were cognitive performance (CP), levels of depression (LD), quality of life (QL) and body image. The used instruments to evaluate PV were the Mini Mental State Examination (MMSE), the Beck depression inventory.
CONTRIBUTIVE HEALTH STUDY OF BSC PHYSICAL EDUCATION AND SPORT MANAGER STUDENTS BY KINANTROPOMETRIC MEASUREMENTS

Ember, A.
Semmelweis University, Hungary

Introduction
A kinantropometric-exercise physiological study has been going on at the University of Pécs, Institute of Physical Education and Sport Science since 2001 only excluding the academic years of 2004 and 2005. From 2006 compared to the traditional Physical Education (PE) MSc teacher training course a new but still sport related course was introduced Sport Manager (SM). No both PE and SM is a 3 years BSc major. The number of students included in the comparative study is not the 100% of the students (PE 1st ay. m=41, dec age=19,77+/1-1,09, f=16, dec age=19,09+/1-0,62, SM 1st ay. m=13, dec age=19,6+/1-1,07, f=6, dec age=19,47+/1-0,91) reading PE or SM though students participating in both 1st and 2nd years study exceeds 50% of the total. In kinantropometric measurements among many factors we monitor students’ somatotype and body composition. Exercise physiological data is not shown in this paper.

Method
Kinantropometric study includes determining somatotype by Heath-Carter using endo-mezo-ectomorphic data and also by Conrad using Plastic Index and Metric Index. Body composition is estimated by skinfolds, girths and widths giving data also on Body Mass Index (BMI), Waist-to-Hip Ratio (WHR).

Results
There is a sex specific difference between male and female students as at the beginning of their courses as in the changing pattern throughout the academic years. PE male students shift from mesomorph to endo-mezomorph (1st ay. 1,28+/1-0,76/13,42+/1-1,06/17,79+/1-1,31/2,98+/1-1,77) and WHR measures as well. Females on the other hand go through a feminine maturation, change body shape and gain fat even on triceps (skinfold mm PE 5,19+/1-0,99/14,17+/1-1,04/1-1,99-/0,85), SM students show similarly (1st ay. 1,33+/1-0,58/13,8+/1-0,95/12,81+/1-0,76, 2nd ay. 3,89+/1-0,99/3,83+/1-0,91/2,07+/1-0,51). The shift can be detected also in BMI (PE 23,05+/1-1,84/22,4+/1-2,05, SM 22,59+/1-1,59/23,18+/1-1,77) and WHR measures as well. Males on the other hand go through a feminine maturation, change body shape and gain fat even on triceps (skinfold mm PE 5,19+/1-0,99/14,17+/1-1,04/1-1,99-/0,85), SM students show similarly (1st ay. 1,33+/1-0,58/13,8+/1-0,95/12,81+/1-0,76, 2nd ay. 3,89+/1-0,99/3,83+/1-0,91/2,07+/1-0,51). The shift can be detected also in BMI (PE 23,05+/1-1,84/22,4+/1-2,05, SM 22,59+/1-1,59/23,18+/1-1,77) and WHR measures as well. Males on the other hand go through a feminine maturation, change body shape and gain fat even on triceps (skinfold mm PE 5,19+/1-0,99/14,17+/1-1,04/1-1,99-/0,85), SM students show similarly (1st ay. 1,33+/1-0,58/13,8+/1-0,95/12,81+/1-0,76, 2nd ay. 3,89+/1-0,99/3,83+/1-0,91/2,07+/1-0,51). The shift can be detected also in BMI (PE 23,05+/1-1,84/22,4+/1-2,05, SM 22,59+/1-1,59/23,18+/1-1,77) and WHR measures as well.

Conclusion
Both male and female students either reading PE or SM change body build, they shift towards endomorph though there is a different rate between sexes. Regarding BMI the majority of students are in the normal, healthy range, among SM students there are some in the overweight area. Observing WHR only a few male students both PE and SM are in the moderate risk field the rest of the males and all the females are in the low risk range.

THE EFFECTS OF DIFFERENT AEROBIC AND STRENGTH EXERCISE SEQUENCES OVER NET ENERGY EXPENDITURE IN A CONCURRENT TRAINING SESSION

Lupi, R., Kruel, L., Alberton, C., Oliveira, A., Pinto, R.
Physical Education School, Federal University of Rio Grande do Sul (UFRGS), Brazil

The regular practice of physical activities has been showed as the most important strategy to maintain the physical fitness. More than a high caloric intake, the inactivity is the determinant factor of weight gain in the course of life. People who exercise regularly increase your energy expenditure and consequently maintain body composition in satisfactory standards. The energy cost in a training session can reduce body fat mass and increase neuromuscular function. The purpose of our study was assessed the difference on energy expenditure in a concurrent training session and recovery when the sequences of strength and aerobic training are changed (sequence strength-aerobic and aerobic-strength). Eight active females (121.2±1.28 years old, 60.75±3.92 Kg, BMI 21.77±2.05 kg m-2) completed two protocols. Both consisted at 2 sets of 8 strength exercises performed to volitional fatigue at previously determined 20 RM and 30 minutes of cycle ergometer at 60-70% of maximal heart rate evaluated at progressive treadmill test, and 1 hour of recovery. Each one protocol was designed to have similar duration: aerobic-strength and strength-aerobic exercise protocol, completed in a randomized mode. The rest metabolism, energy expenditure in exercise session and recovery were measured before, during and after each protocol, respectively, using an indirect calorimetry portable system (Aerospot KB1-C) to estimate energy consumption (O2). The net energy expenditure was estimated using a constant value of 5.05 kcal per litre of oxygen consumed during strength exercise. For aerobic exercise and EPOC, caloric cost was estimated by oxygen consumption and metabolic equivalent of respiratory exchange ratio (RER). In all 3 situations (strength and aerobic exercise, and recovery) net energy expenditure was estimated besides rest conditions. The statistical analysis were realized by Paired T Test. The results showed that the total net energy expenditure per session was significantly greater (p<0.001) during strength-aerobic (146.8±14.9 kcal) than aerobic-strength exercise protocol (111.8±11.5 kcal). Related to exercise time the strength-aerobic exercise sequence showed a major metabolic impact than aerobic-strength sequence (p<0.001). 2.5±0.3 and 1.7±0.7 kcal min-1, respectively.

Based on results we concluded that strength-aerobic sequence showed a greater metabolic impact than aerobic-strength sequence. So, when the goal of training session was a higher energy expenditure, the first one would be the most indicated. Comparing the caloric expenditure only in aerobic exercise between different sequences, there is a higher cost caloric in the strength-aerobic than...
the aerobic-strength sequence. Thus, one of the hypotheses that explain the results of present study would be the transfer of EPOC caused after execution of strength exercise, to the aerobic exercise of strength-aerobic sequence.

ASSOCIATION BETWEEN CARDIO RESPIRATORY FITNESS, COMMUTING TO SCHOOL, TV AND COMPUTER TIME IN A HIGH SCHOOL POPULATION ACCORDING TO GENDER

Aires, L., Gaya, A., Silva, P., Martins, C., Ribeiro, J., Santos, M., Mata, J.
Faculty of Sports - University of Porto, Portugal

Purpose:
The aim of this study was to analyse the association of Cardiorespiratory Fitness (CRF), with Physical Activity Index, Time Spent Watching TV and Using Computer and Transportation to School according to Gender.

Methods:
Participants of this study included 856 children and adolescents, 470 girls (54.9%), aged 11-20 years (X=15.17±1.53 years-old, weight=60.45 ± 12.78 kg, height=1.66 ± 0.094m, BMI=21.85 ± 3.69 kg.m-2). 17% of the girls and 19.2% of the boys were overweight, and 4.5% of the girls and 7.5% of the boys were obese. CRF was evaluated using the Fitnessegram battery test – Shuttle Run (1) with qualified staff, to assure the standardization, validity, and reliability of the measurements. Physical Activity Index (PAI), Active Commuting to School (ACS) and Time Spent Watching TV (TV) and using Computer was obtained by questionnaire. Stepwise method was used to find the best Model in Regression Analysis. The number of laps from Shuttle Run was used as dependent variable, adjusted from Skinfolds (subscapular, tricipital and calf) and Tanner Stage.

Results
In girls, PAI was associated with CRF (β=-0.342; 95% CI: 0.789; 1.373); p=0.000). In boys PAI and ACS was positively associated with CRF (β=0.186; 95% CI: 0.453; 1.373); p=0.000) and (β=0.158; 95% CI: 0.390; 1.065); p=0.002) and negatively associated with TV (β=-0.138; 95% CI: -0.351; -0.009; p=0.000).

Conclusions
Although our study is cross-sectional, the results showed that, after adjustment for Skinfolds and Tanner Maturation, PAI, TV and ACS were associated with CRF in boys. However, in girls the association was found only with PAI. These findings suggest that increasing physical activity levels rather than reducing TV time or using ACS can contribute to improve CRF levels in girls whereas in boys all variables, excluding time spent using computer, can predict CRF.

PHYSICAL ACTIVITY OF PRESCHOOL CHILDREN DURING SCHOOL TIME

Bertels, J., Cools, W., De Martelaer, K., Vandaele, B., Vandervorst, F.
Vrije universiteit Brussel, Pleinlaan 2, 1050 Brussels, Belgium, Department of Movement Education and Sport Training, Faculty of Physical Education and Physiotherapy (LK/BETR), jabertel@vub.ac.be

Introduction: Due to the increasing occurrence of obesity and a low level of physical activity (PA) reported in preschool children, there is a need to refocus attention on the importance of PA in this age group. Low levels of PA during childhood may compromise current and future health and well-being of our society. Seasonality is believed to have influence on the amount of engagement in PAs, although geographical differences are likely (Timmons et al. 2007). Moreover, a child's PA level may also be related to the opportunities and policies of the preschool they attend. For example, a significant predictor for increased PA during a school day is the presence of an involved primary educator (Pate et al. 2004). The school represents a suitable setting to promote PA to benefit next to health related factors also physical, cognitive and social developmental factors. During the school day physical education class and school play time offers children regular opportunities to engage in PA (Ridgers, 2006).

Objectives: The goal of this study is to chart school PA of preschool children. Within this study specific focus is on the relationship between PA, seasonality and opportunities to be physically active at school.

Methods: Two rural and two urban preschools participated in the study. 81 (53.3%) out of 152 parents provided informed consent for participation in the study. 32 preschoolers in rural area preschools (16 boys and 16 girls) and 48 preschoolers in urban area preschools (23 boys and 25 girls) participated in the study. The data is registered in autumn, winter and spring, each during two full school days. Step counts are registered at the beginning and at the end of each school day. Objective measurement of children's PA using pedometry is likely to provide more accurate data on habitual daily PA. The Yamax Digiwalker pedometer type SW-200 was used to register step counts.

Results and conclusions: Preliminary results on children attending preschool (autumn 2007) show average step counts of 7645 +/- 2538. Although children from rural schools (7952 +/- 2594) were slightly more active than their peers in rural schools (7231 +/- 2587) during preschool hours there were no significant differences between both groups (t=1.54; n.s.). Although children spent most their daylight hours (and so their most probable time to be physically active) at school, the school accounts for only half of the amount of recommended PA in preschool children.

THE IMPORTANCE OF OBESITY IN MORPHOFUNCTIONAL DEVELOPMENT OF CHILDREN IN PREPUBERTY PERIOD

Bieniewska, T., Igniasiak, Z., Posluszny, P., Roze, K.
University School of Physical Education, Poland

The obesity is called the epidemic of the 21st century. Main causes of this disease are environmental factors and about 25 to 40 percent of obesity cases result from genetic factors. In recent years we could observe an increase of the number of overweight and obese people, regardless of their age. It is disturbing that numerous children have abnormal weight-height index. Biological and health consequences will appear in the future ontogenesis stages, they can also affect the length of life.
Poland is a country, in which dynamic changes in the number of children with overweight and obesity occur. The aim of the work is to determine the percentage of the overweight children in prepuberty period and to estimate the consequences of this phenomenon for the value and the rate of the morphofunctional changes.

The groups of boys (n=782) and girls (n=830) aged 10-12 were examined. The overweight children were separated according to Cole's standards (2000). There were some somatic and functional parameters measured, such as: body height and weight, three skinfolds (triceps, subscapular, abdominal), body composition and several respiratory system parameters (VC, FVC, FEV1, PEF, MVV). Physical fitness test was used to estimate the speed, coordination, power, strength and flexibility. Body Mass Index was also calculated. The basic statistics were used to describe all of the measured parameters (mean, standard deviation, variability coefficient, I-Student test).

The percentage of the overweight boys was between 15.8%-19.5%, but it was decreasing in the older groups of children. The percentage of the overweight girls was between 13.1%-17.6%. The lowest number of overweight girls was in the group aged 11 and the highest number of overweight girls similar to the groups of boys was in the group aged 10. Among both groups of sexes more overweight children according to Cole's norms were in the boys' groups.

There were statistically significant differences in body height and fatness between the groups of children with normal body weight and the ones with overweight. Such differences (e.g. in fat mass, body fat percentage, the sum of skinfolds) were the consequence of division criteria, but it confirmed the propriety of that partition. Higher morphological measurements of children with overweight suggested that they could be more advanced in somatic development. But motor development was quite opposite. Children with normal weight received better results in most of the motor tests. Sometimes, it is more clear after including basic somatic traits in the comparison. Basic body measurement values (height and weight should be taken into consideration in the comparison of the functional respiratory traits too. There were no significant differences between children with normal and abnormal body weight after relativisation of the functional features of the respiratory system.

THE EFFECTS OF CAFFEINE AND WATER INTAKE ON BODY FLUID LOSS THROUGH URINE PRODUCTION AND SWEAT LOSS DURING 2000-M UNDERWATER WALKING

Takuya, Y., Akira, M., Futoshi, O., Taka furumi, H.
1. Hyogo University Faculty of Health Science, Japan

The aim of this study was to investigate the effects of caffeine and water intake on the body fluid loss during 2000-m walking in the pool. Eight healthy men large: 20.6±0.5 years, height: 173.6±4.2 cm, weight: 70.3±4.7 kg were designated as three experimental conditions: water ingestion (WA: a total of 400 ml water), caffeine ingestion with water (CAF: a total of 250 mg caffeine in 400 ml water), and no fluid ingestion (NO). The fluid was ingested before the start of exercise and during exercise with a rest interval at 1000 m. The pool had 25 m in length and 1.0 m in depth. The subjects walked 2,000 m at a speed of 3 km/h in the pool at a water temperature 30.3±0.3°C, a room temperature 29.5±2.7°C, and a relative humidity 83.5±2.7%. We measured the urine volume and osmorality, sweat loss, heart rate, tympanic temperature, and blood pressure pre-exercise, during exercise with a rest interval at 500 m, 1000 m, and 1500 m, and after exercise. Urine volume after exercise increased in the CAF (253.7±211.3 ml) as compared with the NO (129.9±152.9 ml). There was no difference in the sweat loss among three conditions (NO 321.5±127.5 g, WA 281.3±119.3 g, and CAF 381.3±133.5 g). The total body fluid loss as evaluated with the urine volume plus sweat loss in the CAF (635.0±216.2 g) was significantly increased and that in the NO (432.3±170.8 g) tended to increase that in the NO (442.4±143.4 g) after exercise (p<0.05). Post-exercise tympanic temperature in the NO and CAF was significantly higher than the pre-exercise value. Post-exercise urine osmorality in the CAF and WA was significantly lower than that in the NO (p<0.05). The systolic blood pressure significantly increased during exercise (in the NO at 500 m, in the WA at 1000 m, and in the CAF at 500m and 1500m) compared with the pre-value (p< 0.05). There was no difference in the heart rate and diastolic blood pressure among three conditions. We concluded that water ingestion with caffeine significantly increased total body fluid loss through urine production and sweat loss during 2000-m underwater walking.

THE EFFECTS OF COMBINED EXERCISE TRAINING ON MIDDLE AGED WOMEN WITH METABOLIC SYNDROME

Seo, DI., Jun, TW., Chang, HK., So, WY., Song, W.
Seoul National University, Korea, South

The purpose of this study was to examine the effects of combined exercise training on physical fitness, risk factors of metabolic syndrome, and immunoglobulin in middle aged women with metabolic syndrome. We recruited 5 middle aged women with metabolic syndrome and 5 healthy middle aged women. Exercise session was performed 3 times per week for 12 weeks. The aerobic exercise training was composed of walking at 60~80% HRR, and the resistance exercise training consisted of 15 repetitions of sit-up, bench press, lat-pull down, shoulder press, leg press, and leg extension at 60~80% of IRM (repetition maximum). Twelve weeks of combined exercise training produced significant improved on power, agility, cardiorespiratory function, waist circumference, and diastolic blood pressure in healthy group (p<0.05). However, in metabolic syndrome group, only waist circumference was significantly decreased after the training (p<0.05). These results indicate that the combined exercise training was able to produce enhancement of physical fitness, metabolic syndrome factors, and immunoglobulin in healthy middle aged women.

DOES DAY TIME AFFECT PHYSICAL EXERCISE EFFECTS?

Di Blasio, A., Berchicci, M., Civino, P., Gallina, S., Sablone, A., Ripari, P.
Chieti-Pescara University, Italy

A growing body of literature has confirmed that aerobic acute exercise determines a transient decrease in the normal resting blood pressure and may last up to several hours (MacDonald, 2002); so, physical exercise practice is used both as primary and secondary prevention to hypertension. Even if it is simple to begin training, it is much more difficult to maintain its practice for physiological and psychological determinants that may obscure positive effective of exercise on blood pressure. The aim of this study was to observe heart rate, blood pressure and perceived exertion (PE) response at the same aerobic exercise, performed at different times of day. Forty-six healthy sedentary men, aged 26±2 [years], were recruited. They were randomly assigned to a different day time training: A (9:00-12:00), B (13:00-17:00), C (17:00-21:00). They cycled 50 min at aerobic intensity of which 10 min of warm up at 50% VO2 max, 35 min at 55-60% VO2 max and 5 min of cool down at 50% VO2 max. Heart rate was monitored during each part of the experiment. PE was monitored at baseline and at 10th, 20th, 25th, 30th, 40th and 50th min of exercise, using CR-10 Borg Scale, blood pressure measurement occurred at baseline and at 10th, 25th, 40th and 50th min of exercise and during successive 30 min of siting rest at 5th, 10th, 15th and 30th min. ANOVA analyses
were carried out using SPSS 15 software. Body composition and baseline blood pressure were not statistically different. Group A showed a greater PE than B and C in each measurement. The heart rate after the first minute of exercise was lower in group A than C (p=0.012). Group C started with a greater diastolic blood pressure (DBP) (p=0.000) and mean arterial blood pressure (p=0.000) than A and B. While during exercise, C DBP decreased, A and B DBP increased, during recovery, C DBP decreased more than A and B. These findings show that morning exercise affects negatively PE because it requests a higher strength or more time to reach heart rate target intensity for the lowest heart rate response to exercise. Even if in the evening people start with higher DBP, linked to its circadian rhythm, during exercise and during sitting rest recovery, C DBP variation was better than group A and B. The findings of Jones et al. (2006) showed that there were no differences in the 24-hour variation in blood pressure reactivity to daily activity between normotensive and hypertensive groups suggesting that the best evening reduction of blood pressure to exercise is present independently of blood pressure status. Our results suggest that training effects are optimized when exercise is performed in the early evening.

**PHYSICAL ACTIVITY PROGRAM IN THE WORKPLACE AND QUALITY OF LIFE**

Oliveira, F., Vigarão, P., Costa, A.
FEDERAL UNIVERSITY OF RIO DE JANEIRO, Brazil

*Introduction:* In the past decades small and big companies have adopted some kind of health promotion programs to improve employees’ productivity, wellness and quality of life (QL). Objective: The aim of this study is to investigate the QL of workers enrolled in a physical activity program of an important Brazilian company. Methods: A total of 246 individuals participated of this cross-sectional study (May-July, 2006). All volunteers were enrolled in a physical activity program offered by the company. The QL was evaluated by the questionnaire WHOQOL-Bref, which comprehends four domains of QL: physical, psychological, social relationship and environment. The maximum score permitted in each domain is 20 points that represents better satisfaction with QL. The independent variables considered in the study were: sex, Body Mass Index BMI (kg/m²), <25.0, >25.0 to 29.9 and >30.0 and program adherence, evaluated by the number of Training Sessions per Week (TSW; days/week; <2 and >2). The Kruskall-Wallis and Mann-Whitney statistical procedures were used to compare the scores of the WHOQOL-Bref according to the independent variables. Results are present as mean and standard-deviation or as percentage when appropriated. The level of statistical significance adopted was 5% (software SPSS 13.0 for Windows). Results: It was observed that the sample was predominantly composed by men (77.2%). A total of 69% of the participants was more than 40 years old (age = 42.6 ± 9.0 years) and 43% was classified as having overweight according to the World Health Organization (BMI = 26.5 ± 3.8 kg/m²). The mean TSW was 2.5 ± 1.9 days/week. In relation to the QL, the mean scores of the WHOQOL-Bref of the sample were: physical=16.0 (±2.0); psychological=15.7 (±1.8); social relationship=15.5 (±2.8) and environment=15.0 (±1.8). Men systematically presented higher scores with statistical significance for physical, psychological and environment domains. It was not observed statistical and clinical significant differences between the groups, for all WHOQOL-Bref domains, when it was considered the program adherence (TSW). BMI was inversely associated with QL. Obese people presented lowers scores in all domains of QL (p<0.05) suggesting that body fat may be associated with QL deterioration. Conclusions: Despite the differences observed according to independent variables considered, the group in general is satisfied with their QL considering the variation of the WHOQOL-Bref domains scores. Our results point to the necessity of new researches about this subject, principally cohort studies, to better comprehend the relationship between QL and its determinants and the effectiveness of health promotion programs for enhancing wellness, productivity and QL.

**BODY COMPOSITION AND PHYSICAL FITNESS OF ADOLESCENTS WITH DIFFERENT SOCIAL AND ECONOMIC LEVEL**

Oliveira, F., Miranda, M., Barros, V.
FEDERAL UNIVERSITY OF RIO DE JANEIRO, Brazil

Objective: The aim of this study was analyze the body composition and physical fitness of 76 adolescents (10-15 years), considering the biological maturation and the social and economical level. Material and Method: The body composition was estimated through the measurements of skinfolds thickness, body perimeters, bone diameters, height and total body mass and relative body mass, fat mass, residual mass, bone mass, muscle mass and BMI. Physical fitness test applied: Flamingo balance, Tapping test, Sit and reach, Standing broad jump, Hand grip test, Abdominal test, Bent arm hang, Velocity and endurance shuttle run. The presence or absence of menarche was investigated by Tanner method and the social and economical level was done by the discrimination of school (public or private). The comparison was done by the t-Student test (p=0.05). Results: No significantly differences were found to breasts development between the groups for body diameters and the femur shows a tendency to higher value to the private school. The matured adolescents of public school presented greater (p=0.006) and during sitting rest recovery, C DBP variation was better than group A and B. The findings of Jones et al. (2006) showed that there were no differences in the 24-hour variation in blood pressure reactivity to daily activity between normotensive and hypertensive groups suggesting that the best evening reduction of blood pressure to exercise is present independently of blood pressure status. Our results suggest that training effects are optimized when exercise is performed in the early evening.

INTRODUCTION

Two different lifestyles of Slovenian high school students, which can be differentiated by their sporting activity, were studied on a sample of 681 high school students of both genders with an average age of 18.06 years (±1.41 year). Some indicators of young people's lifestyle relating to eating, drinking, smoking, daily routines, socialising and sports activity were used to demonstrate their habits. Some other factors gender, urbanisation of the environment and the education of parents which could also influence the lifestyles of young people were also studied.

A questionnaire was prepared for the purpose of the study; afterwards, discriminant analyses, a t-test for independent samples, Pearson's coefficient as well as some other suitable correlation coefficients were calculated to analyse the collected data.

The findings confirm the hypothesis that participation in sport has a significant impact on the formation of two quite opposing lifestyles in terms of unhealthy habits. The sports lifestyle is, besides regular sports activity (at least three times 45 minutes per week in addition to PE lessons), also characterised by regular eating habits and the infrequent intake of intoxicating substances. Although the consumption of these substances is largely related to partying, the study found that students with a sports lifestyle socialise and spend their weekend nights similarly to their peers, but not in such an unhealthy way. In contrast, the so-called «cigarettes&coffee» lifestyle is an antithesis to the sports lifestyle when health risk factors are considered. Such a lifestyle is characterised by sporadic sports activity (only a few times a year, besides PE lessons), regular smoking (57% of the population of this group smoke every day) and coffee drinking (43% drink it every day), irregular eating, frequent drinking and staying out late at night. Such a lifestyle brings consequences even in short-term as these students more often take medications against general sickness, stomach cramps and other pains.

Young girls are more likely to live an unhealthy lifestyle than boys. Among other factors influencing the lifestyles of young people, the education of one's mother is very important. This factor is also in correlation with one erroneous systematic governmental measure in Slovenia cutting back on the amount of PE lessons in vocational high schools. In response to the findings of the present research, several measures are suggested to encourage young people to have a healthier lifestyle.

HEART AND BREATHING FREQUENCY RECOVERY AND THEIR RELATIONSHIP WITH THE LACTATE CONCENTRATION AFTER AN INCREMENTAL TEST IN HEALTHY PEOPLE

University Politécnica de Madrid, Spain

Introduction and objectives. Cardiovascular disease constitutes the first cause of death and hospitalisation in Spain. 1. This study attempted to analyze the evolution of various recovery indicators such as heart rate, ventilation and concentration of lactate within the first 20 minutes after an incremental exercise test design, using an equation that measures the recovery percentage-wise with regard to the individual functional capacity.

Methods. Thirty-two young athletes performed a high-intensity incremental cycle ergometer test until exhaustion (5 watts 12 s-1). The test was preceded by 15 minutes of rest, lying face up, during which established the baseline of oxygen uptake (VO2) and carbon dioxide (VCO2). The cardiorespiratory variables were measured with a portable metabolic system (Jaeger Oxycon Pro) and the heart rate was taken with a Polar 810 (Polar Electro, Finlandia).

Variables were recorded from the warm-up to the test end and 20 minutes after exercise. The subjects completed 2 min cycling at low intensity (50 watts), after 18 minutes of passive recovery.

A two way repeated measures analysis of variance (ANOVA) was used.

Results. After five minutes recovery, ventilation was at 85.1 (± 4.6) % of its maximum reserve, while the heart had regained 65.7 (± 6.1) % of the cardiac reserve and the concentration of lactate reached 13.4 % (±12, 9) % of the lactic reserve. After 20 minutes, subjects showed a ventilatory recovery close to 100 %, while heart rate values and especially concentration of lactate were removed from the values of the line of rest. The value obtained in the ANOVA for repeated measures in the testing of the Traza of Pillai (TP), indicates a strong association between the factors 'type of recovery' and 'time', with a value of TP (16,174) = 1492 with p <0,001.

Conclusion. The results showed that there is dissociation between the recovery of factors ventilatory compared with lactate and cardiac, which still increased after 20 minutes of recovery. Therefore, the study of post-exercise recovery rates, at a ventilatory, cardiac or metabolic level, could be applied to patients with ventilatory restrictions, and as a potential cardiac risk marker 3, 4. In addition, it could serve to check the evolution of the different parameters of recovery in a cardiopulmonary rehabilitation program.

ACUTE NEUROMUSCULAR RESPONSES IN HEALTHY MEN AFTER WHOLE BODY VIBRATION EXPOSURE IN A SEATED POSITION

Rantaharju, T., Hakkarainen, A., Lahtinen, M., Salmi, J., Linnamo, V.

University of Oulu, Finland

INTRODUCTION

Some occupational groups such as various machinery drivers are exposed to whole body vibration (WBV) at their work. While WBV training has been shown to have positive effects [1], long-term WBV exposure is known to cause health hazards such as back pain [2]. The purpose of this study was to examine if single (30 min), low frequency (5-10 Hz) WBV exposure would cause neuromuscular fatigue. Transmissibility of vibration in the human body was measured with accelerometers.

METHODS

20 healthy young men, who hadn’t been exposed to WBV or hand-arm vibration at previous jobs, were divided into vibration and control groups. Both groups sat 30 minutes in a custom made vibration bench, the vibration group with random vibration (5-10 Hz) using an average excitation level of 1 m/s²1 r.m.s. and the control group without the vibration. WBV was measured using 3 tri-axial accelerometers; one seat pad by Svantek, Poland situated at the seat interface and the other two (Crossbow, USA) attached to pelvis and forehead.
of the subject. Frequency weighted acceleration r.m.s-values were calculated using weighting factors indicated by ISO 2631-1:1997 standard. Maximal isometric voluntary plantar flexion force (MVC) and aEMG of soleus muscle were measured in a seated condition. H-reflex recruitment curve and maximal M-wave were measured in a passive standing condition. Measurements were repeated to both groups after the 30 min sitting.

RESULTS
MVC decreased [-3.0 ± 4.7%] (p<0.05) in the vibration group and [-4.7 ± 14.2%] (n.s) in the control group while no significant changes were observed in aEMG. Maximal M-wave amplitude increased [4.9 ± 5.8%] (p<0.05) in the vibration group and decreased [-2.9 ± 7.8%] (n.s) in the control group. No significant changes were observed in Hmax/Wmax ratio in either group. The lowest acceleration was observed from the seat pad 1.11 ± 0.17 m/s(2) which was significantly lower (p<0.01) than from pelvis 1.52 ± 0.25 m/s(2) and (p<0.05) from forehead 1.21 ± 0.20 m/s(2).

DISCUSSION

Some small changes in the neuromuscular system were observed after the vibration. Measurements were taken from plantar flexor muscles while the vibration exposure was done in a seated position. Whether the influences had been more substantial if the exposure had been done in a standing position is not clear at present. The observed changes in the neuromuscular system were of such small magnitude that we conclude that the vibration exposure used did not lead to systematic neuromuscular fatigue. Acceleration values measured confirm the resonance behaviour of the human body in the low frequency range [3].

SOCIOGEOGRAPHIC VARIATION OF OBJECTIVE PHYSICAL ACTIVITY MEASURES AMONG PORTUGUESE MALE ADOLESCENTS
Machado Rodrigues, A., Coelho e Silva, M., Mata, J.
University of Coimbra, Portugal

Extensive evidence supports the benefits of physical activity on health outcomes. Adolescence is often viewed as an important period of acquisition and maintenance of health behaviours. It is also assumed that physical activity habits do not occur in a social vacuum. This study examines the sociogeographic variation in a sample of male adolescents.

The sample is composed of 132 subjects ranging from 13 to 16 years of age. Somatic characteristics included weight, stature, sum of six skinfolds and waist circumference. Physical activity was assessed using an accelerometer (Actigraph, model 7164) during five consecutive days assuming a minimum amount of 10 hours of valid data per day [criterion for inclusion]. After presenting descriptive statistics, the hypothesis of sociogeographic variation [urban versus rural] was tested using ANCOVA [chronological age as covariate] on physical activity variables. A significance level of 5% was assumed.

In summary, urban boys seemed to account more physical activity per day, specially during the weekend and due to vigorous portion of physical activity variables. A significance level of 5% was assumed.

Urban and rural boys seemed to have similar mean values on body size [weight and stature], adiposity and waist circumference. Comparisons between groups showed urban adolescents as significantly more active during the weekend days [urban: 477 counts/min, rural: 393 counts/min, F=5.450, p<0.05]. While analysing the moderate, vigorous and very vigorous portion of physical activity, the urban group also tend to be more active in the five consecutive days [urban: 83 minutes/day, rural: 79 minutes/day], although differences were only significant for the weekend [urban: 67 minutes/day, rural: 53 minutes/day, F=5.086, p<0.05].

In summary, urban boys seemed to account more physical activity per day, specially during the weekends and due to vigorous portion of physical activity. Research about the specific context of physical activity and its vigorous portion is lacking. It would also be of interest to replicate the present study in girls.

SUMATOTYPING IN MALE AND FEMALE WORLD GYMNAESTRADA PARTICIPANTS
Taeymans, J., Deriemaeker, P., Aerenhouts, D., Clijsen, R., Clarys, P., Duquet, W., Hebbelinck, M.
Ausbildung Physiotherapie, Switzerland

Aim: This study is a part of the Gymnaestrada Health Project (GHP), conducted at the 13th World Gymnaestrada (Austria, 2007). The aim of this study was to assess the somatotypes (S) of male and female participants of different age groups.

Methods: Participants were recruited during the one week event. Out of 25000 gymnasts 295 males and 820 females volunteered in this study. Anthropometry was conducted following the ISAK guidelines. S was calculated using the Carter&Heath method (Carter&Heath, 1990). Participants were stratified in following age groups: <20, 20-29, 30-39, 40-49, 50-59, 60-69 and >70 yrs. Significance was set at the 5% level.

Results: There were no significant differences between the mean ages of the female and male groups. In the youngest age group, female mean S was central [3.6-4.1-2.7] while male mean S was balanced mesomorph [2.3-4.8-3.0]. In all age groups >20 yrs female mean S were mesomorphic-endomorph [4.1-4.3-2.4, 4.7-4.6-2.0, 5.1-5.3-1.6, 5.2-5.4-1.4, 5.4-5.7-1.2, 5.0-5.6-1.2] for groups of increasing age resp.) while male mean S were endomorphic-mesomorph [2.8-5.8-2.0, 3.2-6.0-1.7, 3.8-6.0-1.5, 3.7-6.5-1.3, 4.0-6.4-1.2, 4.1-6.9-0.9 for groups of increasing age resp.). Significant differences between the genders were observed for endomorphy (endo) and mesomorphy (meso) in all age groups and for ectomorphy in the 20-29 yrs age group. The standard deviations of endomorphy are significantly lower in males than in females.

Discussion: In the cross-sectional age groups the mean S of GHP participants develop from central to the north-west of the somatoplots in the corresponding age groups. Sexual dimorphism is observed in all age groups for endo and meso. The variability in endo is low in males of all age groups. In the youngest age group the mean S is similar to this of elite Belgian female (Beunen, 1981; cit.in Carter&Heath, 1990) and elite Venezuela male gymnasts (Pérez, 1981; cit.in Carter&Heath, 1990). Compared to reference data of adult S from different studies (Carter&Heath, 1990), GHP males and females show somewhat lower endo values in male age groups and high mean meso values for all age groups. The differences range from 0.5 to 1.3 units and increase with age for meso. Clinically, high meso levels may suggest that GHP participants are better protected against age related health risks such as sarcopenia.

Conclusions: The mean S of young GHP participants is comparable with elite gymnasts. The high degree of meso observed in adult GHP participants may be of clinical importance in the subjects of +65 yrs of age. Analyses of the strength test and the IPAQ data are needed to further substantiate our findings.

EFFECTS OF AN EXERCISE PROGRAM ON CARDIOVASCULAR FUNCTION, BODY COMPOSITION AND PHYSICAL ABILITY IN A MIDDLE-AGE GROUP AND ELDERLY GROUP

Nozomi, M., Miyachi, M., Yoshioka, A., Onodera, S.
Graduate school of Kawasaki University of Medical Welfare, Japan

BACKGROUND and PURPOSE
The arterial stiffness and body fat increases with aging. In contrast, physical ability declines. In general, habitual exercise prevents the decline of physical ability with aging. We thought that the exercise program prevented the aging of the middle-aged and elderly people without a habit of exercising. We investigated whether group exercise program influences cardiovascular function, body composition and physical ability.

METHODS
70 middle aged and elderly Japanese men and women living in the same town participated in this study. They have not been habitually exercised. We divided subjects into two groups, a middle-aged group (n=20, 65.9±5.0years) and an elder group (n=50, 76.7±5.4years).

RESULTS
A group exercise program for three months significantly decreased body weight and the body fat percentage in the middle-aged group. The muscle mass of lower limbs increased significantly. PWV and blood pressure decreased significantly in the middle-aged group. In particular a physical test showed a significant improvement in aerobic capacity. In the elder group, there were no changes in body weight. Body fat percentage increased significantly. PWV and blood pressure showed no changes either. A physical test showed a significant improvement in lower limb muscle strength in the elder group.

DISCUSSION
In the present data, the executed exercise program provided weight loss, the improvement of cardiovascular function and physical function in the middle-age group. Therefore, we concluded that the exercise program provided enough exertion to improve these functions. On the other hand, contrary to our hypothesis, the results acquired from the elder group through our exercise program indicate that there was no decrease in weight loss, and no improvement in cardiovascular function. The only improvement shown was in lower limb muscle strength, which we conclude from an improved neuron-muscular system. The lack of positive result of the exercise program in the elder group displays a low exercise intensity or short exercise period was conducted. But it is hard to increase exercise intensity any further because of the participant’s increased age. We suppose that adaptation of the exercise program for the elder group takes time. In conclusion, we suggest the importance of becoming accustomed to exercise before middle age.

PHYSICAL EXERCISE, OXIDATIVE STRESS AND DNA DAMAGE: EFFECTS OF A 4-MONTH TRAINING PROGRAM IN TYPE 2 DIABETIC PATIENTS

Pittaluga, M., Dimarco, I., Ceci, R., Sabatini, S., Tavazzi, B., Parisi, P., Sgadari, A., Caporossi, D.
Rome University of Movement Sciences – IUSM, Italy

Altered redox balance has been suggested as a contributory factor for initiation and progression of diabetes and its complications. An unbalance between prooxidant-antioxidant forces can cause increased lipid peroxidation and DNA damage which have been shown to have an inverse relationship with the metabolic control of diabetic disease. It is supposed that a moderate physical training can lead to adaptive phenomena, decreasing DNA damage by up-regulating antioxidant defences as well as DNA repair mechanism. However, there is a lack of studies evaluating the effect of physical training on oxidative stress in diabetic patients.

In order to investigate this relationship, we evaluated DNA damage in lymphocytes, by means of COMET assay as well as plasmatic 8-hydroxydeoxyguanosine (8-OHdG) levels, and several biochemical markers of antioxidant status, before and after 4 months of moderate physical training.

The sample consisted of 12 healthy sedentary males (62.1±4.3 yrs) as control group, and 12 sedentary males (61.7±3.7 yrs) affected by type 2 diabetes (at least 5 years of disease duration, in therapy with metformin alone or in combination with repaglinide or glyclazide).

Blood samples were collected before and at the end of a 4-month training program consisting of three sessions/week of 30’ of moderate aerobic activity and 30’ of calisthenic gym.

Alkaline (pH>13) COMET assay was performed following the Tice-Vasquez procedure on purified lymphocytes both untreated and treated for 30’ with H2O2 (100µg/ml) that cause an oxidative damage, or Doxorubicin (0.5 µM), a clastogenic drug. Plasma 8-OHdG levels were measured by immunoassay method (8-OHdG ELISA kit, JAICA, Japan). Determination of malonyaldehyde (MDA), oxypurines (hypoxanthine, xanthine, uric acid), ascorbic acid, oxidized glutathione (GSSG) and glutathione reduced form (GSH) content in plasma was performed by HPLC analysis.

Preliminary analysis indicates that after training %DNA in the comet tails result lower, both in untreated and in H2O2 treated samples in both groups. Before training, DNA damage of samples treated with H2O2 was higher in diabetic patients (DP) than in control subjects, while no differences between groups in the untreated samples were detected. After training, 8-OHdG values showed a tendency toward increase in DP, possibly indicating an improvement in DNA-damage repair efficiency and release of 8-OHdG.

As far as biochemical data are concerned, we observed, after training, a significant reduction of DNA levels in DP only, whereas a significant improvement in the oxidant-antioxidant balance was detected in both groups.

Our data suggest that moderate physical training reduces the susceptibility to DNA damage and/or improves the DNA-repair mechanism efficiency. Biochemical data seem to confirm the hypothesis that training can cause adaptive responses in terms of endogenous antioxidant. Further research is needed to investigate the underlying molecular mechanisms.
INFLUENCE OF PHYSICAL ACTIVITY IN MORPHOLOGIC VARIATION OF PROXIMAL FEMUR AMONG PRE-PUBERTAL BOYS

Technical University of Lisbon, Exercise and Health Laboratory, Faculty of Human Movement, Portugal

Research analyzing the influence of physical activity (PA) on skeletal has been focused on bone material properties such as bone mass and few studies were conducted on bone morphologic properties. Purpose: To analyze the influence of PA on morphologic variation of proximal femur in pre-pubertal boys, probably the most active group in non athletic population. Methods: Participants were 68 boys (age: 8.6±0.4 yrs, bone age: 8.9±1.1 yrs, height: 1.33±0.06 m; BMI: 18.0±2.9 Kg/m²). Analysis of the proximal femur was performed in DXA 2D images with a morphometric approach using 18 anatomical and Type III landmarks in order to quantify shape differences among participants. PA was assessed with the Actigraph accelerometer (Model WAM 7164) over seven days. The outcome variable was the number of minutes per day the child engaged in moderate and vigorous PA. A cut point of 1952 counts/min was used to represent moderate and vigorous PA. Results: Exploratory relative warp (RW) analysis performed with TPSReh 1.45 (Rohlf 2007), showed that the first RW (RW1) represented the major axis of shape variation, which explained 65.5% (SV=0.72627) of the total variance of proximal femur. This deformation along the RW1 axis was mainly described by differences in relative positioning of Ward’s area. Two main specimen clusters were found one in the negative extreme of RW1 and the other on the opposite part. Consequently a more detailed description on RW1 and its observed shape differences was conducted. In the negative extreme of the RW1 it was observed that Ward’s area was located at the middle of the upper limit of femoral neck width. In the positive extreme of the RW1, Ward’s area was positioned on the neck axis under the lower limit of femoral neck length. Regression analysis using shape variables as dependent and moderate plus vigorous PA as independent variable demonstrated that PA accounted for 4% of the variance explained (F=3.3 841, df=32, p<0.01). Conclusion: Proximal femur morphologic variation in pre-pubertal boys seemed to be mainly due to differences in the position of Ward’s area, the region of femoral neck with the lowest bone mineral density. Although statistically significant, PA only accounted for 4% of all shape variation of proximal femur. Funded by Portuguese Science and Technology Foundation and POCI 2010,  POCI/DES/58762/2004.

PERCENTILE VALUES FOR MUSCULAR STRENGTH FIELD TESTS IN CHILDREN AGED 6 TO 17 YEARS; INFLUENCE OF WEIGHT STATUS

Castro-Piñeiro, J., González-Montesinos, J., Mora, J., Keating, X., Girela-Rejón, M., Sjöström, M., Ruiz, J.
(1) University of Cadiz, Spain. (2) Karolinska Institutet, Sweden. (3) University of Texas at Austin, United States. (4) University of Granada, Spain

Aim: To provide percentiles values for nine different muscular strength tests (explosive strength Spanish children aged 6 to 17.9 years. We also examined the influence of weight status on the muscular strength level across age groups, with special focus on underweight and overweight-obese groups. Methods: A total random sample of 2778 (1513 boys and 1265 girls) healthy children and adolescents, participated in a cross-sectional study in Cádiz (Spain). Explosive strength was assessed by throw ball test (upper body), standing broad jump, and vertical jump tests (lower body). Upper body muscular endurance was assessed by push ups, bent arm hang, and pull ups tests, and abdominal muscular endurance by sit ups, curl ups 30 s, and curl ups. Height and weight were measured, and body mass index (BMI) was calculated. Participants were categorized according to the BMI international cut-off values as underweight, normalweight, overweight, and obesity. Results: Boys had significantly better scores than girls in all the studied tests, except in the three upper body muscular endurance tests in 6-7 years old group and in the push ups test in the 8-9 age group. Underweight and normalweight children and adolescents showed similar strength levels, except in the bent arm hang and pull ups test where underweight had significantly better scores. Both underweight and normalweight children and adolescents had significantly higher performance than their overweight and obese counterparts in lower body explosive strength tests and in push ups test in boys, and bent arm hang test in both, boys and girls. Overall, overweight had better strength levels than their obese counterparts. Conclusion: Percentiles values of nine muscular strength tests are provided. The presented percentiles values are of interest to identify the target population for primary prevention, and to estimate the proportion of adolescents with high or low muscular strength levels. The obese and overweight children had worse scores than their underweight and normalweight counterparts, while the underweight group had similar performance that the normalweight group. Funding: The study was funded by Centro Andaluz de Medicina del Deporte, Junta de Andalucía, Orden 4/02/105, BOJA nº 37 (Ref. JACT2005-01), the Spanish Ministry of Education (AP2003-2128, AP2004-2745), and the European Union, in the framework of the Public Health Programme (ALPHA project, Ref. 20060120).

RELATIONSHIP BETWEEN PARENTS’ ACTIVE LIFESTYLE, ATTITUDES AND PAST EXPERIENCES TOWARDS PHYSICAL EDUCATION AND THEIR CHILDREN’S ACTIVE LIFESTYLE

Marques, A., Diniz, J., Carreiro da Costa, F.
Faculty of Human Kinetics, Technical University of Lisbon, Portugal

Introduction: School-based intervention is the most recommended strategy to increase young people’s participation in PA. From an ecological perspective, given the fact that the majority of young people’s PA occurs outside school, there is a growing recognition of the importance of involving parents in this process. Objective: Aiming to support a future school intervention, the purpose of this study was to analyze the relationship between parents’ and children’s lifestyle, and the influence that parents’ attitudes towards PE, as well as their previous experiences have on the lifestyle of their children. Methods: A total of 385 fathers (age 47.5±7.1), 385 mothers (age 45.0±5.5) and their children (168 boys, 217 girls), from grades 7 to 12 (age 15.6±3.3), have participated in the study. Questionnaires were used for data collection. Parents were questioned on lifestyle, perception of health, previous experiences in PE classes, and how they have contributed to the practice of PA. Children were questioned on their participation in sports and leisure activities, goal orientation, perceptions of health and competence, and on attitudes towards school, PE and PA. A cluster analysis was used for data processing. Results: Regarding parents, 65% of fathers and 68% of mothers reported that they practice PA. The most commonly practiced activity was walking. More than half of the students claimed to practice physical activities (58% formally, 52% informally). An individual analysis
revealed that for boys (33.9%) and fathers (12.7%) football is one of the preferred activities. Mothers do not practice team sports. The majority of fathers (80.5%) and mothers (82.1%) have participated in PE classes. As for past PE experience, 40.3% of the fathers and 43.6% of the mothers responded to have had a positive experience.

According to the cluster analysis, the active students were characterized by parents who practiced sports two or more times a week and by the importance they attributed to PE classes as part of the compulsory curriculum. The inactive students had parents that were sedentary and felt that PE should be mandatory, but without evaluation.

Parents with negative experiences in PE during their school years do not differ from those with positive experiences. As for mothers, a good experience in past PE is associated with regular informal and formal sports participation and by the perception of an active lifestyle. Parents showed an accurate perception of their children PA levels, characterizing them correctly. Children also showed a correct perception of their parents lifestyle (p<0.03).

Conclusion: This study shows that the most active children are characterized by their parents’ active lifestyle and by the importance they give to PE. Positive PE experiences characterize the mothers that show an active lifestyle. This data suggests that positive PE experiences can stimulate and contribute to the development of a favourable attitude towards the future practice of PA.

RATE OF PERCEIVED EXERTION AND HEART RATE RESPONSES RELATED TO AGE IN ELDERLY WOMEN DURING COLLECTIVE FITNESS LESSON

Schena, F., Cicchetti, E., Figard-Fabrè, H.
University of Trento, Polo di Rovereto, Italy

The aim of this study was to compare the perceptual and physiological responses of elderly subjects according to their age, during the same collective fitness lesson. In this way, twenty seven women were divided into 2 groups: 60-70 years (group 1, n = 14) and > 70 years (group 2, n = 13). Measurements were performed during 1-hour collective lesson of physical adapted activity for elderly people, subdivided in 7 parts: warm-up, aerobic exercise, exercise (throwing with a ball, ex 1), coordination and ability exercise (rowing with a ball, ex 2), force-resistance exercise (exercising on a pulley, ex 3), individual game (throw a ball, ex 4), collective game (with a ball, ex 5) and stretching-cool-down. Heart rate (HR) was continuously recorded at each bout of exercise. Theoretical HRmax (HRmaxTh = 208 - 0.7 × age) was used to obtain relative HR values (%HRmaxTh). After each exercise, the subjects were asked to rate their perceived exertion (RPE, scale 6-20) and, at the end of the session, subjects completed the self-efficacy for exercise scale (SEES).

As expected, mean HR, HRpeak (maximal HR value recorded during the exercise session) and HRmaxTh were significantly diminished in group 2 compared to group 1 (p < 0.05, < 0.001 and < 0.001, respectively). Moreover, %HRmaxTh tended to decrease in group 2 (67 ± 2.5 % in comparison with group 1 (71 ± 2.0 %)). Concerning the perceptual data, no difference was observed for mean RPE and SEES according to the age. However, in group 2, RPE and SEES values were strongly and positively correlated with HR (r = 0.91, p < 0.05 for RPE) and r = 0.74, p < 0.05 for SEES) HR relationship), whereas no correlation was found in group 1. Finally, exercise 5 was perceived as the easier exercise compared to exercises 1 (p < 0.01), 2 (p < 0.05), 3 and 4 (p < 0.001) in the first group and compared to exercise 4 (p < 0.01) in the second one.

The current results show that, advanced age did not alter perceptual responses to physical exercise. Quite the reverse, the older subjects involved in our study had a better perception of effort than the younger group. However, further investigations are needed to thoroughly understand this finding. Interestingly, collective game seems to be one of the main components to integrate in physical exercise collective lesson intended for elderly people. Indeed, without decreasing the physiological constraints, this kind of exercise modality was perceived as less difficult. This fact is important in order that elderly people easily engage in practice of physical activity on a regular basis.

THE EFFECT OF CYCLING EXHAUSTING EXERCISE ON POSTURAL STABILITY IN YOUNG AND OLD ACTIVE SUBJECTS

Melo, F., Armada-da-Silva, P., Lopes, T.
Faculty of Human Kinetics, Technical University of Lisbon, Portugal

Introduction: It is generally accepted that the risk of fall increases with fatigue. Strenuous exercise results in fatigue occurring at both central and peripheral levels (Enoka et al. 1992). Nardone et al. (1998) showed that body balance during quiet stance was affected by fatigue after walking or cycling. The increased body sway observed after fatigue was correlated with the exercise intensity, even if this effect is of moderate extent and vanishes within a few minutes. Importantly, the negative effect of exercise on postural stability is of similar magnitude on both young and adult active subjects.

This effect is of moderate extent and vanishes within a few minutes. Importantly, the negative effect of exercise on postural stability is of similar magnitude on both young and adult active subjects.

**COMPARISON BETWEEN PHYSICAL ACTIVITY LEVELS IN MEN AND WOMEN INSTITUCIONALIZED ELDERLY WITH MTI ACTIGRAPH**

Monteiro, A., Mota, P., Carvalho, J.
Polytechnic Institute of Bragança, Portugal

Introduction: Exact evaluation of the quantity and intensity of physical activity in daily life is considered very important due to the close relationship between physical activity level, functional decline and sedentary habits. Even moderate-to-vigorous intense physical activity (PA) is beneficial when done regularly for a total of 30 minutes or longer on most or all days. We used in this study accelerometers to measured minute-by-minute the movement, to assess PA volume and intensity performed by women and men older adults in different groups. The objective of this study was to analyze the pattern of PA performed by the Women and Men elderly in their daily routine. Methods: The sample was divided into two different groups [19.0±4.7 years old, BMI: 26.0±4.0, 166 subjects constitute the women group (WG) and 131 belong to the men group (MG). The Physical activity levels were directly measured for seven consecutive days using a MTI Actigraph accelerometer model 7164. The assessment of the level of physical activity performed by each individual has been carried out using the values suggested by Freedson et al. (1998). We point the moderate/vigorous PA intensities because we have a few values in vigorous intensity. The habitual physical activity performed by the groups has been monitored and registered during a complete week (activity performed in week days and weekend). The statistical procedures were the Descriptive Statistics (mean, standard deviation and frequency distribution) and a Student t-test was used to compare WG and MG on the physical activity (PA) performances. Results: The results provided are: (i) The mean PA lower at a week by hour (p<0,428), the mean PA lower at a weekend (p<0,893) and de mean PA lower at all week by hour (p<0,622) were slightly higher in the WG than MG. (ii) The mean PA moderate/vigorous at a week by hour (p<0,457), the mean PA moderate/vigorous at a weekend (p<0,053) and de mean PA moderate/vigorous at all week by hour (p<0,167) were slightly higher in the MG than WG. (iii) No statistics significance between groups was found in Lower PA and in moderate/vigorous PA. Conclusion: We conclude that the groups have an equal profile of performance in PA in lower or moderate/vigorous intensities. There was no statistic significance in every intensities.

**AGING ASSOCIATION TO THE EVALUATION OF THE PHYSICAL CAPACITY IN INSTITUTIONALIZED OLD PEOPLE OF BOTH GENDER**

Monteiro, A., Clemente, G., Mota, P., Carvalho, J.
Polytechnic Institute of Bragança, Portugal

Introduction: Recognising the benefits of regular physical exercise among aged people, the importance of knowing the factors that influence the participation of that population in the physical activity relies on the possibility of improving the intervention accuracy, the kinds of offer and activities. This way and bearing in mind the importance that physical activity assumes in life quality and activity performances, it is crucial to determine the levels of physical capacity, which is taken as one of the objectives of the physical activity, either at physical and physiological levels: to increase the physical capacity through the development, strength, resistance, flexibility, coordination and balance, as a way to overpass accurately and effortlessly the challenges of the daily activities, as well as diminishing the probability of the development of some degenerative chronic diseases. The aim of this current study was to assess the levels of Physical Capacity of aged individuals from both sexes, living in care homes and establishing a comparison with ageing. Methods: The sample is composed by institutionalized aged people, from care homes with ages from 68 to 96 (82.85±7,06). The women group (WGI) was 18 subjects and the men group (MGI) was 18 subjects too. We evaluated Body Mass Index (BMI) and to assess the physical capacity parameters we used the battery of tests developed by Rikli and Jones (1999). The test items included: chair stand test (assess lower-body strength); arm curl test (measure upper-body strength); 6-minute walk test (assess aerobic endurance); chair sit-and-reach test (assess lower-body (primarily hamstring) flexibility); back scratch test (assess upper-body (shoulder) flexibility); and 8 feet up-and-go test (asses agility and dynamic balance). The used statistical procedures were the descriptive statistics (mean, standard deviation and frequency distribution), presentation of the higher and minimal values in relation to the variables dependent on sex. And the inferential statistics (non-parametric tests for independent samples and U Mann Whitney). Results: The following results have shown that in average statistics significance was found in BMI (p<0.004). In Rikly and Jones battery tests, no statistics significance was found in every test! Conclusion: The levels of physical capacity that the aged people from the sample show are very low nevertheless the male genre presents higher values in every tests, with the exception of those which assess the flexibility of the upper-body and lower-body.

**RELATIONSHIP BETWEEN HEALTH-RELATED PHYSICAL FITNESS AND OBJECTIVE PHYSICAL ACTIVITY IN PORTUGUESE FEMALE ADOLESCENTS**

Machado Rodrigues, A., Coelho e Silva, M., Mota, J.
University of Coimbra, Portugal

Discussion of physical fitness and its relationship with physical activity is more apparent in adults than in children and adolescents (Malina, 1996). A large portion of the variability in physical fitness is not accounted by physical activity (Malina, 2001). This suggests that, among pediatric subjects, other factors are involved and need to be considered, for example, growth, maturation, and other components of lifestyle such as television viewing (Katzmarzik et al., 1998). The current study examines the relationship between physical activity and physical fitness. The sample is composed of 221 female subjects (14±1.1 years) from Portuguese Midlands. Somatic characteristics included body weight, stature, sum of six skinfolds and umbilical circumference. Physical activity was estimated using an uniaxial accelerometer (Actigraph, model 7164) on five consecutive days assuming a criterion of 10h per day for inclusion. Health-related physical fitness was defined as one-mile run, sit-ups, sit-and-reach and 20-meter shuttle run. After presenting descriptive statistics, data analysis determined the correlation between indicators of health-related fitness and physical activity. Coefficients of correlation between physical activity (counts/min) and the four indicators of health-related physical fitness ranged from 0.17 to +0.58. Between moderate-to-vigorous physical activity and health-related fitness, the magnitudes of correlations ranged from 0.13 through +0.58. Physical activity was significantly and positively correlated with one-mile run and 20-m shuttle-run performance. No significant relationship was found between physical activity and sit-ups or sit-and-reach. In summary, the relationship between 3-day accelerometry data and physical fitness were no more than weak to moderate. The results highlight the complexity of assessing short-term physical activity as a predictor of fitness in adolescents. References.
Introduction: Vibration exercise is a new type of physical training to maintain and/or improve muscle strength and postural stability. However, research about this topic with elderly women has been scarce. Purpose: To investigate the effect of a whole body vibration training program on postural control and quality of life in women aged 60-82 years. Methods: Fifty three women were distributed into two groups, a whole body vibration exercise group (VEG: n=21; 48% of which with high physical function; age: 70.7±6.2 yrs; BMI:26.2±2.9 kg/m²), a combined aerobic plus resistance exercise group (CEG: n=19; 58% of which with high physical function; age: 68.1±5.9 yrs; BMI:26.2±2.7 kg/m²), and a control group (CG: n=13; 31% of which with high physical function; age: 70.7±6.6 yrs; BMI:26.7±3.0 kg/m²). Participants of vibration and combined exercises were randomly assigned to each group. The dissimilarity between these two intervention groups consisted of an additional static and dynamic balance exercises performed by VEG participants during 10 min on a vibration platform (Galileo 2000, with a frequency of 15-25 Hz, in two of the three sessions (1 hour training each session) that both groups accomplished per week during 2 months. The control group did not exercise. Postural control was measured by dynamic computerized posturography, namely, the Limits of Stability Test (reaction time, movement velocity, end point excursion and directional control, the modified Clinical Test Sensory Interaction Balance and Unilateral Stance Test (COG sway velocity). Quality life was assessed using the Short-Form Health Survey, specifically, physical and social functioning, physical and emotional role limitations, mental health, general health, vitality and pain. Results: Analysis of covariance (ANCOVA) was used to compare rate changes of quality of life and balance variables between groups. Due to differences at baseline, comparison of dependent variables between groups was adjusted for the initial values of the respective variable. ANCOVA showed group differences in the rate of change of physical functioning (VEG:10.15 vs. CG:-2.24%, p=0.001; CEG:1.8% vs. CG:-2.4%, p=0.015), unipedal COG sway velocity with open eyes (VEG:-29.14 vs. CG:40.1311, p=0.010; CEG:-4.21 vs. CG:40.1311, p=0.036), end point excursion forward (VEG:30.44 vs. CG:-12.34%, p=0.001; CEG:36.72 vs. CG:-12.34%, p=0.001), maximum excursion forward (VEG:18.35 vs. CG:-14.30%, p=0.002; CEG:21.59 vs. CG:-14.30%, p=0.001), and directional control (VEG:12.23 vs. CG:2.17%, p=0.001; CEG:7.13 vs. CG:2.17%, p=0.003). Conclusion: Adding 10 min of vibration exercise to a 60 min aerobic plus resistance training program during 2 months did not impact postural control and quality of life in women aged 60-82 yrs, since at the end of the intervention programme both exercise groups demonstrated improvements in physical functioning and postural control, particularly on limits of stability.

EFFECTS ON STRENGTH OF VIBRATORY EXERCISE COMPARED TO WALKING IN POSTMENOPAUSAL WOMEN

Raimundo, A., Gusi, N., Tomas-Carús, P.
University of Évora, Portugal

Purpose: to compare the effect of 8 months of low-frequency vibration and a walk-based program in the muscle strength. Methods: twenty-seven postmenopausal women were randomly assigned into two groups: the whole body vibration group (WBV) (n=14) that performed 3 times a week a static exercise on a vibration platform (6 sets of 1-minute with 1 minute of rest, with a 12.6 Hz of frequency and a amplitude of 3 mm); and walking control group (WC) (n=13) performed 3 times a week a 60-minute walk activity. A health-related battery of tests was applied. Maximal unilateral concentric and eccentric isokinetic torque of the knee extensors was recorded by an isokinetic dynamometer. Results: after the 8 months, the time spent to walk 4-meters and to perform the chair and rise test of the Walking group improved 20% and 12% compared to the WBV group (p = 0.011, p = 0.005, respectively). In contrast, the type of exercise program did not show any significant comparative effect on isokinetic measurements. Conclusion: Both programs differed in the main achievements and could be complementary to prevent lower limbs muscle strength decrease as we age ([ISRCTN76235671])

LIFE'S SATISFACTION AND SELF PHYSICAL CONCEPT: THE EFFECTS OF SIX MONTHS OF PILATES-BASED EXERCISE IN WOMEN

Cruz-Ferreira, A., Fernandes, J.
University of Évora, Portugal

PURPOSE The purpose of this study was to determine the effects of Pilates-based mat exercise on life's satisfaction and self physical concept. METHODS Participants were 63 adult women (aged 25-55), 39 yrs (IQR:1.3 +/- 6.7 yrs) who voluntarily enrolled in a Pilates-based mat class for 24-week, 2 times per week on non-consecutive days, 60-minute per session (EG), and 24 yrs (IQR:3.3 +/- 7.7 yrs) served as controls (CG). After being informed on the risk and the benefits of the practice all participants gave their written informed consent to their participation on the study . The committee on Ethics of the University of Évora approved the study. Life’s satisfaction (LS) was measured using Satisfaction with Life Scale and the self physical concept was assessed by the Self Physical Concept Scale. The first questionnaire consisted of five statements with a Likert's scale answer from strongly disagree to strongly agree. The Self Physical Concept Scale questionnaire consists on nine statements, which measures the Self Physical Concept (SPC), the Perception of the Impression that causes in the Others (PIO), the Perception of Physical Appearance (PPA) and the Perception on Function (PF).
Each participant answered the questionnaires in a unique session, and the order application was the same at baseline, after 12 and 24 wk. The repeated measures ANOVA, Bonferroni post hoc test and Syntax were run in SPSS version 15.0 (SPSS Inc. Chicago, IL). For all tests the significant level was set at p<0.05.

RESULTS The results showed statistically significant differences on Life’s Satisfaction (F(2)= 3,790, p=0.025), between week 2 and week 12 (p=0.001) and between baseline and week 24 (p=0.035). In what concerns SPC the results indicated statistically significant differences (F(2)=10,744, p=0.000). These differences were observed between week 2 and week 24 (p=0.000) and between baseline and week 24 (p=0.001). Furthermore, the results indicated statistically significant effect for the three dimensions on the self physical concept: PIO, F(2)=4,007, p=0.021, between week 12 and week 24 (p=0.014) and between baseline and week 24 (p=0.008); PPA, F(2)= 5,296, p= 0.006, between week 12 and week 24 (p= 0.001) and between baseline and week 24 (p=0.037); PF, F(2)=4,473, p=0.013, which were between week 12 and week 24 (p=0.001) and between baseline and week 24 (p=0.004). There were no statistically significant differences between EG and CG, at baseline.

CONCLUSIONS This study demonstrated that adult women exposure to Pilates-based mat exercise during 12 weeks, for two 60-minutes sessions per week was not enough to stimulate statistically significant increases in LS and SPC. However, after 24 weeks the adult women increased the LS, SPC, PIO, PPA and PF. In conclusion, after 24 weeks of Pilates-based exercise, significant improvements attributable to practice effects were found in LS, SPC, PIO, PPA and PFG.
ELECTROMYOGRAPHIC EVALUATION OF SHOULDER EXTERNAL ROTATORS AND TRAPEZIUS MUSCLES IN DIFFERENT EXERCISES

Marta, S., Pezarat-Correia, P., Fernandes, O., Carita, A.
Faculty of Human Kinetics, Technical University of Lisbon, Portugal

Purpose: Specific exercises for strength development of external rotator muscles are necessary to guarantee shoulder balance in athletes. The main goal of this study was to quantify the EMG activity of shoulder external rotators muscles and scapula stabilizers (trapezius muscle) in seven exercises commonly used to strengthen these muscles.

Methods: 20 healthy males (age=22±3.6 years) performed seven exercises in random order: (A) prone horizontal abduction with full external rotation (ER) at 90° of abduction, (B) prone horizontal abduction with thumb forward at 90° of abduction, (C) prone horizontal abduction with full ER at 100° of abduction, (D) side lying ER at 90° of abduction with elbow at 90°, (E) side lying ER with elbow at 90°, (F) standing ER in scapula plane, (G) standing ER with elbow at 90° with a towel roll placed between the trunk and elbow. Each subject performed 8 repetitions in each exercise with a 4Kg dumbbell. Surface EMG was recorded from the posterior deltoid, infraspinatus, teres minor, upper, middle and lower trapezius. The EMG signals were amplitude normalized using as reference the maximum EMG value found in the MVC. Mean EMG value was calculated separately during each repetition and during each phase (concentric and eccentric). For the phase delimitation a movement sensor was used. The Shoulder Synergy was calculated by the formula (ER synergy + Trapezius synergy/2). The ER Synergy was calculated through the average of the EMG values from the infraspinatus, teres minor and posterior deltoid. The Trapezius Synergy was calculated by averaging the EMG value from the three portions of the muscle. A Rotator Cuff Synergy was also calculated using the average from the infraspinatus and the teres minor.

Results: The mean values of different individual muscles and synergies in each exercise were determined. Shoulder Synergy: A=44,96±9,77%; B=39,34±9,23%; C=44,67±8,79%; D=43,83±10,37%; E=28,59±7,28%; F=20,20±4,23%; G=14,45±4,60%. ER Synergy: A=44,08±12,97%; B=40,39±10,63%; C=40,88±9,39%; D=41,61±12,65%; E=31,48±10,27%; F=23,00±7,64%; G=16,32±7,02%. Rotator Cuff Synergy: A=42,91±17,62%; B=34,83±12,91%; C=36,89±12,76%; D=40,56±14,47%; E=37,17±13,70%; F=30,82±10,62%; G=22,73±9,79%. Trapezius Synergy: A=46,81±10,40%; B=38,84±12,46%; C=49,57±12,05%; D=46,43±12,58%; E=26,23±7,75%; F=17,88±4,17%; G=13,36±4,57%. ER Synergy: A=44,96±9,77%; B=39,34±9,23%; C=44,67±8,79%; D=43,83±10,37%; E=28,59±7,28%; F=20,20±4,23%; G=14,45±4,60%. ER Synergy: A=44,08±12,97%; B=40,39±10,63%; C=40,88±9,39%; D=41,61±12,65%; E=31,48±10,27%; F=23,00±7,64%; G=16,32±7,02%.

Conclusions: For the dumbbell mass we used (4Kg), the exercises performed in the prone position presented the highest levels of EMG activation in the ER synergy, Trapezius Synergy and Shoulder Synergy. To activate specifically the ER muscles from the rotator cuff group (infraspinatus and teres minor), with a reduced solicitation of the posterior deltoid muscle, the side lying exercise (E) represents a good option since it presented high activation level of the Rotator Cuff Synergy with low level activation for the posterior deltoid (20,60±8%).

EVALUATION OF HEALTH PROMOTION LIFESTYLE PROFILE AND PHYSICAL ACTIVITY PATTERNS AMONG TURKISH PHYSIOTHERAPISTS

Koz, M., Mert, E., Ersoz, G.
(1) Ankara University (2) Baskent University Hospital, Turkey

Purpose:
Physical therapy interventions implies not only health protection but also health promotion, a concept which includes everything that can promote health and working capacity of patient. Health-promotion lifestyle profile (HPLP) and physical activity (PA) patterns of therapists can be effect their therapy interventions. The purpose of this study was to describe HPLP of 33 Turkish female physiotherapist aged x = 31,38 ± 6,20, and to determine the relationship between their lifestyle behaviors and PA patterns.

Methods:
Data were collected using a questionnaire about HPLP developed by Walker et al [1]. It is composed of 48 items and 6 subscales and consists of questions about health promoting behaviors. Total scores reflects the healthy life-style behavior. To record PA patterns and to estimate energy expenditure of daily living was used SenseWear Armband (SWA)(BodyMedia Inc., Pittsburg, PA). Each participant wore SWA monitors on the upper arm of the dominant hand for an average 47 hours during two consecutive days. Following parameters obtained from SWA monitor:daily energy expenditure (kcal/d), daily number of steps, duration of lying down (min/d), duration of sleep (min/d), daily average METs, active energy expenditure (kcal/d), duration of physical activity (min/d). Data were analyzed using SPSS package program. Descriptive statistics and Pearson Product Correlations were used to determine relationship between HPLP and PA patterns.

Results:
The mean total HPLP score was 128.09 ±16.08, the mean scores of self-actualization, health responsibility, exercise, nutrition, interpersonal support and stress management as follows: 38.82±5.72, 24.43±5.21, 8.60±2.95, 17.83±2.67, 20.87±2.85, 17.52±3.23, respectively. Total energy expenditure was 2266.93±310.72 kcal/d, number of steps were 10089.17±3502.39, duration of lying down was 347.79±81.84 min/d, daily average MET value was 1,55±0.23, active energy expenditure was 519.93 ±253.60 kcal/d; duration of physical activity was 120,21±65,97 min/d. There were significant correlations between duration of sleep and self-actualization (r = 0.430), and nutrition (r = 0.456) p < 0.05.

Conclusions:
It was concluded that physiotherapists participated in the study were generally at medium level of health promoting behaviors, and the highest mean score was health responsibility and the lowest was exercise. For increasing and supporting health promoting behaviors of the physiotherapists, exercise promotion interventions and opportunities should be included in their daily working schedules.

FAMILIAL AGGREGATION OF OBESITY INDICATORS AND HYPERTENSION: A POPULATION-BASED STUDY IN RURAL MADEIRA

Silva, R., Rodrigues, A., Almeida, M.
University of Madeira, Portugal

Introduction.
In children and adolescents, waist circumference (WC) has been identified as the best predictor of Metabolic Syndrome. This study was carried out to determine the association between WC of 10 to 18-year-old children and adolescents from a rural area in Madeira, and their parents' risk factors for cardiovascular disease such as WC and blood pressure (BP).

**Methods.** Participants in this study were 176 students (86 M, 65 couples, 153 mothers aged 42.3 ± 6.1 years and 69 fathers aged 45.3 ± 8.4 years. Subjects were measured for weight, height, WC and BP. Central obesity (CO) in the students was classified according to the thresholds by Katzmarzick et al. (2004), and WC >80cm and 94cm for their mothers and fathers, respectively (IDF, 2006). Hypertension was defined in children using the Task force definition (NHBP, 1998) and for their parents, according to the IDF (2006).

**Results.** Of the students examined, 2.3 % were obese (OB), 17.0% overweight (OW), 71.6% normal and 9.1% underweight, according to Cole (2000, 2007). Of all mothers 28.1% were OB (BMI>30), 31.4% OW (BMI>25<30) and 40.5% non-OB (BMI<25); 12.7% of fathers were OB (BMI>30), 49.2% OW (BMI>25<30) and 38.1% non-OB (BMI<25). Interestingly, only 23.8% of the fathers were classified as at risk for CO, in comparison to mothers with a prevalence of 52.3%. The prevalence of hypertension was 70.3% for fathers and 64.5% for mothers. Significant positive correlations were found for mother-offspring pairs, mother-daughter (r = 0.28, p = 0.009, n = 88) mother-son (r = 0.27, p=0.016, n = 82) but not for father-offspring (p > 0.05, n = 34). Daughters presented a higher risk for hypertension (OR 1.10; CI 95%, 0.42-2.92) and CO (OR 3.00, CI 95%, 1.01-8.88) comparing to sons. Compared with daughters whose mothers did not have hypertension, the odds ratios in daughters with a hypertensive mother were 1.10 (CI 95%, 0.42-2.92) and similarly for CO, odds ratios were 3.00 (CI 95%, 1.01-8.88). A lower risk was found in sons whose odds ratios were 0.68 (CI 95%, 0.26-1.82) for hypertension and 1.32 (CI 95%, 0.38-4.58) for CO. Converse results were found regarding BMI in which, boys presented higher odds ratios for being OW or OB (OR 2.33, CI 95%, 0.58-9.43) compared to daughters (OR 1.57, CI 95%, 0.48-5.09) when their mothers were OB or OW.

**Conclusions.** In Madeiran rural families with adolescents, there is a familial aggregation of waist circumference, with daughters resembling their mothers more than sons, but not fathers. This may be explained by the fact that fathers presented a much lower risk of central obesity and professions requiring manual labour. The obesity relationship between mother and daughter advocates for the mother as a key player in the obesity prevention.

**RELATIONSHIP BETWEEN PHYSICAL ACTIVITY, NUTRITION, AND EATING BEHAVIORS DURING WEIGHT MANAGEMENT IN OVERWEIGHT AND OBSESE WOMEN**

Faculty of Human Movement, Technical University of Lisbon, Portugal

**PURPOSE.** Physical activity (PA) may contribute to improved compliance with recommended eating behaviors, and indirectly improved weight control. The goal of this study was to analyze the relationship between changes in PA, nutrition and eating behavior variables during a weight management program for overweight and obese women.

**METHODS.** 253 women (age: 37.0±7.1 years; BMI: 31.6±4.3 kg/m2) who initiated a 12-month behavioral obesity treatment program during a weight management program for overweight and obese women. The Dutch Eating Behavior Questionnaire, the Emotional Eating Scale, and the Three Factor Eating Questionnaire were used to measure cognitive eating behavior. A Food Frequency Questionnaire was used for dietary intake, and for PA the 7-day Physical Activity Recall (moderate+vigorous), pedometry (walking), and the Obesity-specific Physical Activity Recall (Ob-PAR, lifestyle PA) were used.

**RESULTS.** During the program, participants significantly increased cognitive eating restraint (p<0.001), and decreased eating in response to depression symptoms (p=0.035) and external eating (p=0.030). Correlation analysis show significant associations between PA and nutrition: all exercise variables were associated with a decrease in fat consumption (p<0.033); walking was associated with increases in carbohydrate intake (p=0.022). Associations between PA and eating behaviors also matched this pattern of improvements: lifestyle and moderate-vigorous PA were associated with increases in eating restraint and decreases in all other variables (disinhibition, hunger, external, and emotional eating, p<0.029). Eating restraint (p<0.001), external eating (p=0.027) and eating in response to depression (p=0.033) distinguished active from insufficiently active participants.

**CONCLUSIONS.** In overweight women, these analyses provide support to the usefulness of increasing exercise and PA for improved eating control, especially through the reduction of overeating episodes. If confirmed, this interaction among weight-healthy behaviors has important implications for future programs. Further studies are needed to clarify the psychological mechanisms and/or measurement issues underlying these associations.

**GENDER DIFFERENCES IN HEART RATE INTENSITY DURING RECREATIONAL MOUNTAIN BIKING**

Hotter, B., Kornexl, E.
University Innsbruck, Austria

**Introduction.** Mountain biking (MTB) is a popular alpine outdoor activity, performed by 5% of the population in the Alpine countries (1) with a male female ratio of 2.5:1. Competitive off road cycling heart rate intensity has been analysed (2), but most recreational MTB research has investigated accidents and trauma. Therefore the aim of this study was to analyse heart rate intensity of recreational mountain bikers.

**Method.** A total of 49 (20 female / 29 male) bikers performed two tests. The lab test was a maximum progressive exercise protocol to determine maximal heart rate. The field test was a 7km MTB route with variable climbs at a self determined pace. Results were analysed by gender and age (younger: defined as 20-30 years, elderly: 50-65 years). The relative heart rate (%HR) was defined as the absolute (peak) heart rate divided by the maximal heart rate.

**Results.** At the self determined pace the mean time for the fixed MTB route was 61±8.7min. Men of all ages were faster than women, in the 20-30 group the mean time (55±6.1min) was significantly shorter for men, while in the 50-65 group men were faster but there was no statistically significant difference. The younger groups were faster independent of gender. Mean heart rate was 158±17.3bpm. Older women had a significantly higher heart rate (160±15.8bpm, p<0.01), whereas no gender specific difference was found in younger bikers. The mean relative heart rate was 89.5 %, and all women reached higher values than the men. The difference in the younger age group was 2.4% and the difference in the older group was significant [3.4%, p<0.01].

**Discussion.**
A relative heart rate of 90% during one hour of recreational sport is rare. This observation could be due to a high motivation. Relative heart rates of 70-74% have been found in ski mountaineering (3) and 62-68% in nordic walking. No gender specific differences were found in the absolute heart rate of the 20-30 group, but the 50-65 year old women were significantly higher than the men. Higher absolute heart rates in women during endurance sport have been reported in the past, explained by a lower hemoglobin level and oxygen pulse (4,5). A possible explanation for the similar heart rates in the young subjects could be motivation, as young men may identify more with their performance. This study demonstrates a high heart rate intensity during recreational MTB, so MTB is an effective cardiovascular training method.

ALTERNATIVE REPRESENTATIONS OF THE WING-KRISTOFFERSON MODEL
Diniz, A., Barreiros, J., Crato, N.
Faculty of Human Kinetics, Technical University of Lisbon, Portugal

Many human activities share the purpose of coordinating movement with time. A specific problem within this more general scenario is the coordination and timing of repetitive movements and, particularly, the conservation of a given interval in repetitive tapping. Stevens (1886) developed a simple experimental design in tapping tasks called the synchronization-continuation paradigm. Wing and Kristofferson (1973) introduced a model which offers a decomposition of the inter-response intervals in this kind of tasks, founded on a cognitive component and on a motor component. In the original approach, based on experiments with short continuation phases, the intervals related to the cognitive and to the motor components are regarded as independent white noise sources. Gilden et al. (1995) used long continuation phases and some spectral techniques and suggested that the intervals related to the cognitive component are drawn from a long-memory process (i.e., a stationary process whose autocorrelation function decays slowly following a hyperbolic decay). We performed an experimental study involving tapping tasks with two target frequencies (1.250 Hz and 0.625 Hz) and analyzed the corresponding time series. We propose a new theoretical approach, in which the intervals related to the cognitive component are modelled as a fractionally integrated process and the intervals related to the motor component are treated as a white noise process, independent of each other. Under these assumptions, we obtain the autocorrelation function and the spectral density function of the model. The estimation results point to a fractional parameter d around 0.4 which shows the presence of long memory. There is empirical evidence that many real data exhibit an autocorrelation structure with long memory. Currently, there is a vast literature on this topic including estimation methods and stochastic models (e.g., Palma, 2007). More specifically, there are some statistical explanations for long-memory processes. We suggest two statistical representations of our model that generate long memory and provide some information about the underlying biological system. The first one is based on an error duration model (Parke, 1999) and the second one is based on a regime switching model (Liu, 2000). Once again, the estimation results point to a parameter d close to 0.4 which reflects persistent long memory.

ACCELERATION PERCEPTION - A NEW SPIN
Li, F.X., Sheppard, A.
University of Birmingham, United Kingdom

Most previous research suggests that humans are not able to perceive target acceleration and utilise it in the guidance of acceleration (e.g. Craig et al. 2006). This is counter-intuitive in view of the prevalence of acceleration in the natural environment. The present experiment revisited this question, but included a) a physical 3D display rather than a virtual representation, b) participants with a great deal of experience of intercepting accelerating targets and c) a task giving greater freedom for participants to perform more ‘naturally’ than previous studies. Comparisons of catching movement efficiency are made between the experienced interceptors and participants without particular expertise in intercepting accelerating targets.

Experts and novice table tennis players were asked to catch table tennis balls that were projected with no spin (normal trajectory), backspin (flatter trajectory) or topspin (more curved trajectory) into the vicinity of the catcher. Ball delivery was in a random order with 12 trials for each spin condition. The ball was launched by a machine hidden behind a low curtain so that the kinematics of the ball launch were not visible to participants. The final 5m (or 6m) of the ball trajectory was visible to catchers. Four dependant variables were calculated reflecting the efficiency of the catching movements straightness of the total hand trajectory, and RMS acceleration, RMS jerk, and ‘linex’ (a measure of endpoint duration), of the hand trajectory in the final 500ms of the action.

Experts moved more efficiently than novices - their hand trajectories were straighter and showed less acceleration in the 500ms before the catch, F(1,16) = 8.54, p = .01 and F(1,16) = 5.49, p = .03 respectively. Movements became less efficient with greater trajectory curvature (p < .02 for all efficiency measures) but more so for novices than experts (group by spin interaction effects p = .01 for RMS acceleration and jerk, and p = .04 for linex).
The declining movement efficiency with increasing trajectory curvature for both groups suggests that first order information strongly influences catching behaviour. However, the ability of the experts to perform more efficiently then the novices, especially as trajectory curvature increased, suggests that this particular sub-population are able to perceive target acceleration and to incorporate it to some degree into the guidance of interceptive actions. We conclude that it is possible for humans to utilize target acceleration in the guidance of interception, and that relevant task experience influences the degree to which it can used. The discrepancy between current findings and the results of previous studies are discussed with particular consideration of the differences in tasks and populations investigated.

EFFECT OF CYCLING CADENCE ON KNEE AND ANKLE ANGULAR KINEMATICS AND GASTROCNEMIUS MUSCLE LENGTH
Li, F.X., Connick, M.
University of Birmingham, United Kingdom

Propulsion during cycling occurs between Top Dead Centre (TDC) and Bottom Dead Centre (BDC) with peak torque occurring between 90 and 105 degrees. The gastrocnemius muscle is partly responsible for transmitting forces generated from the hip and thigh muscles to the pedal and is therefore of particular interest during the second half of propulsion and prior to BDC. Sanderson et al. (2006) found a single period of lengthening during propulsion followed by sustained shortening, through BDC, of the muscle-tendon at all cadences ranging from 50rpm to 110rpm. Gregor et al. (1991), however, observed a second gastrocnemius lengthening during the final part of propulsion prior to BDC. These authors found the length change occurred when cycling at 90rpm but not at 60rpm where a similar muscle length profile to Sanderson et al. (2006) occurred. Therefore this study aims to clarify the effect of cadence on gastrocnemius muscle/tendon length.

Results showed that the gastrocnemius muscle operated at significantly shorter lengths, over the course of the crank cycle, as cadence increased. Significant differences were observed in the behaviour of the gastrocnemius muscle between 40-50% of the crank cycle. Gastrocnemius muscle lengthened 0.1% and 0.29% at cadences 90 and 100rpm. However, at 50, 65 and 75rpm the muscle shortened 0.51%, 0.34%, 0.11% respectively over the same portion of the cycle. Mean ankle angular displacement increased (plantar-flexion) significantly with cadence from 87 to 97 for 50rpm to 100rpm respectively. Mean knee angular displacement significantly decreased (flexion) with increasing cadence (p<0.05).

The results support the data of Gregor et al. (1991). The gastrocnemius muscle exhibits a double lengthening phase at higher cadences during the propulsive phase with lower cadences showing a single lengthening phase. At higher cadence the shorter lengths of the gastrocnemius were due to changes in both knee and ankle angular kinematics. Although the range of motion for both joints is similar to those reported by Sanderson et al. (2006), the ankle angle is different. These changes of the ankle angle at higher cadences may allow a better transmission of forces to the pedal through BDC.

EFFECTS OF INTERNAL, EXTERNAL AND PREFERENCE OF ATTENTIONAL FOCUS FEEDBACK ON LEARNING VOLLEYBALL TENNIS SERVE OF 12-13 YEARS OLD CHILDREN
Kirazci, S., Ayan, D.
Middle East Technical University, Turkey

The purpose of this study was to examine the effects of internal focus feedback, external focus feedback and preference of attentional feedback on skill learning at age of 12-13 years.

Feedback related with body movements was given as internal focus, whereas feedback related with movement effects was given as external focus. As a task “tennis service” in volleyball was used for both acquisition and retention measurements. Elementary school children with very limited knowledge and experience about the tennis service skill (N=78) were randomly assigned to three groups which were internal focus feedback group (IFF), external focus feedback group (EFF) and preference groups (PF). Subjects in PF group received feedback on skill learning at age of 12-13 years.

The results support the data of Gregor et al. (1991). The gastrocnemius muscle exhibits a double lengthening phase at higher cadences during the propulsive phase with lower cadences showing a single lengthening phase. At higher cadence the shorter lengths of the gastrocnemius were due to changes in both knee and ankle angular kinematics. Although the range of motion for both joints is similar to those reported by Sanderson et al. (2006), the ankle angle is different. These changes of the ankle angle at higher cadences may allow a better transmission of forces to the pedal through BDC.

References

This study indicated that for young children with limited amount of knowledge about a skill, internal focus feedback is more appropriate compared to external focus feedback in terms of retention. Being able to choose among internal and external focus of attention also seems to make a difference in retention performance of novice children indicating that active participation on the learning variables is an important concept.
TECHNOLOGY OF TEACHING SPORTS TECHNIQUE OF GYMNASTICS EXERCISES

Niznikowski, T., Sadowski, J.
Joseph Plisudsky University of Physical Education in Warsaw, Poland

Introduction: The increasing of complexity and difficulties of programs’ range for gymnastic competition introduced by International Federation of Gymnastics (FIG), is manifested by the new, more effective means, forms and methods of teaching. The process of teaching complex exercises along with a constantly rising level, quality and stability is getting more and more difficult. It is necessary to apply new techniques for a better analysis of the structure of sports exercises in order to identify the most significant elements of a particular movement. Information concerning the most characteristic and the most significant, from the point of view of teaching the movement, stages of a physical movement is necessary to prepare effective training programs. Identifying such stages, described in literature as key elements of sports technique, should be an initial step to prepare pedagogical technologies of training. Therefore, the aim of the paper was to describe an effective pedagogical training technology of the process of teaching gymnastics exercises.

Method: Pedagogical experiment and 60 HZ UVC GR-DVL, 9800 NTSC camera with APAS 2000 cinematographic analysis systems were used to describe the round-off tucked back somersault (n=30) and straight back somersault after flickflack and round-off (n=9).

Results: On the basis of the research it was concluded that pedagogical technology of teaching includes three components: the first one a biomechanical analysis of phase structure of movement, the second one didactic teaching structure, and the third one contemporary teaching technology including algorithms as well as programs of teaching acrobatic exercises.

Conclusions: The effective teaching of gymnastics exercises is possible due to introducing pedagogical technology of teaching key elements in sports technique.

Many authors have similar opinions. It is often claimed that effective teaching depends on the so-called key elements, i.e. the main movements of the body or its parts. These elements are said to be indispensable to do a particular activity.

The acquisition of key elements of technique provides a positive transfer to perform the whole exercise or its profile (e.g. tucked back somersault - double tucked back somersault).

CYCLING: HEAD STABILIZATION ON IRREGULAR TERRAIN

Catela, D., Branco, M., Mordomo, B.
Escola Superior Desporto Rio Maior, Portugal

An image stationary on the retina permits to perceive undisturbed visual information about events that happen in front of us (Howard, 1993). Animals with flexible necks and whose eyes are fixed, generally attempt to stabilize the head, with the intent to stabilize the gaze (Troje & Frost, 2000). A chicken walking keeps its head stationary in space while the legs move the body forward (Davies & Green, 1988), this head-bobbing is synchronized with the movement of the feet (Dagg, 1977). Cycling on irregular terrain disturbs head and eyes stabilization. We tried to verify if adults use head stabilization during cycling on an irregular terrain, according to their experience. Head vertical oscillations and standard deviation of angle variations on elbow, hip and knee, were observed of one expert on all terrain cycling and eight inexperienced adults. Each subject had to cycle twice along a waved and a plain terrain. Images were treated in a movement analysis system (APAS), with a 5Hz low pass filter, and 6 co-planar points. Data revealed that inexperienced subjects could be divided on 2 sub-groups (immature, intermediate), namely, on head oscillation (Kruskal-Wallis = 11.378, p<0.01), on waved condition. For the waved condition, expert subject had stabilized head significantly more than immature (n= 5) and intermediate (n=3) groups (Wann-Wilhney, p<0.05, and p<0.05, respectively); intermediate group also differed significantly from immature group (p<0.01). On the waved condition, expert subject revealed greater standard deviations (n.s.) on the angle of elbow and knee joints (±61.51°, ±75.51°, respectively, than intermediate (±53.59°, ±58.27°) and immature (±57.85°, ±59.89°) groups. Additionally, expert subject produced greater mean angle (n.s.) on ankle join (74.69°) than intermediate (64.89°) and immature (67.31°) subjects. Coefficient of variation confirmed these results, on intermediate (±53.59°, ±58.27°) and immature (±57.85°, ±59.89°) groups. Additionally, expert subject reveal greater standard deviations (n.s.) on the angle of elbow and knee joints (±61.51°, ±75.51°, respectively) than intermediate (±53.59°, ±58.27°) and immature (±57.85°, ±59.89°) groups. Additionally, expert subject reveal greater standard deviations (n.s.) on the angle of elbow and knee joints (±61.51°, ±75.51°, respectively) than intermediate (±53.59°, ±58.27°) and immature (±57.85°, ±59.89°) groups. Additionally, expert subject reveal greater standard deviations (n.s.) on the angle of elbow and knee joints (±61.51°, ±75.51°, respectively) than intermediate (±53.59°, ±58.27°) and immature (±57.85°, ±59.89°) groups. Additionally, expert subject reveal greater standard deviations (n.s.) on the angle of elbow and knee joints (±61.51°, ±75.51°, respectively) than intermediate (±53.59°, ±58.27°) and immature (±57.85°, ±59.89°) groups. Additionally, expert subject reveal greater standard deviations (n.s.) on the angle of elbow and knee joints (±61.51°, ±75.51°, respectively) than intermediate (±53.59°, ±58.27°) and immature (±57.85°, ±59.89°) groups. Additionally, expert subject reveal greater standard deviations (n.s.) on the angle of elbow and knee joints (±61.51°, ±75.51°, respectively) than intermediate (±53.59°, ±58.27°) and immature (±57.85°, ±59.89°) groups. Additionally, expert subject reveal greater standard deviations (n.s.) on the angle of elbow and knee joints (±61.51°, ±75.51°, respectively) than intermediate (±53.59°, ±58.27°) and immature (±57.85°, ±59.89°) groups. Additionally, expert subject reveal greater standard deviations (n.s.) on the angle of elbow and knee joints (±61.51°, ±75.51°, respectively) than intermediate (±53.59°, ±58.27°) and immature (±57.85°, ±59.89°) groups. Additionally, expert subject reveal greater standard deviations (n.s.) on the angle of elbow and knee joints (±61.51°, ±75.51°, respectively) than intermediate (±53.59°, ±58.27°) and immature (±57.85°, ±59.89°) groups. Additionally, expert subject reveal greater standard deviations (n.s.) on the angle of elbow and knee joints (±61.51°, ±75.51°, respectively) than intermediate (±53.59°, ±58.27°) and immature (±57.85°, ±59.89°) groups. Additionally, expert subject reveal greater standard deviations (n.s.) on the angle of elbow and knee joints (±61.51°, ±75.51°, respectively) than intermediate (±53.59°, ±58.27°) and immature (±57.85°, ±59.89°) groups. Additionally, expert subject reveal greater standard deviations (n.s.) on the angle of elbow and knee joints (±61.51°, ±75.51°, respectively) than intermediate (±53.59°, ±58.27°) and immature (±57.85°, ±59.89°) groups.

VISUAL REACTION TIME DIFFERENCES BETWEEN SEXES: EFFECT OF SPORT PARTICIPATION & DRIVING

Kiraci, S., Tanyel, E.
Middle East Technical University, Turkey

The purpose of this study was to investigate whether sport participation and extensive driving has any effect on the differences between sexes in visual reaction time (VRT). It has been generally demonstrated that across all age groups females have slower reaction times (RT) than males and that practice seem to have not much effect on the difference. A recent historical meta-analysis paper by Silverman (2006) argues that the difference between sexes is getting closer at least in visual reaction time (outside the USA) possibly due to more women’s participation in fast-action sports and driving.

Three groups of (control, sport and driver) 40 subjects (20 males & 20 females) participated to the study. The sport participation group (SPRT) comprised of athletes from taekwondo who were training at least for 5 years, minimum 3 days per week annually. The driver (DRV) group included males (M) and females (F) that were working as representatives of a company and driving at least 20,000 km annually for the last 4 years. University M and F students who neither drive nor regularly exercise were in control (CON) group. Participants were measured 3 times for simple VRT and choice visual RT for dominant and non dominant hands. Group and sex differences were examined with MANOVA.

The result indicated statistically significant interaction between sex and group for dominant hand (Wilks’ Lambda= 66, F(222,8)=6.27, p<0.05) and non dominant hand (Wilks’ Lambda= 60 F(222,8)=7.98, p<0.05) in favor of M and for most of the comparisons. For example
analyses for the dominant hand indicated that on VRT, the highest RT score was observed for F in CON group (M=40, SD=04) whereas the lowest RT score belongs to F in DRV group (M=29, SD=02). While the score of M participants (M=35, SD=02) in CON group was lower than that of F participants (M=40, SD=04), both SPRT and DRV group have faster times than F (M exercise=30, SD=03 & M driver=29, SD=02) than M (M exercise=32, SD=03 & M driver=31, SD=02). The sex difference in mean RT scores among groups was the highest in CON group. The mean scores of F SPRT (M=30, SD=03) and F DRV (M=29, SD=02) groups were similar and it is so for M SPRT (M=32, SD=03) and M DRV (M=31, SD=02) groups. The differences on RT scores between F participants who are in CON group and in SPRT and DRV groups are higher than the differences between M participants who are in CON, SPRT and DRV groups.

This study indicated that long term sport participation requiring visual information and driving extensively shorten visual reaction of the participants compared to their counterparts who were not active in sport & driving. Visual reaction time differences between sexes seem to be affected by sport and driving experiences.

THE ANALYSIS OF THE ADJUSTMENT OF THROWING ANGLE IN JAVELIN THROW

Tazuke, S.
Doshisha University, Japan

Introduction

The throwing angle is important for better performance in javelin throw in Track & Field. The best throwing angle is 37 degrees for 85m+ throwers, 36 degrees for 65m to 84m throwers, 35 degrees for 60m to 64m throwers, 34 degrees for 50m to 59m throwers, and 33 degrees for 40m to 49m throwers. In this study, throwing angle, motion and what angle subjects want to achieve when throwing javelin were examined in both standing and with an approaching throw.

Methods

Subjects were 7 javelin throwers (aged 19.29 years±1.796, best performance 54.93m±9.146, career of javelin throw 49.43month±27.098, body height 171.13cm±6.807, body weight 69.59kg±11.622), 2 female and 5 male throwers. The experiment was carried out from the standing throw, which enables measuring the throwing angle, initial velocity and angle of attack immediately, right after throwing. Sub-jects got their throwing angle after throwing from this gate. For the first time, they threw the javelin normally. In the second and third time, they were to declare their target throwing-angle beforehand, e.g. more high or more low. Their target throwing-angles were recorded by a video camera before throwing. Every throwing motion was filmed with high-speed video camera, film rate 250 / sec. by NAC, and analyzed with motion analysis software, Dynas-2D by Shin-Okoso Shokai Co., Ltd. As for the standing throw, followings were calculated; the angle between each [A1] throwing arm (wrist shoulder), [A2]torso, [A3]javelin, [A4] the axis (the center and top of sternum to left talus (right hand thrower) and horizontal plane, and [A5]the angle between [A1] and [A2] by [P1]the standing throw position, [P2]left foot contact on the ground (right hand thrower), [P3]power position and [P4]release.

As for the approach throw in addition to the standing throw, by [P5] taking off the left foot from the ground before throwing position and [P6]ight foot contact (right hand thrower) along with the phase in standing throw were calculated.

Results and Discussion

A clear relationship was not observed among the subjects target throwing-angle and actual angle. There was also no clear relation with body angle of [A1] to [A5] in each phase [P1] to [P6]. The angle of body was controlled in total, generally, e.g., if [A2] was large at [P1], it was small at [P2], large at [P3] and small at [P4]. The subjects 3rd throwing was based on feedbacks from their 2nd throwing, e.g. at [P2] if [A1] was large in the 2nd throwing, it was small in the 3rd throwing. It was suggested when man drives own body with their intention, motion converges in ones past acquired motion. If we want to change our motion, we need exercise with overblown movement in the throwing motion.

TEMPORAL CONSISTENCY OF QUADRUPEDAL GAIT IN ADULT HUMAN SUBJECT

Serbelar, I.
TEACHER FACULTY ZAGREB, Faculty of Teacher Education, Zagreb, Croatia

INTRODUCTION

Rhythmic interlimb coordination tasks with motor actions among multiple effectors are not so often investigated. In present case study paradigm of quadrupedal gait (crawling) was used to see temporal relationships between limbs.

METHODS

One adult subject performed the crawling task paced by metronome (1 Hz) on a 10-m gait mat, made of conductive rubber, which had a 6-V potential from one end to the other. Pewter electrodes were placed on the participants shoes and on his gloved hands. The electrodes were connected via National Instrument A/D card to computer. When the subject contacted the rubber mat, an electric circuit was closed and a measure of voltage was provided. The voltage measures were scaled through the mat. Temporal data was gathered from 100 Hz sampling frequency. The direction of travel was forward and body orientation was constrained to prone but coordination pattern was not specified. Front-hind and lateral symmetries were determined.

RESULTS

Similarly to the findings of Sparrow (1989), lateral sequence of limbs touchdowns in crawling was adopted (left foot, left hand, right foot, right hand). According to Hildebrand convention (Whitall et al., 1997), the key parameter for symmetrical gaits is the relationship between forelimb and hindlimb on the same side, phasing between limbs was determined by calculating the midpoints of hand stance relatively to the time of the duration of the left foot contact. Temporal midpoints of the left foot hand in average in 61.06 % of the of the duration of the left foot contact [SD 13.89], while temporal midpoint of the right hand fall in average on 55.62 % of the duration of the right foot contact [SD 13.89].

THE ENHANCEMENT OF NOISE-TO-SIGNAL RATIO IN MUSCLE ACTIVITY THROUGH AN ELASTIC CORD TECHNIQUE
TRAINING DEVICE DURING TREADMILL RUNNING

Birklbauer, J., Haudum, A., Müller, E., Kröll, J.
Christian Doppler Laboratory Biomechanics in Skiing, University of Salzburg, Austria

Stabilization through destabilization is a leading aspect of contemporary technique training concepts, e.g. the differential learning approach by Schöllhorn 2006. Such concepts are based on self-organization, which refer to noise, or movement variability, as an inevitable part for a stable movement outcome. According to Bernstein (1967) movement outcome results from forces directly generated by muscle contraction and reactive phenomena (RP: gravitation, inertia, stored forces). Changes in these RP require different neuromuscular impulses for a stable movement outcome. To acquire an appropriate neural network to compensate or even use RP, the variability of such forces should be increased in training, but not exceed the solution space. This could be realized with elastic cords simulating external muscles to increase the DOF and thus provoke higher variability in neuromuscular impulses. The objective of our study was to compare running with and without elastic cords in muscle activity and in noise-to-signal ratio between strides.

Six males ran 2 x 30 min intervals at 2.9 m/s on a treadmill separated by a 30 min rest period. After 5 min of free running, elastic cords were fastened at iliosacral joint and both heels for 20 min of either the first or the second 30 min-interval. The cord length was standardized at 40 % of the leg length (producing ~48 N at 100 % leg length). EMG was recorded for rectus fem (RF), tibialis ant (TA), lat gastrocnemius (LG). Stride duration (ST) and IEMG for each stride was analyzed. Variance-to-signal ratio (VS-R, Merletti 2004) between strides in 2-min-blocks was calculated to assess noise-to-signal ratio.

Comparing cord to free running a 2 X 7 ANOVA (running condition X time blocks) indicated strong effects in average IEMG and VS-R for all three muscles. Average IEMG was 30.7 to 87.5 % higher in cord running (Et2a=.61,75, p<.07), whereas ST changed by 1.0 % (Et2a=.20; p>.30). An increase of 11.3 to 22.0 % in cord running is also observed in VS-R (TA: et2a=.47, p<.13; RF; et2a=.45, p<.14; LG; et2a=.22, p<.30). Though ST-ratio increased by 73.6 %, the VS-R in free running is only 1 % of the VS-R of the muscle activity. This is a reflection of the higher variability in EMG-values than the macroscopic ST parameter. In contrast to RF, TA and LG showed a strong interaction between treatment condition and the seven analyzed time blocks (et2a=.33, p<.11 and et2a=.58, p<.01) revealing an adaptation to the cords over time.

The observed increase in IEMG and noise-to-signal ratio could be the consequence of the inability to manage the forces generated by the cords due to the subjects’ inexperience. On the other hand, an increase in EMG variability could also reflect the ability to accurately use those forces. In that case, the movement outcome would be more stable, which was not confirmed by the variability in ST and the increase in average IEMG. The decreasing variability over time in TA and LG during cord running.

DOES SKILL ACQUIRED BY OBSERVATIONAL LEARNING TRANSFER?

Yuko, M., Masaki, G., Makato, M., Yukako, I., Sunao, U.
Waseda University, Japan

There are many occasions for athletes to learn technique from observing activities of experts. This phenomena has been known as observational learning. There have been many studies to show observational learning occurs. But a question arises whether how much external skill could be transferred to the acquired skill itself. In fact, it has also been known that acquired skill could transfer to improve related skills. Weigelt et al. (2000) reported that the improvement of ball-juggling could also improve ball approach skill. However, whether improved skill by observational learning could transfer has not been well studied. In this study, we examined whether a skill acquired by observational learning transfer. Subjects were 21 female college softball players. As a pre-test, soccer ball juggling and ball-targeting were performed. Ball-juggling only permit subjects to use their insteps and average of ten trials were recorded (no time limit in each trial). Ball-targeting rolls a soccer ball by inside kick closer to a 20-m away target. Five trials were performed and an average distance between ball and target were recorded. Twenty three subjects were divided into three groups considering the average abilities of both tests showing significant differences among groups. The first group (P group) practiced ball juggling ten minutes a day for four weeks [16 days]. The second group (O group) observed them. The third group (C group) did not do any practice. After four weeks ball-juggling and ball-targeting were tested again. Ball-juggling were significantly improved in the P group (p = 0.002) and O group (p = 0.03). But, C did not improve significantly. The difference of improvement between P group and O group was significant (p = 0.01). Results from ball-targeting did not show any significant differences before and after ball-juggling practice in all groups. However, the improvement level (differences between pre- and post- practice values) of ball-juggling and ball-targeting showed positive correlation in P group but did not reach the significant level (r = 0.58, p = 0.172). O group showed statistically no correlation between two improvement levels (r = -0.43, p = 0.395).

The present results show that observational occurred in soccer ball juggling. However, the acquired juggling skill did not transfer to ball-targeting. Although the present result did not reach the significant level, the improvement level of ball-juggling and ball-targeting showed positive correlation and the correlation coefficient was high. In O group, this did not show high correlation coefficient. This may indicate transference is weak in observational acquired skills with actual practice. This might be because subjects learned only a part of the entire movement by observation.

IS THERE A SECULAR TEND TREND IN MOVEMENT SKILLS IN PRESCHOOL CHILDREN?

Roth, K., Ruf, K., Ahnert, J., Schneider, W., Hebestreit, H.
University of Würzburg, Germany

Introduction: Among professionals working with children in preschools, schools and sports clubs it is assumed that children have deteriorated in their movement skills over the last decades. However, there are few data supporting this hypothesis, especially in preschool children.

Methods: For this study, we analyzed the data of 700 preschool children from the Prevention through Activity in Kindergarten Trial [PAKT] with regard to motor skills and anthropometric measurements. The children completed a standing long jump (SLJ), balancing backwards (BBB and target throwing task [TT] and an obstacle course [IOC]). Furthermore, the children’s height and weight were assessed. The results of our sample were compared to those of previous studies using identical methodology. SLJ measurements were compared to samples from Vogt (1978; VS) and Kunz (1990; KS). OC results were compared to the KS. BB and TT were compared to a sample recruited for the LOGIK study (1985).
Introduction

Physical Training causes important metabolic changes, regarding protein turnover in skeletal muscle, enhancing protein degradation and free fatty acids oxidation. In growing individuals, these effects should be even more pronounced, due their higher protein needs. Branched-chain aminoacids are metabolized in muscle, replenishing leucine and increasing muscle glycogen content. The aim of this study is to verify if Branched-chain supplementation can reduce protein degradation and increase muscle glycogen deposits in young trained rats.

Methods

80 male Wistar young (age 21-days) rats were divided into 5 groups (BCAA trained, BCAA sedentary, Control Diet Trained, Control Diet Sedentary) and were trained using a swimming protocol of 6 weeks, 1 hour a day, 5 days a week, with a 5 % load attached to their tails. They consumed an AIN-93G diet supplemented or not with BCAA (45 mg/kg body weight/day of each BCAA). One day before the final experiment they rested and were divided into two more groups: 16-h fasting group or fed group. They were euthanized, blood and tissues were collected and kept in liquid N2. Muscle glycogen (MG), Plasma Tyrosin Levels (Trt), Epidydimal Fat (EF) and growth curve were measured.

Results

Sedentary rats featured an increase in body weight regardless of their diet. MG was higher in Trained Control group compared to Sedentary Control rats. Plasma Trt levels were higher in Sed Contr group compared to Sed BCAA. EF was reduced in both trained groups compared to sedentary ones.

Discussion/Conclusion

BCAA supplementation reduced protein degradation in sedentary growing rats but not in trained ones. Other expected BCAA effects like higher muscle glycogen deposition, equal growth curve and lower EF deposits were not achieved in our experimental conditions except by physical training regardless of diet. We concluded that BCAA can minimize protein degradation in growing sedentary animals but cannot improve metabolic some metabolic drives when considering exercise and growth simultaneously.

LONGITUDINAL STUDY OF DIETARY INTAKE AND BODY COMPOSITION IN ADOLESCENT FEMALE BALLET DANCERS

Garrido, G., García, A., Muñoz, T., Donoso, A., Torres, A., Sillero, M.
1Faculty of Physical Activity and Sport Sciences-INEF (Technical University of Madrid, UPM, Spain) and 2Hospital Niño Jesús, Endocrinology, Spain

Introduction

Classical dance may begin at an early age and its practise requires the development of physical abilities: strength, flexibility and power. A group of ballet dancers (BD) were enrolled in a 3 year longitudinal study to determine dietary intake and body composition. The decision to continue or discontinue dancing is often made during adolescence. Those adolescents that decide to continue dancing must ensure that they do not compromise their health with poor nutrition. The aim of this study was to clarify in early age female BD the risk of poor nutrition and its relation to body composition.

Methods

Twenty three BD initiated the study (age=11.5±0.8 yr; weight=33.6±5.0 kg; height=142.7±7.4 cm; BMI=16.5±1.5 kg/m2) and 13 BD (age=14±1.8 yr; weight=46.2±4.7 kg; height=157.6±6.9cm; BMI=18.6±0.9 kg/m2) completed the 3 years study. Dietary intake was estimated with a five day nutrition survey in four occasions, one per year. Anthropometric measurements (skinfolds, bone diameters and perimeters) were taken every six months. During the same days they completed a 24h activity questionnaire to provide energy expenditure estimation (EER).

Results

Energy intake (EI) and EER found in the 1st measurements EI=2193±414 Kcal/d, 67±17Kcal/Kg; EER=2083±196 Kcal/d showed an energy balance, three years later (4 th diet analysis) a reduction in EI (Kcal/Kg) [p<.01], an increase [p<.01] in EER (EI=1834±233Kcal/d, 42±14
Kcal/Kg EER=2215±171) and a negative energy balance were found. All the skinfold measurements (triceps, subscapular, ileac crest, abdominal, thigh and gastrocnemius) presented a negative correlation (p<.01) to total EI (Kcal/Kg). Energy distribution from snacks had a positive relation (p<.001) to total EI, and the %EI consumed at breakfast presented a negative relation (p<.01) to body weight. Moreover, carbohydrate and fat intake (g/d) presented negative correlation (p<.05) to body weight. We found an excess of protein consumption expressed as relative to weight means values between 2.2 and 2.8 g/Kg/d. We found marginal micronutrient intakes (according to DRI's) for folic acid, vitamins E and D, calcium, magnesium and zinc. The percentage of marginal diets in one or more micronutrient increased in the last year of the study, and another micronutrient (iron) was also marginal in the last year.

Discussion/Conclusion
Adolescence is a critical period in female BD. The fourteen year old age group showed an increase in marginal micronutrient diets, since DRI for most nutrients are higher with respect to the previous age range. We suspect that an under-recording of nutritional data, when they get older or when they gain fat, could explain the negative relation with skinfold measurements. It is essential that dance academies and schools emphasize healthy nutritional practices prior to adolescence.

THE MUSCLE CARNOSINE AND TAURINE CONTENT OF ELDERLY NON-OBESE KOREAN MALES WITH IMPAIRED GLUCOSE TOLERANCE

Korea National Sport University, Seoul, Korea, 1University of Seoul, Seoul, Korea, 2Chonbuk National University, Jeonju, Korea 3University of Chichester, Chichester, UK, 4Natural Alternatives Internat, Korea, South

Carnosine (Beta-Alanylhistidine, Carn) is highly effective in buffering H+ over the physiological range and is probably the only such-active compound in skeletal muscle where the concentration can be changed by diet and/or exercise. Carn synthesis is limited by the availability of Beta-Alanine synthesised in the liver from Uricol and transported to muscle fibres, but is enhanced by the inclusion of Beta-Ala (or a Beta-Ala source such as Carn) in the diet. Whilst the transport of Beta-Ala into muscle is still not fully understood there is evidence that this may be linked to the action of insulin. Taurine (Tau), a beta-sulfonic amino acid which shares the same transporter as Beta-Ala in the diet. 602

THE ROLE OF NUTRITION AND KINESIOLOGY IN THE TREATMENT OF OBESITY

INTRODUCTION

SINGLE SODIUM PYRUVATE INGESTION MODIFIES OXYGEN CONSUMPTION DURING EXERCISE

Olek, R., Kujach, S., Laskowski, R.
Academy of Physical Education and Sport, Poland

Introduction
Pyruvate is a byproduct of carbohydrate metabolism. During low intensity exercise it’s converted to acetylCoA and oxidized in mitochondria. When the metabolic rate of the muscle increases during the work at higher intensity (e.g. above the lactate threshold), the glycolytic rate increases. Higher pyruvate concentration decreases NADH/NAD+ ratio via the lactate dehydrogenase equilibrium. The cytosolic NADH reoxygenation allows to continue glycolysis reactions and thus ATP resynthesis (1, 2).

The aim of the present study was to estimate the effect of single sodium pyruvate ingestion on the exercise metabolism at the intensity above lactate threshold.

Materials and methods
Six healthy volunteers participated in the study. In a randomized double-blind placebo-controlled crossover study, we tested the effect of single oral sodium pyruvate intake on exercise metabolism. Subjects ingested sodium pyruvate (0.1g or 0.05g / kg b.w.) prior to 6 minutes exercise at 90% VO2max.

Results
Our data indicated that higher dose of sodium pyruvate (0.1g / kg b.w.) ingested 30 min prior to exercise tend to decrease oxygen consumption (p=0.1) during workout at 90% VO2max. This effect was not observed when sodium pyruvate was ingested at lower dose (0.05g / kg b.w.), or at higher dose (0.1g / kg b.w.) ingested 15 min prior to exercise. Blood lactate concentration after the exercise was not affected by pyruvate intake.

Conclusion
We conclude that single sodium pyruvate ingestion at dose 0.1g / kg b.w., 30 min prior to exercise results in a lower oxygen demand during workout at 90% VO2max. This effect occurred without an increase in lactate concentration. It seems that the energy production is more efficient due to pyruvate ingestion.

13th Annual Congress of the European College of Sport Science
Obesity is a serious disease and the prevalence of overweight and obesity is increasing worldwide at an alarming rate in both developing and developed countries. There are many factors that contribute to causing obesity including genetics, gender, endocrine diseases, the environment and behavior (overeating, alcohol consumption, lack of physical activity). Environmental and behavioral changes brought about by economic development, modernization, and urbanization, have been linked to the rise in global obesity. Obesity is increasing in children and adults, and complete health consequences may become fully apparent in the near future. Persons with obesity are at risk of developing one or more serious medical conditions, which can cause poor health and even premature death. Obesity is associated with more than 30 medical conditions and the most common of these are: type 2 diabetes, coronary heart disease, high blood pressure, osteoarthritis. Treatment options for obesity are very diverse: moderate deficit diet, physical activity, lifestyle changes, pharmacotherapy and even surgery. The purpose of this study was to investigate how a specific nutritional program and a certain kinesiologic treatment influenced and improved the health state of 20 adult women during a 12-week program.

Keywords: obesity, fat, low-calorie diet, kinesiology, BMI.

METHODOLOGY

The sample under research included 20 adult women, with ages varying between 28 and 54. All subjects were diagnosed with severe obesity (third degree) and some of them also suffered of other conditions such as: dislipidemia, hypercholesterolemia, constipation, type 2 diabetes, asthma, irritable bowel syndrome or hyperuricemia.

Methods: biographical research, descriptive research, observations, diet therapy, determination of Quetelet index (BMI), biochemical tests, effort capacity tests, applied kinesiology procedures.

RESULTS AND CONCLUSIONS

It was observed that all subjects lost weight depending on their ages and on their health states. The younger and the healthier subjects lost more than the older ones. The nutritional program was based on 5 properly balanced meals per day and they lost about 0.5 kg per week. The body mass index was decreased in all subjects and the degree of obesity was improved. The applied kinesiology procedures were efficient but, at the same time, limited by the presence of the other pathologies associated with obesity. It was also noticed that all subjects improved their neuro-psychological tonus and this directly and positively influenced their social and private life.

NUTRIENT INTAKE AND ESTIMATED ENERGY EXPENDITURE IN WOMEN WITH BULIMIA NERVOSA

Konstandinidou, K., Vrabas, I., Papadopoulou, S., Simos, G., Fahantidou, A.

 Aristotle University of Thessaloniki, Greece

INTRODUCTION: Bulimia Nervosa (BN) is an illness that is most commonly found in females beginning usually during adolescence. The main characteristics of BN are the frequent occurrence of binge-eating episodes, and the over-concern with body weight and shape. Purging behaviours usually follow a binge eating episode, while restricted eating or excessive exercising also used, intended to prevent the otherwise inevitable consequence of weight gain. Resting energy expenditure (REE) has been found to be lower in normal weight bulimics compared to controls and it has been speculated that metabolic abnormalities might underlie bulimia.

PURPOSE: This study determined the dietary intake and energy expenditure of active females with BN and active healthy subjects.

METHODS: 14 female with BN and an equal number of healthy comparable mass controls (C) participated in this study (BMI: BN=21.50±1.62; C=21.25±1.92 kg/m2). Percent body fat was estimated using skinfolds. The energy intake was assessed using an 8-day weighed food record which was analyzed using the nutrition analysis package Nutrianalysis (Mougias 2002). Daily energy expenditure was calculated from 7-day activity records.

RESULTS: Both groups had similar body fat percentage (BN=21.85 ± 5.88; C=20.36 ± 6.69%). Mean energy intake was not different between groups (BN=2263.3 ± 326.8; C=2030.8 ± 302.14 kcal/day) with higher however proportion of fat intake (BN= 46.24 ± 3.63; C= 45.58 ± 5.24%) and lower proportion of carbohydrates (BN=39.57 ± 4.54; C=40.67 ± 6.24%) for both groups according to the recommended normal daily allowance for active individuals. Regarding to micronutrients, BN had statistically higher values in polyunsaturated fatty acids, vitamin E, iron , Na, K, Mg, compared to C, but comparing both groups with the recommended dietary allowances (RDA), the values fall below the chosen RDA cut off in vitamin A (BN & C), B2 (BN), B6 (BN & C), iron (BN & C), K (BN & C), Ca (BN & C), Mg (C), Zinc (BN & C) and ribbers (BN & C). BN had higher daily energy expenditure (EE) (BN=2681.82 ± 347.51; C= 2412.56 ± 226.64 kcal/day). Both groups had negative energy balance (BN= -418.49 ± 428.33; C= -381.74 ± 399.65 kcal/day).

CONCLUSION: Total energy consumption did not differ between BN and C. The higher intake of several micronutrients in BN and lower intake of macronutrients in C might have explained from the higher energy intake, or due to the fact that BN consumed healthier items. The observation that although female with BN have the same energy intake compared to C are more active, can possibly be explained by the reduced resting energy expenditure that is reported for women with BN.

NUTRITIONAL SUPPLEMENT USE BY HIGH-LEVEL PORTUGUESE ATHLETES

Sousa, M., Teixeira, V., Moreira, P.

Faculty of Nutrition and Food Sciences of University of Porto; Portuguese Athletics Federation, Portugal

This study aimed to characterize nutritional supplement (NS) use among a group of highly-trained athletes. Subjects were asked to respond to a self-report questionnaire in order to characterize the type, frequency and amount of consumption, reasons of use, sources of information and advice, the associations between supplementation habits and years of competition, type and volume of training, competition level, gender, schooling and occupation, were also examined. Twenty five athletes (12 women and 13 men), with a median age of 25.2±5.1 (18-37 years), attending to nutritional counselling in the Portuguese Athletics Federation (PAF), volunteered to participate in this study. The study was performed in a training period, i.e., between December 2007 and January 2008. The prevalence of NSs consumption was 92% during a median of 3.5 years. Between NSs users, 69.6% were employed and 8.7% were full-time athletes. Over half (60.8%) were in high-school or college. Athletes have been regularly training and competing since their official affiliation on the PAF (on average, 12.1±4.2 years). Some were Portuguese international representatives, with a maximum of 50 international events. The most frequently cited reasons for taking NSs were ‘accelerate recovery’ (87.0%), ‘have more energy/reduce fatigue’ (69.6%), ‘improve sports performance’ (65.2%) and ‘increase strength’ (52.2%). For male athletes, ‘stay healthy’ was also an important motive (58.3%). Those not taking any type of supplement (8%) referred ‘ignorance’ and ‘lack of supplement habit’ as the main reasons. For male athletes, ‘stay healthy’ was also an important motive (58.3%). Those not taking any type of supplement (8%) referred ‘ignorance’ and ‘lack of supplement habit’ as the main reasons.

PREFERENCE OF SUPPLEMENT USE

Those taking supplements (92%) responded to a self-report questionnaire in order to characterize the type, frequency and amount of consumption, reasons of use, sources of information and advice, the associations between supplementation habits and years of competition, type and volume of training, competition level, gender, schooling and occupation, were also examined. Twenty five athletes (12 women and 13 men), with a median age of 25.2±5.1 (18-37 years), attending to nutritional counselling in the Portuguese Athletics Federation (PAF), volunteered to participate in this study. The study was performed in a training period, i.e., between December 2007 and January 2008. The prevalence of NSs consumption was 92% during a median of 3.5 years. Between NSs users, 69.6% were employed and 8.7% were full-time athletes. Over half (60.8%) were in high-school or college. Athletes have been regularly training and competing since their official affiliation on the PAF (on average, 12.1±4.2 years). Some were Portuguese international representatives, with a maximum of 50 international events. The most frequently cited reasons for taking NSs were ‘accelerate recovery’ (87.0%), ‘have more energy/reduce fatigue’ (69.6%), ‘improve sports performance’ (65.2%) and ‘increase strength’ (52.2%). For male athletes, ‘stay healthy’ was also an important motive (58.3%). Those not taking any type of supplement (8%) referred ‘ignorance’ and ‘lack of supplementation habit’ as the main reasons. For male athletes, ‘stay healthy’ was also an important motive (58.3%). Those not taking any type of supplement (8%) referred ‘ignorance’ and ‘lack of supplement habit’ as the main reasons.
more likely get information from other athletes (36.4%). Regarding the type of supplement, the most used were multivitamins (73.9%), magnesium (69.6%), sport drinks (60.9%) and proteins (52.2%). There were some gender-based differences, with male athletes reporting a more prevalent use than female athletes for multivitamins (75.0% in men and 72.7% in women) and magnesium (75.0% in men and 63.6% in women), while the opposite was seen for sport drinks (63.6% in women and 58.3% in men), proteins (54.5% in women and 50.0% in men), and creatine (63.6% in women and 33.3% in men). Thirteen percent of the athletes taking supplements were sponsored by a commercial brand in the area of supplementation and 43.5% of them benefit from a reduction in the price. So, given the easy and privileged access that athletes have to NSs and their almost generalized use, in many cases by self prescription, it has become increasingly important that clearer and more accurate information about their effect on physical performance is available for high-level athletes.

PREVALENCE OF THE DIETARY SUPPLEMENTS INTAKE IN BRAZILIAN ROAD RUNNERS
Salgado, J., Lollo, P., Miyasaka, C., Chacon-Mikahil, M.
Universidade Estadual de Campinas - UNICAMP, Brazil

INTRODUCTION
The practice of road races has exhibited an exponential growth in the last decade(1) and the consumption of dietary supplements is significant in practitioners of physical activities in Brazil(2). The aim of this study was to identify the reasons of the consumption of dietary supplements in road runners.

METHODOLOGY
817 volunteers were interviewed in four different road races from the Brazilian’s schedule in 2004. The races were: Maratona de Revezamento Pão de Açúcar(=201); Volta Internacional da Pampulha(=204) and São Silvestre (=206). The tabulation of the data was made with the words used by interviewees. The statistic analysis was through the SPSS 13.0 software. This study was approved by the Ethic Committee in our University.

RESULTS
In road runners sampled 28.33% reported having used some type of dietary supplement, and the men was 81.74% of this total, the average age of consumers was of 37.5 ± 10.77 years old, with average time of practice between 3 and 5 years, training weekly 3-4 days. It was observed that the consumption of supplement is strongly correlated (R2 = 0.93) to the running distance a week, and good correlation (R2 = 0.74) with years of practice of the sport, the longer the time a runner has practiced the sport, the higher is the training volume and the supplement intake. The most consumed dietary supplements by road runners were: carbohydrates 52.17%, vitamins 28.70% and proteins 13.48%. The 5 most frequent reasons for consumption were: enlargement the energy 29.5%, improvement of the performance 17.1% and endurance 10.3%, replacement of nutrients 11.1% and avoid the fatigue 10.3%. Around 29.5% of the consumers declared more than one reason to intake dietary supplements.

DISCUSSION
The main motivation of the dietary supplements intake was to increase the performance, cited by 17.1% directly and indirectly by 54.7% of the runners. In this study, the use of dietary supplements by road runners in Brazil reached lower levels if compared to the USA in 1987(3) and the gymnasts in Portugal(4). The gymnasts mean bone mineral density increased among the season, as well as their height and weight. Gymnasts were weekly submitted to a training programme that differed significantly (p<0.05) from preparatory period [15.4 (± 6.1) hours] to transitory period [11.0 (± 3.2) hours] and competitive period [9.8 (± 3.2) hours] of training. The primary aim of this investigation was to study and to compare the effect of physical exercise in bone mass in sixty competition female gymnasts [11.2 (± 3.2) years; 140.8 (± 13.1) cm; 35.2 (± 9.75) Kg] of Federação de Ginástica de Portugal (Portuguese Gymnastic Federation) in preparatory and transitory training periods.

The primary aim of this investigation was to study and to compare the effect of physical exercise in bone mass in sixty competition female gymnasts [11.2 (± 3.2) years; 140.8 (± 13.1) cm; 35.2 (± 9.75) Kg] of Federação de Ginástica de Portugal (Portuguese Gymnastic Federation) in preparatory and transitory training periods.

The training information was assessed using a questionnaire where the subjects reported the amount of time spent training per week. It was observed that the consumption of supplement is strongly correlated (R2 = 0.93) to the running distance a week, and good correlation (R2 = 0.74) with years of practice of the sport, the longer the time a runner has practiced the sport, the higher is the training volume and the supplement intake. BONE MINERAL DENSITY AND CALCIUM INTAKE IN YOUNG ATHLETES DURING A SEASON
Silva, M.
University Fernando Pessoa, Portugal

The practice of physical exercise can help to prevent bone mass lose, which can be associated to age and menopause. It is still unknown the effect of physical exercise in competition athletes, before the peak bone mass is acquired and according to the sport. The practice of road races has exhibited an exponential growth in the last decade(1) and the consumption of dietary supplements is significant in practitioners of physical activities in Brazil(2). The aim of this study was to identify the reasons of the consumption of dietary supplements in road runners.

THE EFFECTS OF CHO FEEDING ON FUEL SELECTION DURING LOW-INTENSITY SHIVERING
Blondin, D., Peronnet, F., Imbeault, P., Haman, F.
University of Ottawa and Université de Montréal, QC, Canada

During cold exposure, carbohydrates (CHO) play a substantial role in providing substrate for shivering muscles. Little is known about the advantages provided by CHO feeding for shivering endurance and cold survival. Results from a recent study showed that maximal exogenous glucose oxidation (~180 mg/min) is attained when 50g of glucose is ingested over 2-h in men shivering at a low-intensity (~2.5
times resting metabolic rate or 20% VO2max. Exercise studies have shown that rates of exogenous glucose oxidation are influenced by the type and quantity of CHO being ingested, the timing of ingestion, and the exercise intensity during ingestion. These factors ultimately affect the bioavailability of the ingested glucose. During moderate intensity exercise (~50% VO2max), maximal exogenous glucose oxidation was found to reach ~1 g/min when CHO was given intermittently throughout an exercise bout (see Jeukendrup (2004) for review). Whether exogenous glucose oxidation can approach rates seen during exercise, or can be increased above the values previously seen in cold exposure studies, remains to be determined. The purpose of this study was to determine (1) the effects of ingesting glucose at the onset of cold exposure versus following 60 min of shivering and (2) the effects of ingesting two types of CHO in combination on fuel selection. Using a combination of indirect calorimetry and stable isotope methodologies, whole body fuel selection and exogenous glucose oxidation rate was monitored in 6 non-acclimatized adult men wearing a liquid conditioned suit perfused with 4 degree Celsius water for 150 min, following a 120 min baseline period. Participants ingested solutions which delivered glucose at a rate of 0.8 g/min at the onset of cold exposure (G0), 0.8 g/min after 60 min of cold exposure (G60) or delivering both glucose and fructose at a rate of 0.4g/min (10.8g/min total) after 60 min of cold exposure (GF60). Results showed that although CHO and lipid oxidation and their relative contribution to heat production increased during cold exposure when ingesting a CHO beverage, the timing in which it was ingested did not modify fuel selection. Further, ingesting different CHO in combination had no effect on fuel selection. However, exogenous glucose oxidation during cold exposure was significantly greater in the G0 and GF60 condition relative to G60 (p<0.05) but no significant difference was found between the G0 and GF60 conditions. In conclusion, whether a CHO beverage is given at different times during cold exposure or contains a combination of CHO had no effect on whole body fuel utilization. Further work is needed to determine the partitioning of the CHO utilization in order to identify whether the contribution of carbohydrate sources are modified, particularly to determine whether glycogen is spared as a result of ingesting these beverages.

EFFECT OF THE CREATINE SUPPLEMENTATION ASSOCIATED TO THE WEIGHT TRAINING PROGRAM ON MUSCULAR STRENGTH IN YOUNG WOMEN

Trindade, M., Avelar, A., Yuge, M., Dodero, S., Cyrino, E., Tirapegui, J.
University of São Paulo – São Paulo, São Paulo, Brazil. Londrina State University – Londrina, Paraná, Brazil. Group of Study and Research in Metabolism, Nutrition and Exercise (GEPEMENE) Brazil

Introduction: Several studies have demonstrated that creatine supplementation is claimed to increase muscle reserves of this substance, enhancing the gains of muscular strength, results of the weight training program, by the increase of the corporal mass due to the water retention and/or increase of the protein synthesis. Objective: To verify the effect of the creatine supplementation associated to the weight training program on muscular strength in young women. Methods: Thirty-one women (20.2 ± 2.8 years, 58.8 ± 8.3 kg, 165.2 ± 5.2 cm) were divided by a double-blind design in creatine supplementation (CR, n = 16) or placebo (PL, n = 15) groups after 16 weeks of regular resistance training. The creatine supplementation or placebo (maltodextrin) was consumed in four 5 g/day doses during the first five days (20 g/day). Therefore, a single 3 g/day dose was ingested in the following 51 days. The muscular strength modifications were measured by the 1-RM test, applied in three exercises (bench press, squat and biceps curl) in two moments (pre-supplementation and post-supplementation) during the study. ANOVA with repeated measures, followed by the post hoc Scheffé test, when P<0.05, were used for data treatment. Results: In the exercise of bench press, the muscular strength increased significantly after the period even for the supplementation CR group (+7.7%, P <0.001) than PL group (+3.1%; P <0.001). However, there was significant difference in the post-supplementation moment among the groups (P <0.01). Besides that, in the squat exercise, a significant increase of the muscular strength was only observed in the CR group (+4.4%, P <0.001). In the biceps curl exercise, both groups presented gains of significant strength, CR group (+4.4%, P <0.001) and PL group (+5.1%, P <0.03), indicating an improvement in the performance of the pre-supplementation group comparing to the post-supplementation group. Conclusion: Based in the results, we can conclude that the creatine supplementation seems to enhance the gains of muscular strength in women included on a weight training program.

FOOD INTAKE OF ADOLESCENT ELITE FEMALE ARTISTIC GYMNASTS IN TWO DIFFERENT SETTINGS (BUFFET VS. FIXED MENU) DURING PRESEASON TRAINING PERIOD

García, A., Siliero Quintana, M., Garrido Pastor, G.
Technical University of Madrid (UPM), Spain

Introduction
Competitive female artistic gymnasts dedicate a great deal of their day to training, and live outside their family environment from an early age. These athletes reach maximum performance during adolescence, a time in which nutrition takes on a crucial role. During the same training period we assessed food intake of these gymnasts following a buffet (B) or a fixed menu (FM).

Methods
Subjects were 16 Spanish adolescent gymnasts from the National Team. Ten gymnasts (age=16.1±1.4 yr; weight=45.5±6.5 kg, height=152.0±0.0 cm; BMI=19.6±1.9 kg/m2) were enrolled in B, and twelve gymnasts (age=15.0±1.7 yr; weight=42.5±3.9 kg, height=150.0±0.0 cm; BMI=18.7±1.1 kg/m2) in FM. Six from each group were evaluated twice. Diet composition was estimated by food weighing (Mettler-Toledo Scale with 1g accuracy) for 2 days. During the same days they completed a 24h activity questionnaire to provide energy expenditure estimation (EE(R)I). Results
Similar energy intakes (Kcal/d) and EER (Kcal/d) were found in B (EI=1998±246; EER=2113±121) and in FM (EI=2021±216; EER=2028±182). Energy distribution from macronutrients was modified toward healthier profile when gymnasts consumed FM, in which carbohydrates (%CH) increased from 48% to 56% (p<0.01) and lipids (%L) decreased from 34% to 25% (p<0.01). These positive modifications were especially significant in dinner (increased %CH (p<0.01) and decreased %L (p<0.01)). Moreover, absolute CH and L intakes (g/d) increased (p<0.01) and decreased (p<0.05) respectively in FM group. In both settings we found marginal micronutrient intakes (according to DRI’s) for %vitamin E, %calcium and %magnesium, but with setting B all of them were much more suboptimal.

Discussion/Conclusion
Although values of energy intakes in both setting were similar we found a better energy distribution when gymnasts consumed a FM, which could be beneficial to their successful performance due to body image and weight control are areas of concern in this sport. These young sport women did not select health food items and the marginal intakes increased with B setting. Nutritional counselling and intervention can be more effectively when suspected inadequate diets are confirmed with this type of studies. Nutritional education is necessary for elite sport teenagers because nowadays hotels and high performance centers tend to offer buffet setting)

THE ANALYSIS OF THE RESPIRATORY FUNCTION IN MEN WITH ASTHMA IN RELATION TO OBESITY
Rozek, K., Markowska, D., Ignasiak, Z., Piechura, J.
University School of Physical Education in Wroclaw, Poland

The recent research revealed that both obesity and the incidence of asthma and severity of its course has been increasing greatly over the last years [1,2]. There is also evidence that there is a correlation between BMI body mass indicator and increased risk of asthma. The aim if this study was the assessment of chosen parameters of the respiratory system in males suffering from asthma in relation to their obesity.

Material and methods
The object of the analysis was a group of 60 patients divided into three groups depending on the level of obesity estimated by means of BMI, WHR, LBM factors and fat body mass according to Wielinski formula [3] Group I were 20 obese men (average age is 59.9, bronchial asthma average duration is 19.7 years), group II were 20 overweight men (average age equal to 63.4, asthma average duration equal to 23.6 years), group III were the 20 men with regular body mass (average age equal to 62.1 years, bronchial asthma average duration equal to 19.6 years). The value of somatic traits were measured according to Martin’s and Seller’s technique [4]. Spirometry parameters was measured for all individuals. Measurement was made by FLOWSCREEN spirometer (780, 578, v. 1.3) Erich Jaeger, in sitting position. In an exerted outbreath trial the correlation between flow and volume of the expired air was analysed. The following parameters were used: FVC, FEV1, FEV1/FVC, PEF, MEF50, MEF25. Diagnosis of functional changes was conducted according to Quanjer’s criteria [5]. The results of investigations were analysed by means of Statsoft’s STATISTICA 6.0 analytics software package using of the basic descriptive statistics measures. To check that exist significant differences of mean values of investigated parameters between the groups, NIR, MANOVA test was used.

Conclusion: It was concluded that the average functional parameters of the respiratory system are considerably lower in the obese patients than in overweight patients and in patients with regular body mass. It indicates that obesity has an unfavourable effect on the respiratory activity.

OXIDATION OF MALTOSE AND TREHALOSE DURING PROLONGED MODERATE INTENSITY EXERCISE
Jeukendrup, A., Venables, M., Brouns, F.
University of Birmingham, United Kingdom

Purpose: The aim of this study was to compare the effects of trehalose (TRE) and maltose (MAL) ingestion on exogenous CHO oxidation rates and blood metabolite responses during prolonged moderate intensity cycling exercise. Methods: Nine trained subjects performed 3 randomly assigned bouts of exercise separated by at least one week. Each trial consisted of 150-min of cycling at 55% of maximal power output (Wmax) while ingesting a solution providing either 1.1 g/min TRE, 1.1 g/min MAL or water (WAT). Results: Total CHO oxidation rates were significantly higher (P < 0.05) in both the MAL (2.09 ± 0.18 g/min) and TRE (1.92 ± 0.32 g/min) trials compared to the WAT trial (1.62 ± 0.28 g/min). Peak exogenous CHO oxidation was significantly higher in the MAL trial compared to the TRE trial (0.91 ± 0.19 and 0.73 ± 0.22 g/min respectively, P < 0.05). The MAL trial resulted in significantly reduced endogenous CHO oxidation rates compared to the WAT trial (0.72 ± 0.25 and 1.62 ± 0.28 g/min respectively, P < 0.05). When compared to the WAT trial, total fat oxidation over the same period was significantly reduced in both CHO trials (0.91 ± 0.19, 0.68 ± 0.19 and 0.79 ± 0.19 g/minWAT, MAL and TRE respectively, P < 0.05) and tended to be lower in MAL compared to TRE (P < 0.06). Discussion: Both solutions maintained high plasma glucose concentrations. MAL had a sparing effect on endogenous CHO stores. The reduced exogenous CHO oxidation rate of TRE compared to MAL is probably due to a reduced enzymatic hydrolysis rate within the small intestine, causing a slower delivery to the muscle.

BODY COMPOSITION CHANGES DURING TWO SEASONS IN ELITE SOCCER PLAYERS, WHOSE NUTRITION CONDITIONS WERE CONTROLLED
Pehlivan, A., Odabas, Camliguney, A.
Marmara University, Turkey

The object of this study was to examine the changes in the body composition of elite professional soccer players during two seasons, whose nutrition composition were controlled, and to determine the effects of nutrition and body composition control on soccer players.
18 soccer players of the professional soccer league of Turkey (age 24.6±4.1 years, height 180.7±4.8 cm) participated in the study. In order to determine the body composition in total 10 anthropometrical measurements have been made during two seasons in intervals of 2 months. Skinfold thickness was taken from eight different locations of the body (Holtain caliper: 0.02mm sensitive) and the Yuhazs formula was used for calculating the body composition. For the arrangement of their nutrition plan, the nutrient elements equal to the energy to be taken daily as to the ideal body weight of the players have been determined, and this information has been conveyed to the players. On days, on which extensive single trainings of one and a half hour were performed, the daily needed average energy was 3484.6±28 kcal in the 1st season and 3499.5±28 kcal in the 2nd season. According to the results of each body composition measurement, the nutrition program of the respective player has been arranged again. In the statistical evaluation of the difference between the measurements the Paired-Samples T test has been used. The following values were obtained for the anthropometrical measurements: body weight was respectively for the first and second season 76.9±6.6 - 77.4±6.8 kg, BMI 23.4±1.1 - 23.5±1.4, FFM 68.7±5.7 - 69±5.8 kg, fat 10.6±1.2 - 10.7±1.6%, and fat mass 8.2±1.4 - 8.4±1.4. No significant difference (p>0.05) have been found between all measurements performed in both seasons. As a result, it has been understood that fat-free body weight losses affecting performance are inhibited in soccer players, whose nutrition and body compositions have been controlled during the whole season.

EFFECT OF SHORT-TERM ARGinine SUPPLEMENTATION ON NITRIC OXIDE, VASODILATION, AND PERFORMANCE IN ATHLETES

Liu, TH., Lo, YW., Wu, Cl., Chiang, CW., Chang, CK.
Taiwan Sport University, Taiwan

It has been shown that supplementation of arginine could induce vasodilation via increased nitric oxide (NO) production. The purpose of this study was to investigate the effects of short-term oral supplementation of arginine on endothelium-dependent vasodilation (EDVD) and exercise performance in well-trained athletes. This study used a cross over design. Ten male college judo athletes completed arginine trial (ARG, 6 g/d for 3 d) and placebo trial (CON) in a random order. Sixty minutes after consumption of the last dose of arginine or placebo, the subjects underwent a repeated high-intensity anaerobic test on a cycle ergometer (resistance 0.05 kp/kg BW, each set contains 20 sec all-out exercise and 15 sec rest, total 13 sets). Blood samples were obtained via an indwelling cannula before, during and 0, 3, 6, 10, 30 and 60 min after exercise. EDVD were measured using a photoplethysmography before and after exercise. There was no significant difference in peak and average power in each set of exercise between the two trials. Nitrate and nitrite (NOx) concentrations were significantly higher during and 6 min after exercise compared to pre-exercise levels in both trials. ARG showed significantly higher stiffness index than CON at 3 min after exercise. No significant difference was found between the two trials in plasma NOx, reflection index, stiffness index, and heart rate at other time points. The results suggested that short-term arginine supplementation had no effect on NO production, EDVD, and anaerobic exercise performance in well-trained male athletes.

ERASMUS MUNDUS MASTER IN ADAPTED PHYSICAL ACTIVITY: AN IDEAL STRUCTURE FOR INTERCONTINENTAL COOPERATION IN TEACHING AND RESEARCH

Djobova, S., Dobreva-Faria, I., Vancoppenolle, H.
National Sports Academy, Bulgaria

In January 2005, a proposal for a joint Master Program in Adapted Physical Activity (APA) was selected for a period of 5 years, under the call of Erasmus Mundus Master Programmes from the European Commission. Erasmus Mundus aims to enhance the quality of higher education in Europe by improving the cooperation between European Universities and providing a joint diploma for non-EU and EU students. The European Consortium is formed by the K.U.Leuven (Belgium), Norwegian School of Sport Sciences (Norway), University of Limerick (Ireland), Palacky University of Olomouc (Czech Republic). The Erasmus Mundus framework allowed us to extend the original European Master in APA beyond the borders of Europe by providing substantial scholarships for both students and scholars from outside Europe to either attend or teach in the course. A partnership was established with three non-European Universities as well - the University of Queensland (Australia), the University of Stellenbosch (South Africa) and the University of Virginia (USA). In the dynamically changing world, the issues of globalisation certainly influence the sustainable development of APA as an academic discipline. This presents a significant challenge for the European APA scientists. In terms of the internationalisation process, the objectives of the Partnership between the Consortium and the non-European universities are to discuss means of co-operation through exchanging expertise in teaching and research. At the time of increasing demands toward the service provision, our aim is to reach excellence in the preparation of human resources with essential scientific backup in the area of APA. The international cooperation will enable students and academic staff to gain experience abroad which in term will enrich our European programme with intercultural aspects. Since the development of the science of APA has older traditions in North America and Australia as compared to Europe, this partnership will contribute to the European developments in APA. The program has duration of 1 year, consists of 60 ECTS and involves a study period in at least 2 of the 4 consortium universities within Europe. It is a postgraduate university program, providing a state-of-the-art on research and teaching methodology in adapted physical activity (APA), and the social, pedagogical, and technical aspects of physical activities and sports, adapted to the needs of the persons with a disability. A unique feature and an example of best practice is the fact that every year EMMAPA gathers together in one place the top experts from all over Europe in the field of APA. Every year the best professors in the APA field from all over the world have been invited to come and give presentations as well. This opportunity gives numerous benefits, mainly in terms of students’ knowledge and awareness towards the latest developments and research in this specific academic area.

SPORT, ALCOHOL SPONSORSHIP REGULATIONS AND YOUTH DRINKING: A STATUS REPORT

Sparks, R., Pinsky, I., Castaneda, L., Jette, S.
The University of British Columbia, Canada

This presentation examines the current status of international efforts to restrict alcohol sponsorship of sports and cultural events as a means to limit youth exposure to potentially harmful messages that associate drinking with social status, sexual prowess and health. Sport, as defined by the ECSS, has a broad range of individual, group and population-level benefits, including physical fitness, mental well-being, social relationship formation and enhancement, and personal and collective self-expression and identity formation (www.ecss.de). These benefits are becoming better documented, as are best practices for configuring, implementing and conducting sports activities in ways that capitalize on sports’ benefits. Nevertheless, in many countries the broader social practice of sport still engages ulterior activities such as smoking and drinking that can detract from these benefits, and public messages about sport are integrated with commercial messages about tobacco and alcohol products and the benefits of their consumption. While regulations governing tobacco sponsorship and sports-related tobacco marketing are becoming more widespread, alcohol regulations are much less developed globally (Sparks et al., 2005). One reason for this is that the epidemiology of alcohol use has not been as widely studied in the sports context, particularly among youth.

What is clear at this juncture is that the celebratory context and group cohesive and culturally expressive force of sports is a highly productive and profitable framework in which to market alcohol products, particularly beer. It is also clear that major transnational breweries such as Inbev, Heineken, Anheuser-Busch and SABMiller are increasingly using sports and cultural events as opportunities to build brand equity among youth, maximize market penetration and increase sales as they jockey for position within an emerging oligopoly in the global beer industry. The presentation provides a summary of global regulations in alcohol sponsorship and evaluates the efficacy of these regulations in view of the marketing practices of the beer industry. Case examples are taken from the EU (Portugal and Latin America) and Brazil. Issues raised include the health burden of drinking rates among youth, the ineffective nature of current regulations, and the innovative capacities of the alcohol industry including its ability to capture the attention and interests of youth. The presentation concludes with suggestions for how to better regulate alcohol sponsorships by using a transnational regulatory model similar to the WHO Framework Convention on Tobacco Control.

A SURVEY ABOUT THE PERFORMANCE OF IRAN SPORT FEDERATIONS AND ORGANIZATIONS IN INFORMATION AND COMMUNICATION TECHNOLOGY (ICT)

Yarahmady, J., Gholamian, J., Golzar, S., Gholamian, S.
Islamic Azad University of Abade, Iran

Aim: The world web sites are charged as a useful media for communication the knowledge and information on sport society union. These webs are the gates of distributing the special information, the same organization, and the mentioned information is a kind of expressing about the same organizations for its partners, the aim of this survey is the investigation about the situation of Iran sport federations and organizations web-sites, based on public and specific evaluation.

Procedure: The attendant survey is related to investigate on 78 web-sites on Iran sport sport federations and organizations by using the modern abilities and possibilities in three motor search as like Google, Yahoo and Lycos in the regions of com, ir, org. we could not get to 22 sites through these 78 sites, the instrument of Data gathering and evaluation list have prepared some fields caused of question standable by experts and was possible that we could get a primary studying in context by kranbakh alphabet (82%).

Results: some results of this survey are as following:

1-57.1% of these sites are becoming up-to-date, and through these sites we have only 7% sites that they are up-to-date in 24 hours a day and night.
2-The access speed to the Electronic address is 78.6% and the access speed to the joints is 37.5% and they are evaluated in good rate.
3-62.3% of these web-sites acted uncompleted and 76.8% of them did not answer to messages at all.
4-In 65.6% of these sites have not been declared institutional and scientific articles.
5-68.23% of them paid attention to Athletic News, 57.87% to domestic News, 9.55 to Sport for All, 5.62% to sport events and 2.07% to women sport.
6-In a comparison there is a noticeable and significant relation between the Athletic and public sports (r=-0.351, p= 0.01)
7-There is a noticeable relation between the lack of attention to public sport and woman sport that it was on the level of 0.05% on web-sites.

Discussion: based on the survey results the sport federations and organizations in Iran acted weekly in declaring the information sources, and also their attendance in different web-sites all over the world is not regulated and also is not on a correct program and political procedure. So, it is suggested that these kinds of organizations will be programmed according to international big political procedure in web-sites and fields to communicate the mentioned information to their partners and audiences all over the world.

THE MANY FACES OF THE LINEAR MIXED-EFFECTS MODEL: APPLICATIONS TO SPORT SCIENCES DATA

Champely, S., Chaboud, P., Guillot, A., Rouffet, D., Verdot, C.
Centre de Recherche et d’Innovation sur le Sport, EA647, Université de Lyon, Université Claude Bernard Lyon 1, France

Repeated measures, longitudinal data and multilevel data arise frequently in sport sciences due to the high statistical power of the corresponding experimental designs. Such grouped data are commonly analysed by repeated measures analysis of variance (ANOVA) but it requires making stringent assumptions (compound symmetry), needs balanced data (no missing value) and lacks flexibility. The linear mixed-effect (LME) model from Pinheiro and Bates (2000) combines the usual parameters describing the fixed effects in the population and the random residual errors with a new feature: a random part describing the effect of the grouping factor (ie. usually the subjects) which leads to a natural modelling of the within-groups correlation, especially in longitudinal data. Moreover, a freely available package (nlme) extends the R statistical software for plotting grouped data, estimating LME models and testing hypotheses. Computer operations are detailed in an accompanying research report (freely available from the authors) based on four real sport sciences examples from a variety of research areas: neurosciences, psychology and kinesiology. First, nine novice skiers performed a course inspection before the start of the competition. Motor imagery times were recorded after the reconnaissance, before the start and after the physical performance. These times were compared with their actual durations. The [4] missing values problem was solved in this repeated measures ANOVA setting by the LME model.
Second, four groups of 24 subjects were studied: sedentaries, climbers, handball players and sprinters. Their capacity of temporal anticipation was tested in four reaction time tasks with variable foreperiod duration. The LME model was used to analyse the effects of sporting activity and experimental task on their performance.

Third, two groups of inmates (11 sedentaries and 15 sportmen) were compared to study the effect of physical practice on the evolution of stress (measured six times) in prison. Three covariates were considered: age, time spent in detention and penal status. An analysis of covariance, including repeated measures and many missing values, was performed as a LME modelling.

Finally, the electromyographic (EMG) activity of three lower limb muscles was recorded in 21 non cyclist subjects while pedalling on a bicycle ergometer at five cadences. The LME model was used to describe the influence of cadence on EMG responses for each muscle separately and to compare these muscles in a multilevel data framework.

In these examples, the LME model appears as a very versatile statistical tool which allows an easy modelling of grouped data. It may thus be considered a reliable and useful extension of the repeated measures ANOVA, especially by handling missing values, covariates, heteroscedasticity and ad hoc correlation structures.

QRS DETECTION ACCURACY STRONGLY INFLUENCES MEASUREMENT OF HEART RATE VARIABILITY IN HYPERTERMIA

Walsh, A., Racinais, S., Grantham, J.
ASAETAR, Qatar

Purpose: To investigate the effects of ECG QRS detection algorithm and fiducial point selection in measurement of heart rate (HR) and common indices of heart rate variability (HRV) under hypertermic treadmill walking.

Methods: A single subject walked on a treadmill to exhaustion under hot conditions (room temperature 50°C, relative humidity 50%) whilst being monitored by single lead ECG in a lead II configuration. Two different implementations of a popular QRS detector (Pan, Hamilton and Tompkins) were used to locate R-waves for subsequent HR and HRV analysis for standard deviation of RR intervals (SDNN) and low frequency/high frequency (LF/HF) ratios. A third algorithm using matched filtering was used to accurately locate R-waves as detected by Hamilton’s open source implementation and the resulting HRV parameters compared with the results of the original two algorithms.

Results and Discussion: At rest, all three algorithms produced similar results for HR and the HRV indices. Treadmill walking under hot conditions led to increased HR and decreased overall HRV as measured by SDNN. At exhaustion, all three algorithms produced similar HR, but different HRV measurements, which varied by as much as 10:1 for LF/HF ratio. Examination of the detection points showed the differences in HRV measurements were due to a combination of missed beats and irregular reference point locations. These inaccuracies can become particularly large when HF energy is low, which could lead to very different interpretations of the results in terms of sympathetic/parasympathetic balance.

Conclusion: Precision of QRS reference point location is of vital importance in measurement of HRV, particularly when overall HRV is low. Knowledge of the ECG signal (as opposed to a simple list of RR intervals) is very useful as it allows the researcher to examine accuracy of fiducial point locations.

FIGHTING SPORT PROJECT 2000: CREATING A SOFTWARE FOR TRAINING PROGRAMMING IN COMBAT SPORTS

Gasperini, D., Scaringella, S., Distaso, M., Villani, R.
Cassino University; IUSM Rome, Italy

Introduction
In modern combat sports and martial arts competitions, the training and the high level of specialization of the athletes, play a key role. Therefore is very important to program and plan training in a functional and scientific way.

Filling in a questionnaire, the 95.65% of Italian Karate technicians said to know the advantages of training programming, but only the 86.96% of them actually plan their work. Moreover, only the 22.61% of them stated to know software for training programming, but only the 64.35% of them would be interested in specific software for Karate programming.

On the basis of those data, we thought to create a software based on the basics of training methodology, which might suit Karate technicians needs.

FSP 2000 features
FSP 2000 was created taking the cue from several software employed in other disciplines, such as those of the TOP series of the Prof. Pellis, the Pro Pulses Perf of the Prof. Cometti, the Pro Judo 4 of the Prof. Villani, etc... The software is able to plan trainings starting from the age and the technical-athletic features of each athlete, identifying the program’s objectives through the so called match analysis method and questionnaires (those functions are included in the software).

Such trainings might be organized following the classical model of periodization (Matwejew, Tschiena) or the blocks one (Vercosaszkij), or also mixed models. With FSP 2000 you can decide what to do during your training session: Karate's agonistic training or technical teaching (low level belt and young activity). The performance of each exercise is shown by a descriptive and a multimedia section (through video and images). You can also choose the parameters of the exercise: execution time, recovery time, repetitions, series, volume, density, intensity, loading percentage. The software is able to display the trend of the training’s loading, both for a single session and a longer one, through the intensity/volume chart and the time sharing for each objective.

Conclusions
FSP 2000 is ever growing in order to meet every problem and variable the modern theory and methodology of training and the several needs of sport technicians present.

Now we are modifying some program’s functions to optimize the programming process and we are trying to adapt it to the needs of others combat disciplines (judo, wrestling, boxing, TKD, kick boxing...).

EVALUATION OF VISUAL POSITION ESTIMATION IN BEACH VOLLEYBALL USING COMPUTER VISION

Koch, C., Mauthner, T., Schrapf, N., Tilp, M.
Karl-Franzens University, Austria

In nearly every sports game, coaches are interested in the position of the player during action. For notational analysis of positions, it is common to divide the playing field into zones. For reasons of economy and usefulness an unequal division of playing area is often used (Hughes & Franks, 2004). In beach volleyball the area near the net is of great importance for setting and therefore often defined finer. But the absence of center and attack line and also the distortion caused by the perspective view complicates orientation and assignment to zones for analysts. Nevertheless positions are often estimated with the naked eye due to a lack of available systems or because of high costs.

The aim of this study is the comparison of position estimations by humans with computed measurements. We measure play field positions and the particular zones, using the perspective image transformation between image coordinates and world coordinates of the play field. Assuming a normal distributed measurement error with a variance of 2.5 pixels, evaluated over 2000 user clicks, plays field coordinates and their uncertainties are computed. A detailed description of this uncertainty model is given in Criminisi (1997).

In total, we analyse the results of 14 participants, estimating the positions of the setter at the moment of ball contact in 150 video clips. The playing field was recorded from an elevated position behind the baseline. We divided the playing area into 4 zones at the net border and 2m distance to the net and one zone containing the rest of the playing field. Every clip includes 2 seconds before and after the setter touched the ball. In a first round the participants were asked to assign the position to one of the 5 zones. In the second round test persons marked the position of the setter by clicking on the foot position.

Results prove that humans have great problems in position estimation. Merely 59% votes match to the calculated results. This means that in 41% of all cases people have been fooled. Especially the estimation of the distance between the net and the player induced wrong decisions (82% of all errors). In contrast the assignment towards the 4 zones along the net seems much easier (18%). Findings also reveal that assignment at the court behind the net (44% incongruities) is more difficult than in front (38% incongruities).

In conclusion we found that visual position estimation by humans is very error-prone. Therefore solutions as presented are a great relief in notational analysis. In future projects we want to investigate the effects of a moving camera when analysing positions in sports games. Furthermore we are interested in the influence of different camera perspectives and how visible marks improve the estimating process.

PROCALYSIS: A SOFTWARE TOOL FOR NONLINEAR TIME SERIES ANALYSIS IN SPORT SCIENCE

Çoluk, B., Besting, A., Müller, G., Perlitz, V.
Marmara University, Turkey

The various complex processes in sport can be conceptualized in the framework of dynamic system theory. At least four interrelated hierarchical systems should be considered. 1. The molecular and cellular system, 2. The physiological and psycho-physiological system, 3. The meta-neuronal system, and 4. The social system. The complexity of these system interactions genuinely result in nonlinear and transitional dynamics. In this context Nonlinear Time Series Analysis (NTSA) of one or multiple system parameters provide a promising methodology for comprehension of the facet system outputs in sport processes.

The advent of digital technology and sophisticated algorithms has revolutionized analytical procedures in almost all scientific disciplines. In this context NTSA algorithms were developed e.g. for physiological routines, such as EEG, EMG and ECG. The adaptation or routine employment of NTSA algorithms to the practical sport settings, however, is still hampered by the lack of appropriate software tools, or simply those available fail to provide properties needed for scientific tasks.

We therefore defined specifications, designed and developed a software tool which we termed Procalysis which answers to the needs of scientific and professional environments. In summary, those needs are: 1. experimental and routine data analysis supplied as in conventional tools and, as a key to manageability, 2. data organization. The latter provides a multi-user environment allowing team members work simultaneously, organization of data and sharing primary (raw) and secondary (analyzed) data objects and documents. The architecture developed to meet and the workflow to apply these needs is graphically displayed. First testing suggests widely improved scientifically relevant functions.

We have previously shown that using functions to analyze complex data patterns reduced time spend on data analysis by 85%. This efficacy was further greatly improved by features paralleling work needed in experimental work environments. Applying these procedures in a professional sport environment or extended scientific projects with excessive data loads helps maintain these data structured and secures job efficacy. Sophisticated safety features embedded in Procalysis protect data from unauthorized access.

PREDICTORS OF METABOLIC ENERGY EXPENDITURE FROM BODY ACCELERATION AND HEART RATE MEASURES IN NEW GENERATION COMPUTER GAMES

Böhm, H., Böhm, B., Hartmann, M., Oberhoffer, R., Senner, V.
Technische Universität München, Germany

INTRODUCTION: Individuals that successfully overcome obesity often have difficulty maintaining weight, fitness and physical activity (1). Adolescents spend most of their leisure time in front of the computer or TV screen, excluding sleeping hours (2). New generation active computer games use this time to stimulate movement. However, game design lacks fundamental knowledge about the correlation between energy expenditure and the body movement. It is questionable whether the very successful single arm movement tennis game (Nintendo, Wii) consumes comparable metabolic energy as the whole body active game (Playstation, EyeToy Kinetic).

The purpose of the study is therefore to first report the differences in energy consumption, heart rate and kinematics between the Nintendo Wii tennis game and the EyeToy Kinetic whole body active game. Second to define predictors of metabolic energy expenditure from heart rate and body kinematics.

METHODS: 20 subjects (age 22-25 yrs, BMI 20.8-24.5) performed a 10 min Nintendo Wii tennis and EyeToy Kinetic game. The order of the games were randomized, second game started when heart rate was at rest level. On separate days before the intervention, subjects were familiarised with both games. Spiroergometry, heart rate (K4, COSMED) and whole body kinematics (Vicon MX-460) were meas-
RESULTS: Heart rate and energy consumption were significantly higher in EyeToy Kinetics whole body game (p<0.001) and (p=0.003) respectively. Best predictors for energy expenditure were the acceleration of the thighs followed by those of the trunk.

DISCUSSION AND CONCLUSION: The results show clearly that the EyeToy Kinetic whole body game consumes significantly more energy. This might be explained by the more intensive movement of the legs compared to the Nintendo console tennis game since thigh movement was the best predictor for all subjects for the energy consumed in all interventions. A sound physiological explanation is that large muscle mass is involved into leg movement. Game designers are therefore advised to increase leg movement during game play to intensify the energy expenditure.

TRANSFER FUNCTION PREDICTION OF CORE TEMPERATURE FROM FOREHEAD AND CALF TEMPERATURES IN HOT ENVIRONMENTS

Walsh, A., Racinais, S., Grantham, J.

ASPETAR, Qatar

Purpose: To determine the feasibility of using generalized transfer functions (identical transfer function parameters for an entire population) to permit estimation of body core temperature from forehead or calf temperature measurements in hot environments.

Methods: 15 subjects (10 male, 5 female) ages 23 - 40 were subjected to hot conditions in an environmental chamber (mean 50ºC, 50% RH) for an average of 20 minutes in which they undertook a variety of tasks (10-15 minutes of walking, followed by resting, then psychological and neurological testing). No form of body cooling was used. Subjects wore light clothing without head cover. Core temperature was measured by radio transmitter temperature capsule (Jonah TM, Mini Mitter) whilst forehead and gastrocnemius medialis temperatures were measured by skin temperature patches (Mini Mitter). MATLAB TM System Identification Toolbox was used to determine the best transfer functions that related inputs (forehead or calf temperatures) to output (core temperature), after the forehead temperature exceeded core temperature for each subject (below this point the core temperature remains fixed near 37ºC so linear transfer functions are not suitable models).

Results: Second order low pass filters were found to accurately model core temperatures from forehead temperatures or calf temperatures with generalized transfer functions. Pearson correlations were 0.93, 0.94 and 0.99 with RMS errors of 0.27ºC, 0.27ºC and 0.1ºC for forehead, calf and forehead+calf temperature inputs (p < .001 for all).

Discussion and Conclusion: The Critical Internal Temperature hypothesis suggests that humans reach exhaustion at core temperatures near 40 ºC, independent of physical activity. It would be therefore beneficial to measure core temperatures in people at risk of hyperthermia, such as those who work outside in hot climates. However, continuous estimation of core temperature is not a trivial task. The wireless transmitter pills used in this experiment are expensive when used many times. Temperature sensors inserted in the ear canal can be uncomfortable in field use and their accuracy has been questioned in comparison with true core temperature. Although the environmental conditions in this study were well regulated, the generalized transfer function approach permitted good estimation of core temperature. Further studies with larger number of subjects, under different environmental conditions and clothing types are warranted.

SPORTS SOCIETIES AND ORGANISATIONS AT THE TURN OF THE 19TH AND 20TH CENTURY IN PSKOV PROVINCE

Belyukov, D.

Velikie Luki State Ac demos of Physical Education and Sport, Russia

Introduction. The history of physical training and sports of Russia at regional level is studied insufficiently. Especially it concerns the period of occurrence of sports movement organisations at the turn of the 19th and 20th centuries.

The purpose. 1. To reveal all sports societies and the organisations of the Pskov province at the turn of the 19th and 20th century (till 1917).
2. To classify them according to their goals.

Methods: Problem-chronological, comparative-historical, historic-typological, statistical, local (studying of the sports organisations in concrete region).

Results. There were 2 types of sports societies at this period. The first type developed only one sports event. They are: The Pskov gymnastic society that was the first officially registered in the territory of Pskov province. It was founded by the German lived in Pskov. The Pskov society of bicyclists, the Bezhanitsky society of skiing, the society of athletics and physical development in Pskov, the gymnastic Society ‘Falcon’ in Phlom, the Pskov gymnastic society ‘Falcon’ that was founded by the Czech experts V.L.Sedijachik and K.M.Kovarzh. The chair- man of the society (A.G. Goltib) was included in Council of the Russian “Falcons”. K.M.Kovarzh was the participant of the second generally congress of the Union Russian “Falcon” in Kiev in 1913. The Pskov chess circle. Some “chess maestro” H. Kapablanka (the future World Champions), Znosko-Bohrovsky, Z. Tarrass visited Pskov.

The second group didn’t focus main sports event but gave the opportunity to their members to take different kinds of sport (The Pskov society of fans of sports, the Opochetks society «Health and force». Its purpose was to promote physical development of persons of both sexes. Its chairman was a woman. The Pskov society of assistance to corporal education of studying youth. The Purpose was.” to pro-mote of corporal education of pupils in educational institutions of Pskov and to unite, whenever possible, all actions in the field of school sports«. The society «Sports and education» in Pechory.)

Conclusion. During the carried out research there were established that at the turn of the 19th and 20th century in Pskov province there were 11 sports societies with different goal orientation. Among them there were 9 officially registered and 2 without registration (The Bezhanitsky society of skiing, «Sports and education» in Pechory).

SPORT CREED BETWEEN ISLAMIC REFERENCE AND GLOBALIZATION ORIENTATIONS

Elkholl, A., Afifi, M.

Helwan Un - Suez Canal Un, Egypt

Islam considers sport as a valuable part of the civilisation and the historical tradition. Physical activities are to be found in numerous and various cultures and they existed long before the 6th century, the time when Islam emerged. Prophet Mohamed practiced sport and he
encouraged men and women to follow his example. There are many Islamic texts which refer to the benefits of physical activities and which give guidelines how to practice sport. Basis of this paper is a historical and philosophical analysis and an interpretation of Islamic texts which show that Islamic laws with regard to sport are consistent with human, moral and social values all over the world. Thus, Islamic rules do not conflict with sport activities.

HORSEBACK ARCHERY OF JAPAN: FOCUSED ON THE EXISTING SKILL, YABUSAMÉ
Fujitara, T.
Tokyo University of Science, Japan
At the end of the 11th Century, a powerful battle skill called horseback archery existed in Japan. It combined the mobility of a horse with the bow and arrow. Horseback archery was renowned as 'an archery horse's way', and regarded as an important battle skill at the time. Because horseback archery is the combination of archery and horsemanship, great skill was required in both areas. Warriors devoted many hours of dedication and great expense to this practice horseback archery was certainly not easy to master.

When training, the warriors mainly practiced three skills known as kisha mitsumono. The first was called yabusamé, where they would shoot three targets at a gallop, one after the other. The second, kasagaké, involved shooting one target placed far away, again while galloping. The third was inu-umono, in which warriors had to shoot a dog released in the training grounds while on a horseback. Although horseback archery played a vital part in warfare, as time went by it was used less and less. There is no exact theory behind why this happened, but factors such as changes in the army formations, weapon-manufacturing skills, and military strategy could have had an effect on its decline. Despite this, horseback archery remained known as a warrior's finest skill. In present day, the only skill of kisha mitsumono that is still practiced is yabusamé. It has been preserved under the rule of Edo Shogunate as Ogasawara-School, and under the Higo Hosokawa feudal domain (currently the Kumamoto Prefecture) as Takeda-School. Conventional skills have been preserved in both schools, but neither is considered a practical form of martial art.

The difference between horseback archery performed by warriors in the past and horseback archery of today lies not only in the skills of the riders but also in the horses. If there is renewed study of classical horseback-archery techniques, then it is thought that such would enable linkage to a more faithful and true preservation of tradition.

DETERMINATION OF PHYSICAL FITNESS AND MOTOR ABILITIES OF 10-15 YEARS OLD PUPILS IN AUSTRIA
Fastenbauer, V., Birklbauer, J., Müller, E.
Department of Sport Science and Kinesiology, Austria
Many teachers and coaches perceive the decline of the physical fitness of Austrian Youngsters. Based on the latest countrywide data collection in 1995, this study aimed to get a current insight into the physical performance level and motor abilities of the 10-15 years old pupils in Austria. Furthermore the collected data should be used as reference data for age- and sex-dependent inter- and intrindvidual analyses.

In order to provide a countrywide data collection and a sustainable usage of the gained results teachers all over the country were asked to conduct a 5-tests battery, which focuses on the items: speed, leg strength, arm and upper body strength, coordination, and endurance. In addition to the fitness data parameters like sex, age, body weight and height, school type, class type, county and school environment have been collected. Between March and June 2007 data from more than 40.000 pupils (age/percentage of universal set: 10/1,3, 11/11,1, 12/40,4, 13/28,6, 14/11,5, 15/3,3) were collected. The distribution between the sexes was approximately the same. The data were analysed by descriptive statistical methods. The statistical analyses show worrying results. Despite the favourable physical viability girls between the ages 10 and 15 disclose nearly no development in their performance level in all analysed fitness parameters. Boys reveal in speed, leg and arm strength a recognizable development in their performance level, but their motor ability and endurance level remain static like the ones of the girls. As expected pupils in sport classes showed better results in their fitness level which they are also able to improve better than the pupils in regular classes during adolescence. Considering the school type independently of their sex pupils in grammar school reveal nearly in all analysed fitness parameters and at all age groups a higher fitness level compared to comprehensive school pupils. Furthermore our study denotes that pupils aged 10 to 15, regardless of their sex, have a higher BMI than the reference data of the WHO/AGA whereas comprehensive school pupils have a much higher BMI compared to WHO/AGA reference data.

This study approved the perception of teachers and coaches that the physical fitness level and motor abilities of the Austrian Youngsters is really alarming. To get a more detailed insight into the health beneficial factors apart from school and class type additional sociocultural factors should be revealed. For example the living conditions, peer group or sports club membership, daily physical strains, etc. should be surveyed. Similarly to a recent health survey in England, we also detect a worrying increase in the BMI, which appears to have the similar relation in the class and school type like the analysed physical fitness parameters.

EMPE: BRAZILIAN YOUNG ADULTS SPORTS PARTICIPATION MOTIVATION ASSESSMENT
Krebs, R., Barroso, M.
CEFID / UDESC, Brazil
The present study aimed to investigate the Participation Motivation Questionnaire (PMQ. Gill et al., 1983) validity and reliability after its adaptation to assess Brazilian young adult athletes participation motivation in sports. Beaton et al's (2002) recommendations were followed for cross-cultural instruments' adaptations. An experts' commission assessed the content validity. Three health-related questions were added to the original 30 PMQ items after athletes’ suggestion during the pilot study, and the original 3 points Likert scale was replaced by an 11 points interval scale (from 0 to 10). After collecting data among 132 intercollegiate athletes (64 men and 68 women),
We observed that 19% of students have overweight and 5.6% obesity. These initial results show us that PE in school needs to integrate...

Boys had significantly higher % fat free, weight and abdominal girth, while the girls had a greater and higher % of body fat. Used in data analysis. To analyze the body mass index for overweight and obesity by sex we used the international reference table of health status measures. Institute of Work & Health, American Academy of Orthopaedic Surgeons (AAOS), 2002.

Among the new challenges facing the school are those resulting from the increase of obesity in school population. The World Health Organization’s report (1997), states that the prevalence of childhood obesity is increasing rapidly around the world. This trend is a sign for the school and mostly for Physical Education (PE) in school. Innovation in PE obliges to take into account these new problems in order to get proper answers for student’s new needs. Furthermore, between the roles of the current PE is its contribution to health education. This study is part of a broader study where health is considered as an educational category and whose purpose is to assess sport activity and health indicators among school population. The sample was made of 1172 students of both gender of seventh to twelfth grade (ages ranging from 11-19 years) from 13 schools of the metropolitan region of Porto. We considered indicators of weight, height, % body fat, % fat free mass, abdominal girth and body mass index. Basic descriptive measures and student t-test from independent measures were used in data analysis. To analyze the body mass index for overweight and obesity by sex we used the international reference table of health status measures. Institute of Work & Health, American Academy of Orthopaedic Surgeons (AAOS), 2002.

We observed that 19% of students have overweight and 5.6% obesity. These initial results show us that PE in school needs to integrate these data in order to redefine sport activities and PE classes that can also include long-term sport practice.

HEALTH INDICATORS AMONG STUDENTS FROM SEVENTH TO TWELFTH GRADE - IMPLICATIONS FOR PHYSICAL EDUCATION IN SCHOOLS

Matos, Z., Batista, P., Duarte, J., Silva, P.
University of Porto, Portugal

Among the new challenges facing the school are those resulting from the increase of obesity in school population. The World Health Organization’s report (1997), states that the prevalence of childhood obesity is increasing rapidly around the world. This trend is a sign for the school and mostly for Physical Education (PE) in school. Innovation in PE obliges to take into account these new problems in order to get proper answers for student’s new needs. Furthermore, between the roles of the current PE is its contribution to health education. This study is part of a broader study where health is considered as an educational category and whose purpose is to assess sport activity and health indicators among school population. The sample was made of 1172 students of both gender of seventh to twelfth grade (ages ranging from 11-19 years) from 13 schools of the metropolitan region of Porto. We considered indicators of weight, height, % body fat, % fat free mass, abdominal girth and body mass index. Basic descriptive measures and student t-test from independent measures were used in data analysis. To analyze the body mass index for overweight and obesity by sex we used the international reference table of health status measures. Institute of Work & Health, American Academy of Orthopaedic Surgeons (AAOS), 2002.

THE RESEARCH CENTRE OF PHYSICAL EDUCATION AND SPORTS OF CHILDREN AND ADOLESCENTS (FOSS); AIMS AND RESULTS OF THE TRIAD-CONCEPT OF RESEARCH, EDUCATION AND TRAINING PROGRAMS, AND TRANSFER OF KNOWLEDGE

Seidel, I., Bös, K.
FoSS at the Institute of Sports and Sports Science, Germany

Starting position:
The university location of Karlsruhe should get a country- and nationwide unique reputation in the domain of school and movement research by the foundation of the FoSS. This goal should be accomplished via practical research in sports, play and movement, as well as the development of teaching programs, and the transfer of knowledge.

Therefore an agreement was signed between the University and the ministry for science, research and art (MWK) of the federal state Baden-Württemberg for a period of four years (2004-2008). Based on this agreement the FoSS was built up with the status of a project and with a budget of 180.000 Euro per annum. The same benefit was contributed by the University of Karlsruhe (TH).

Structure, Goals and Implementation:
The objective of the University of Karlsruhe (TH) and the University of Education (PHI) Karlsruhe under one umbrella is a unique structural characteristic of the FoSS. The institutes of sports science of both universities work in close collaboration in the fields of sports and physical activity of children and adolescents.

The structure of the FoSS consists of an executive board including the managing director, an advisory board, a coordination office with one staff, and two and a half staffs for research, teaching, and transfer of knowledge. The topics of the FoSS are: (1) development, implementation and evaluation of intervention measures in different settings like school, kindergarten, and sports clubs, (2) effectiveness analyses of intervention processes in different action fields like PE, sports in school, health sports, competitive sports of young elite athletes or integration sports, (3) development of materials for lessons, education and training (4) services and advice for different institutions, including scientific policy advice.

Results:
Within the last three years we built up a network with local, regional and national partners. Together with these partners we were carried out 63 projects: 26 in research and development, 16 in education and training, 5 in service, and 16 events for the transfer of knowledge.

The duration of the projects is up to four years. Third-party funds of 800,000 EUR were raised since 2005. Thereby the scientific and teaching staff could be increased by four half-time positions per annum. To transfer the results of our projects, and to improve our network, we co-organized for instance the national Children Congress in 2007 with round about 800 participants.

Conclusion:
The results show, that the concept of the FoSS is successful. To verify this, the FoSS was evaluated in 2007. Four international experts evaluated the FoSS in its concept, its structure and its results. Based on their report the University of Karlsruhe (TH) and the MWK have decided to enhance the FoSS in a second phase. At present, a subsequent agreement on objectives is prepared.

THE TRANSFORMATION EFFECTS OF THE RHYTHMIC GYMNASTICS BASIC BODY ELEMENTS APPLICATION IN PE CLASSIS’ ON THE SOMATIC DEVELOPMENT IN CHILDREN (AGED 9-10 YEARS)

Ignjatovic, A., Popovic, R., Aleksić, D., Kocic, J.

1 Teachers College, University of Kragujevac, Jagodina, Serbia; 2 Faculty of Sport and Physical Education, University of Nis, Serbia; 3 Faculty of Physical Education, University of Pristina – Lesovac, Serbia and Montenegro

Rhythmic gymnastics belong to one of the oldest Olympic sports and, as such, it found its place in the programs of physical education teaching at elementary and secondary schools, from the very beginning of the organized studying of physical training. Our research tried to establish whether the systematic application of the elements of rhythmic gymnastics during the regular classes of physical education, could influence the improvement in morphological characteristics among the schoolgirls of younger school age. The research has been realized on the sample of 105 examinees divided into two sub-samples, experimental and control group. The subject were 3rd and 4th grades (between 9 and 10 years of age) elementary school girl’s pupils in Serbia. The research of the longitudinal character has been conducted, in duration of 36 weeks (one school year), within which the exercises twice a week in duration of 45 minutes were performed. Experimental group had an experimental program in teaching physical training where the elements of rhythmic gymnastics were implemented while control group had the regular physical education classes. Assessment of the examinees’ morphological characteristics was conducted by the help of 13 anthropometrical measures, chosen according to the International Biologic Program (IBP), by Martin method in order to cover the four dimensional model. Particularly following the characteristics on which the greatest transformations could be made under the influence of exogenous factors, such as the subcutaneous fat tissue. Examining the results, it can be concluded that the experimental treatment had a significant influence on decreasing the subcutaneous fat tissue. Even thou systematic application of the elements of rhythmic and artistic gymnastics during the regular classes of physical education could influence the improvement in some capabilities among the schoolgirls of younger school age, we should still search for the more efficient application of these elements in the physical education classes which will be more efficient and in the same time give substantial gain in sociological and emotional sense.

PHYSICAL EDUCATION TEACHER EDUCATION CURRICULA AND BEST PRACTICES: AN INVESTIGATION OF STATUS OF ART IN THE LAST THREE YEARS (2004-2007) IN ITALIAN SECONDARY SCHOOL

Cazzoli, S., Cecchin, S., Grisieri, G., Scaglia, R.

SIS (School Interateneo of Specialization for Secondary Teacher) University of Torino Politecnico of Torino Università A.Avogadro, Italy

Introduction: In Italy the Physical Education teaching is compulsory from primary to secondary schools (students aged 3-19).

Aims: to investigate the PE curricula in the best practice of Italian secondary school.

Method: is based on questionnaires. The data was collected from 100 secondary schools, 900 classrooms, 22,500 students in Piedmont (north-west Region of Italy). The survey lasted three years (2004-2007) at the SIS-University of Turin (Italy). The data indicated the contents of PE curriculum in the secondary school: physical activity and health, development of motor and sport skills, physical activity and expressiveness, physical activity and interdisciplinary knowledge used in the best practices. The statistic analysis is descriptive and used percentages. The questions investigated:

A) Contents of PE curricula in the 5 years of the secondary schools (students aged 14-19)
B) Analysis of content of Health Education

Results and discussion: the data collected from the questionnaires showed:

A) Contents of PE curricula are physical activity and health; development of motor and sport skills; physical activity and expressiveness, physical activity and interdisciplinary knowledge, in the 5 years of the secondary schools (students aged 14-19).

B) Health contents in PE curricula are: 19,66% of annual time (1st Class-students aged 14); 16,95% (2nd Class-students aged 15); 17,4 (3rd Class-students aged 16); 19,60% (4th Class-students aged 17); 22,04% (5th Class-students aged 18)

C) Development a motor and sport skills are: 40,07% of PE curricula annual time (1st Class-students aged 14); 39,49% (2nd Class-students aged 15); 35,45% (3rd Class-students aged 16); 33,24% (4th Class-students aged 17); 31,53% (5th Class-students aged 18)

D) Physical activity and expressiveness are: 11,29% of PE curricula annual time (1st Class-students aged 14); 12,97% (2nd Class-students aged 15); 11,60% (3rd Class-students aged 16); 10,79% (4th Class-students aged 17); 10,43% (5th Class-students aged 18)

E) PE and interdisciplinary knowledge are: 15,29% of PE curricula annual time (1st Class-students aged 14); 11,30% (2nd Class-students aged 15); 16,61% (3rd Class-students aged 16); 20,99% (4th Class-students aged 17); 22,74% (5th Class-students aged 18)

Discussion: The PE curriculum planning in the best practices data shows the trend of: increase the contents of Health with the age of the students, reduce the contents of Motor and Sport Skills with the age of the students, equal the contents of Physical Activity and expressiveness, increase the content of interdisciplinary knowledge with the age of the students.

Conclusion: The survey investigation on the PE curricula best practices can suggest indication for the future PETE (Physical Education Teacher Education) oriented not only to traditionally sport (gymnastics, athletics, swimming, volleyball, basketball, soccer) but also to health prevention, expressiveness PA and interdisciplinary knowledge.

THE ABILITY TO SKIP A ROPE IN LOWER - SECONDARY SCHOOLS IN NORTHERN ITALY

Vago, P., Mondoni, M., Frattini, G., Marchetta, S., Melica, S., Cereda, F., Galvani, C., Casolo, F.

UNIVERSITA’ CATTOLICA, MILAN, Italy

INTRODUCTION. Rope-jumping was one of the most famous courtyard games practised in Italy. Most often children do not practice any physical activity and spend much of their leisure time doing static games such as computer games. The purpose of this study was to show that this serious reduction in children physical activity not only impacts on motor performance and coordination, but is also associated with an increase in body mass. Specifically this study shows that, across the last thirty years, a simple motor task such as skipping a rope is significantly reduced both in boys and in girls aged 11 to 13 years. METHODS. This study was conducted in North of Italy on a large population of 10-13 years old students (Total 498, 249 males and 249 females) and compared with data collected in a similar children population 30 years ago (Total 1078, 538 males and 540 females). The data were collected through the scholastic system after a rope-skipping test submitted to boys and girls aged 11 to 13 years old in the primary schools during PE lessons. Each student was asked to perform ten rope jumps. The test has been considered valid if: 1) such goal was achieved in independently of the technique and rhythm
of execution of the skip, 2) the skips were performed consecutively without interruption. RESULTS. After 30 years meaningful differences are noticed in body mass, height and BMI. BMI data were compared with the NCHS Growth Charts (I) and a dramatic increase in the proportion of overweight children was observed: 42% of the 11 year-old, 38% of the 12 year-old and 32% of the 13 year-old boys and girl. Concerning the ability to skip the rope we noticed, when comparing the present data with those collected 30 years ago, a deterioration in the ability to perform the task in every age-group. The increase in the percentage of failure in the test of rope-skipping was 16.78%, 15.95%, 15.79% respectively in 11, 12 and 13 years old boys and 9.66%, 12.77% and 11.53% respectively in 11,12 and 13 years girls. Similarly to thirty years ago, also today the girls are better than boys in rope-skipping. Differences among the participants according to their age and birth date were analysed with Pearson's Chi-square test and statistical significance was confirmed by the O.R. (odds ratio) values.

CONCLUSION. The disappearance of the old courtyards, the increase of static games, the lack of motor activities in natural environment and the lack of realization of the scholastic programs and coordinative exercises with small equipments, are likely factors contributing to the observed reduction in rope-skipping ability. In order to combat inactivity and obesity, and promote mobility in school children we propose: to encourage teachers in their didactic scheme to suggest coordinative exercises using simple equipments, such as skipping ropes; to invite parents to choose gifts requiring child movement.

VALIDITY AND RELIABILITY OF THE PEABODY MOTOR DEVELOPMENTAL MOTOR SCALE-2 (PDMS-2): A PILOT STUDY WITH PORTUGUESE PRESCHOOLERS

Saraiva, L., Rodrigues, L.
Polytechnic Institute of Viana do Castelo, Portugal

The Peabody Motor Developmental Motor Scale (PDMS-2, second edition) is a norm-referenced motor test designed to assess motor development in children from birth to 71 months of age. The PDMS-2 is composed of six subtests: reflexes, stationary, locomotion, object manipulation (Gross Motor Composite), grasping, and visual-motor integration (Fine Motor Composite). A Total Motor Composite score combines the Gross Motor Composite and Fine Motor Composite subtests. Five types of scores can be obtained from the PDMS-2: raw scores, age equivalents, percentiles, standard scores for the subtests, and quotients for the composites. This study was designed to examine construct validity and internal consistency of the Peabody Motor Developmental Motor Scale II (PDMS-2) using a Portuguese sample. Two hundred and seventy children’s aged 27 to 71 months, from different preschools were assessed, and its results tested by a CFA. The structural model showed a good fit (INF= 97; CFI= 98; RMSEA= 016) to the original structure proposed by Folo and Fewell (2000), and good internal consistency (ALPHA Cronbach’s = 084), with all coefficient loadings being significant. Future studies will examine the validity and reliability of the PDMS-2 with larger samples, and adding the 27 to 27 months-old group age which is inexistent in this sample.

HEALTH IN PHYSICAL EDUCATION TEACHER EDUCATION CURRICULA AND BEST PRACTICES: AN INVESTIGATION OF STATUS OF ART IN THE LAST THREE YEARS (2004-2007) IN ITALIAN SECONDARY SCHOOL

Cazzoli, S., Cecchin, S., Griseri, G., Scaglia, R.
SIS (School Interateneo of Specialization of secondary school teachers) University of Torino- Politecnico of Torino- Università A. Avogadro, Italy

Introduction: the scholastic Physical Education is compulsory from primary (3-11 year olds) to secondary schools (11-19 year olds) in Italy. The PE teachers are generalist in the primary school and they attend the University Faculty of Education for four years. The PE teachers are specialists in the secondary schools and they attend at Faculty of Physical Education and Sport Science for five years. Than they attend at SIS (School Interateneo for Secondary School teacher specialisation) and they obtain the licence for became PE professor in the secondary school (student aged 11-19). The survey aims it is investigated the relationship between Health and PE curricula. Method: is based on questionnaires. The questionnaires were made up of closed answers and multiple choice. The questionnaires has been given to 100 PE in-service teachers in the secondary schools. The data was collected from 100 schools, 900 classrooms, 22,500 students in Piedmont (nord-west Region of Italy). The survey lasted three years (2004 – 2007) at the SIS-University of Turin (Italy). The survey investigation on the PE curricula best practices can suggest indication for the future PETE (Physical Education Teacher Education) oriented not only to traditionally sport (gymnastics, athletics, swimming, volleyball, basketball, soccer) but also to health prevention.

PHYSICAL EDUCATORS’ CONCEPTIONS ABOUT PHYSICAL EDUCATION AND STUDENTS’ HEALTH-RELATED PHYSICAL ACTIVITY

Zounhia, K., Kossiva, I., Hatziharistos, D.
University of Athens, Greece

Introduction
The existence of quality in physical education (PE) programmes depends largely on the way PE is perceived and practiced by those who are responsible for its teaching. Appropriate amounts of moderate to vigorous physical activity (MVPA) for at least 50% of lesson time are suggested [3]. Some of the barriers that inhibit PE teachers to teach effectively are inadequate facilities, lack of time, poor quality programmes etc. Aside from these barriers teacher's attitudes and beliefs regarding physical education play an important role [1]. The purpose of this study was to investigate the relationship between teachers' conceptions toward physical education and what is taught in their classes.

Methods
The Physical Education Conceptions Questionnaire was applied to 32 middle school PE teachers. The questionnaire consisted of four constructs, namely PE as entertainment, PE as training, PE as teaching and PE as health enhancement. The students' behaviours were assessed through the SOFIT [2] during three lessons for each teacher. Descriptive analysis and percent occurrence of intervals were calculated for each SOFIT subcategory. The categories of walking and very active were combined to create a measure of time spent in MVPA. The two categories of teachers' behaviour, promotes and demonstrates fitness, were summed to create one category teachers' fitness behaviour. Pearson correlation was applied to estimate the relationships between PE teachers' conceptions about physical education and their teaching behaviour.

Results
The PE teachers consider that PE should: firstly, promote health related physical fitness (M=3.80 on a scale of 1 to 5); secondly, promote skills (M=3.98); thirdly, be organized according to PE as entertainment (M=3.82); and, finally, be organized according to PE as training (M=3.62). Results from SOFIT indicated that while students on the average performed MVPA for 27.47 min (77.57 % of class time), teachers spent only 7.64 min (21.88 % of class time) to promote fitness. A significant correlation (p<0.01) between PE teachers' conceptions toward physical education and what is taught in their classes was found only between students' MVPA and physical educators' conception regarding PE as training.

Discussion/Conclusion
Although the class time spent in MVPA in this study surpasses greatly the percentage of time found in other relative studies, the time provided for promoting fitness by the PE teachers is much less [2, 3]. This result combined with the fact that MVPA did not correlate with teachers' fitness behaviour (i.e. with PE as health enhancement) leads to the conclusion that the large percentage of time, spent in students' MVPA was not planned by the PE teacher.

THE IMPACT OF REQUIRED PHYSICAL EDUCATION PROGRAM ON FOSTERING A SENSE OF BELONGING TO THE UNIVERSITY
Leung, F.L., Wong, H.S.
The Chinese University of Hong Kong, Hong Kong

Introduction
Alumni are important assets of their universities. Their contributions are vital to the continuous development of their universities, especially at the time when the universities are facing budgetary constraints. It is a common understanding that the sense of belonging of the alumni to their universities might affect their links and supports to the universities. One of the benefits of recreational sports programs was providing opportunities for students' interaction [Dalgarn, 2001]. These interaction and collaboration might be essential factors for fostering a sense of belonging to their communities. The purpose of this study is to compare the impact of different physical education (PE) programs on fostering a sense of belonging to the universities.

Purpose
To compare the impact of different PE programs on fostering a sense of belonging to the universities.

Method
Alumni (N=1329) of two comprehensive universities in Hong Kong, the Chinese University of Hong Kong (CUHK) and the University of Hong Kong (HKU), were invited to answer a questionnaire on-line. CUHK provides two-credit required PE courses whereas HKU has no such requirement for graduation. The self-administered questionnaire was sent by e-mail to all alumni of both universities who had graduated between 2001 and 2005. They were requested to complete and return it via the Internet. The questionnaire collected demographic data and information about their perception of the impact of PE programs on fostering a sense of belonging to their universities.

Results
CUHK alumni gave greater value (mean±SE, CUHK vs. HKU: 3.34±.046 vs. 3.15±.042, P<65308, .05) to their university's PE courses in terms of their impact on fostering a sense of belonging to the university, when compared with the HKU alumni who did not have required PE program.

Conclusions
Results of this study suggested that required PE courses in university contribute to the enhancement of fostering a sense of belonging to the university. Such findings were important for the continuous development of universities as they might become more willing to provide support for their Alma Mater whenever necessary.

AN EXAMINATION OF THE RELATIONSHIP BETWEEN PHYSICAL ACTIVITY, SELF-ESTEEM AND ACADEMIC ACHIEVEMENT
Law, K., Hill, D., Matthews, N.
University of Gloucestershire, United Kingdom

It is suggested that physical activity (PA) can enhance the educational experience of children within the school setting [Co et al., 2006]. Indeed, several studies have demonstrated that academic standards can be improved by introducing PA into the school day [McKenzie et al., 1997]. It is assumed that this positive affect occurs through an increased level of self-esteem (SE), as physically active children often have higher SE and display increased persistence, effort and general motivated behaviours as a result. It is these behaviours that are thought to facilitate academic achievement [Lagault et al., 2006].
Some researchers however, have questioned whether a correlation between PA and academic achievement (AC) exists, and some have suggested that this relationship is in fact negative (see Tremblay et al., 2000). Therefore, there is a clear need for further investigation. This study has adopted a two-staged mixed methods approach, with both stages aiming to identify whether a relationship between PA, AC and SE exists. Stage 1 involved the cross-sectional analysis of PA behaviour (PA questionnaire designed for the study), SE (PSQD, Marsh, 1996; SES, Rosenberg, 1965) and levels of AC (SATs grades) within a sample of secondary school pupils (n=90; age=13-14).

Within Stage 2, a sample group of participants were chosen, based on whether they demonstrated low and high scores on the previous Stage 1 measurements (n=6 per group). The group was questioned with regards to their PA behaviour, aspects of SE and attitudes towards academic work. The findings (to be completed by June 2008) will provide a further opportunity to identify a PA / SE and AC relationship, and can be used to offer an explanation for any causal link.

A STUDY OF PHYSICAL EDUCATION IN THE FIRST, SECOND AND THIRD GRADES IN ELEMENTARY SCHOOLS OF IRAN (A NEW PROGRAM)

Ramezani, A., Ghiaomy, M.
Rajaee University, Iran

A Study of Physical Education in the First, Secand and Third Grades in E lementary , Schools of Iran

Preface.
Implementation of Physical Education subject in the form of a devised nationwide program took place for the first time in the year 2003.
The aim of this study was to examine how the program implemented at schools in terms of teaching methods and facilities.

Method.
This is a descriptive field study with a researcher made questionnaire. The statistical sample of the study were 8100 teachers of the first and second grades of elementary schools. The cluster sampling was done in 29 provinces of the country.

Findings of the study.
The teachers in the related provinces were well informed regarding the purposes of Physical Education program and %64.67 of them had participated in the predicted courses and %98.32 of teachers were interested in the continuation of training courses. %74.01 of teachers stated that the content of program was balanced with the abilities of students. Also, %44.92 of teachers rated the condition of Physical Education Facilities in schools as good and very good.

Discussion:
According to this study the limiting factor in the way of successful implementation of physical Education program includes: not using PE specialists, shortage of space and facilities, lack of interest and supervision on part of the authorities allocation of mager time to PE in the school curriculum and a lack of interest and supervision on part of parents.

TEACHERS’ AND STUDENTS’ THOUGHT PROCESSES IN PHYSICAL EDUCATION

Pereira, P., Carreiro da Costa, F., Diniz, J.
Porto Polytechnic and Faculty of Human Kinetics, Portugal

The purpose of this study, in which 4 teachers and 198 students took part, was: to analyze teachers’ and students’ thoughts in physical education (PE); to find out if the teacher’s knowledge of his students’ cognitive processes induces his own thoughts. Questionnaires were used to collect data on the students’ way of thinking. The teachers’ thoughts were examined through interviews, thinking aloud and stimulated recall. Regarding students’ thoughts the outcome showed that: during PE classes, the students’ attention is directed to subjects connected with the lesson; in PE, students’ orientations favour the task; they generally have a good perception of ability in PE and a favorable attitude towards it; they consider that the main aim of PE should be health improvement; they show a high level of satisfaction towards classes. Concerning teachers’ thoughts, some points should be emphasized: when planning PE classes, the teachers’ thoughts mainly focus on the syllabus contents and on classroom management; during interactive teaching, the teachers’ thoughts frequently fall upon aspects related to instruction; the majority of the teachers’ interactive decisions are of immediate nature; teachers’ pre-interactive and interactive thoughts as well as interactive decisions are not influenced by the knowledge of their students’ cognitive processes.

THE EFFECT OF EXHAUSTION EXERCISE ON IMMUNE CELLS

Nameni, F.
azad islamic university, Iran

The effect of exhaustive exercise on immune cell
Nameni, F.1, Nik Bakhht, H.2
1 Islamic Azad university, ,Pishva -Varamin
2 Islamic Azad university,Olum va Tahghighat
In vivo depletion of lymphocyte subsets allows investigation of the role of specific subsets in protective immunity. Immune cells are potent intracellular, that regulate inflammation and immune response. The others have shown that exercise causes changes in specific types of immune cells . The changes depend on duration and intensity of exercise.
This study examined the effect of exhausting exercise on the CD4 and CD8. 20 recreational active women volunteered for this study. Who were normal healthy, with no positive clinical finding. After having the procedures fully explained to them written information consent. Height, weight, BMI, body fat and Vo2max of them measured, later subjects performed exhaustive exercise. Protocol exercise was an incremental treadmill. Blood sampling were obtained before and after exercise and were drawn from an antecubital vein with subjects in the seated position. Lymphocyte subsets were determination by 3 color flow cytometry using monoclonal antibodies for T helper (CD4) and T suppressor (CD8).

Statistical analysis: Paired t-test were used to determine before versus after exercise differences, was set at 0.05. Data are presented as mean ± standard error of the mean.

Results: The concentration of cluster designation CD4 and CD8 (T subsets) decreased and there is a fall in the ratio of CD4 to CD8 T cells after exercise (P < 0.05). Reductions of CD4 and CD4 / CD8 were significant. The effect of exhaustive exercise on subjects was significant that may be transient and related with intensity and duration. The results suggest that the exhaustive exercise induced changes in lymphocyte subsets but may not induced suppression immune function.

Key words: exercise, CD4, CD8.

A STUDY ON EFFECTIVENESS OF TEACHING RESPONSIBILITY MODEL IN SCHOOL PHYSICAL EDUCATION CLASS IN JAPAN

Umegaki, A.
Osaka University of Health and Sport Sciences, Japan

In Japanese Physical Education, social behavior learning has been incorporated in educational instruction as part of schools’ teaching curriculum. However, studies on social behavior learning in Japan have not yet been developed enough to propose clear learning contents and teaching strategies. On the other hand, in the U.S.A., there are programs developed for Physical Education, with specific teaching methods. One of their representative programs is known as Hellison's Teaching Personal Social Responsibility (TPSR) model. Hellison’s TPSR model gives clear instruction for teaching strategies by providing the learning contents in different levels from 0 to 5 in order to clarify in each the content of learning. Furthermore, the program also includes exemplum, modeling or reinforcement of the learning objectives and reflection time (allowing students to look back on their own attitudes and behaviors in the class), which makes the teaching strategies more well-defined.

In this study, a supplementary examination of Hellison's TPSR model is implemented towards a group of Japanese university students. It was done in university Physical Education classes that offer lessons on “Karada-Hogushi No Undo,” the stretching exercises. Two classes served as the experimental subjects; one was the control group, and another the experimental group. Hellison’s TPSR model was introduced only to the second group, while the first group conducted its ordinary program.

The effectiveness of Hellison’s TPSR model was examined by the following measures: a social skills measure, a character self-evaluation check list, a formative teaching evaluation of team building, a questionnaire and participants’ personal comments.

Following are the findings of the experiment:
1. There was a significant improvement in social skills and character development among the members of the experimental group whereas those in the controlled group did not improve as much.
2. It was found that social skills do not improve simply by offering the Karada-Hogushi No Undo. In order to develop social skills, a certain method such as Hellison’s TPSR model is required.
3. Hellison’s TPSR model had a positive effect on students’ moral behavior.

DIDACTIC LABORATORY LIKE SUPPORT SYSTEM FOR MOTOR SELF-EVALUATION

Gomez Palorna, F., Baldassarre, G., Sibilio, M.
University of Salerno, Italy

The axiological dualism body-mind in the field of education has conditioned the school means like a learning setting, marking out logistically its spaces in classrooms and gymnasiums, defining and calling them, respectively, as places of cognitive and places of the operating (Gardner 1991).

During the training of university teachers of primary school, the path of a motor laboratory can be a training mode that allows the student to activate perceptive and learning processes related to a new vision of the body considered like a subject of communication and self-consciousness (Merleau Ponty, M. 2002).

Starting from this field of inquiry in 2000 at the University of Suor Orsola Benincasa of Naples was conducted a search combining the experimental model, the model of action research (Kemmis S. & R. McTaggart 1988) and observational practices.

The objective of this research was to analyse the function of laboratory didactic methodology in the processes of motor self-evaluation. Research has involved 45 students of the first year of the course in Science of Primary Formation that qualify elementary school teacher, that was administered a self-evaluation questionnaire input to track the profile motor in each. Students were asked in the questionnaire to express an opinion on its ability to spatial and time organization, direction and dexterity, static and dynamic balance. Later it was realized a motor laboratory on capacities which students had self-evaluated. The methodology of the laboratory has committed a triangular structure based on the role play (Sibilio, 2002), having provided for the exchange of role (three) between students: simulator, observer and director of physical activities within their group. The experience, which lasts 12 hours, thanks to the performance of students in different functions (role), had a formative connotation based on the model of action research with deliveries simple but specific.

At the end of the laboratory were given the same questionnaire which showed a different self-motor highlighting the potential of this methodology to support teaching evaluation system.

The methodology used in motor field can therefore represent an area of increased awareness of the declared, perceived and represented that allows us to recognize the relationship between action and intention, between desire and act which is one of the crucial points of the process of teaching-learning.

618 13TH ANNUAL CONGRESS OF THE EUROPEAN COLLEGE OF SPORT SCIENCE
HYPOTHESIS OF A DIDACTIC AND EXPERIMENTAL RESEARCH PROTOCOL FOCUSED ON SPORT-PLAY EXPERIENCE DURING CHILDHOOD IN ITALY

D’Elia, F., Galdieri, M., Salvia, M., Sgambelluri, R., Sibilio, M.
University of Salerno, Italy

The structure of research in the educational field about motor-sports activities has its own specific procedures, decisions, actions, objectives, contents and methods, involving qualities and specific properties which are very different from those that characterize other disciplines.

A didactic survey conducted at primary school in Italy requires an agreement of a series of theoretical models and the use of scientific procedures which must be appropriate to the complexity of the Italian educational system.

The action research is the most widespread at school. This puts the practice to the test in order to improve and to deepen one’s knowledge, building at the same time a dynamic structure of come into action ideas (Kemmis & McTaggart 1988). The limit of this model lays into the lack of check procedures to ensure the existence of the problem and of its causes, moreover no tools are provided to verify the beginning and the end of the process evaluating variables.

This protocol provides for the integration between action research and observational research and the introduction of procedures and phases that help to give a scientific support the aforesaid problems, introducing starting and final evaluation as a procedure which becomes a part of the school activities.

The proposal provides for some preparatory choices linked to the complexity of educational research in motor-sports field. The first choice is to create a synergy between school and universities and research institutions through the sharing of theoretical elements, methodological frame and procedural aspects. It is therefore essential to create an integrated research team of researchers and teachers who preliminarily share the same methodological approach. The second choice is to include the research activities in the ordinary activities of the school, instead of presenting the proposal as an activity outside the didactic contest. The third choice is to use validated methodologies and tools of observation which should be included in the daily training, sharing their usage. The part of the research to affect change and to overcome the problem needs an unintrusive and very stimulating didactic methodology, considering the delicate period of childhood. The didactic laboratory can be a teaching methodology which allows a not prescriptive use of physical activities and sports games and provides for a internal to the group but not invasive teacher’s function, trying to predominantly produce a inference and avoiding interferences if possible. In the end the protocol requires researchers’ specific skills in sports education, because they are essential both in the choice of tools and methodologies and for the efficacy of observational phases and procedures.

HYPOTHESIS FOR A SEARCH OF SPORT ACTIVITIES IN TECHNOLOGICAL FIELD FOR DIFFERENT ABLED PERSON - DISABILITY AND VIRTUAL SPORT

Galdieri, M., Raiola, G., D’Elia, F., Salvia, M., Corona, F., Sibilio, M.
University of Salerno, Italy

Recent surveys Multiscopo Aspects of daily life carried out by the Italian National Institute of Statistics relating to behaviour leisure, culture and social integration of people with disabilities showed that out of the Italian population of approximately 59,131,287 people, 4.3% are disabled whose 83% do not regularly play physical activities. Analysis of the presence of architectural barriers, such as the lack of elevators in their own house, showed that 75% of disabled people in Italy is not allowed to move on their own. These mobility limitations impact on the participation of people with disabilities to physical activities and constitute an input to the search for alternative contexts in which one could satisfy the natural need to know, move and play. In 2001 about 37.6% of disabled people in Italy aged between 18 and 44 years said they use the pc, in 2006 the 46.2% of the disabled population in the same age group had used computer tools radically transforming their way of access to culture and social life. The hypothesis of an applicability of new technologies to sport and to adapted sport experience, through the technological simulator, redefining part of the rich sensory-perceptual and functional inventory of sport. The first stage of this research work is the analysis of movement during virtual sport activity and the evaluation of the differences between virtual and real experience. The system of motion capture as a technology that permits to study the movement through inertial miniaturized sensors and a specific dynamometrical platforms, lends itself to the analysis and the evaluation of the quantities involved in the movement: posture, gestures, physical sequences and coordinative models of disabled people. These are faithfully reproduced on the monitor and describe lines and graphic path through an electronic file. These maps on the evolution of motor, spatial and postural learning engines allow to the disabled person to restore their awareness of the relationship between body attitude and graphical representation opening at the same time new perspectives for research activities between motor-sports activities, technology and different ability.

References.
Studies on evaluation systems used for motor-sport activities at school must not ignore the differences between sport practice and sport education, between two experiences which could seem similar, but are substantially and deeply different.

Goals of the study is to determine the correlation between 4 and 6 years old preschool children’s PA and their FMS developmental status.

Methods: Two rural and two urban preschools participated in the study. 80 (52.6%) out of 152 parents provided informed consent for participation in the study. 32 preschoolers in rural area preschools (16 boys and 16 girls) and 48 preschoolers in urban area preschools (23 boys and 25 girls) participated in the study. The data is collected in autumn, winter and spring. Each period consists of four full days of which two school days and two weekend days. Registering starts at waking up, step counts are recorded at the beginning and end of each school day and at bedtime. Fundamental movement skill development is assessed with the MOT 4-6 (Zimmer & Volkamer, 1987) in autumn and in spring. The Yamax Digiwalker pedometer type SW-200 was used to register step counts. In addition, the preschooler’s were weighted with a digital balance and measured with a standard measuring tape. Data are analyzed using SPSS for Windows.

Results and conclusions: Preliminary results show no significant relationship between preschool children’s daily step counts and their fundamental movement skill development ($r = 1$, n.s.). In addition, these results show no significant ($t = 0.39$, n.s.) differences in PA between girls ($M = 11,110 \pm 3,339$) and boys ($M = 10,775 \pm 3,140$).

MEASUREMENT FOR EVALUATION OF MOTOR AND SPORT ACTIVITIES IN THE EDUCATIONAL FIELD, DURING CHILDHOOD IN ITALY

Carloromagni, N., Raiola, G., Galdieri, M., D’Elia, F., Minghelli, V., Sibilio, M.

Studies on evaluation systems used for motor-sports activities at school must not ignore the differences between sport practice and sport education, between two experiences which could seem similar, but are substantially and deeply different. The motor-sports activities practices at primary school with its aims (The New Didactic Programmes for Primary Schools of 1985 according to D.P.R.12 of February 1985, No. 104, National Recommendations of the Ministry of National Education of 2007), its values, its cultural, structural, organisational and didactic characteristics does not equals to sport practiced at a sport federation or at an association. The aims, the methods of teaching, the skills of experts who lead sport experience are different. Also measurement for evaluation in motor-sport and educational activities at primary school must be adapted and shaped according to the educational structure, characteristics, functions and methodologies of primary school.

In order to conform itself to the requirements of National Programmes and the Recommendation for primary school the evaluation system must meet the requirement to appreciate and to measure the relationship between child’s action and motor behavior during activities, through the identification of indicators and causes of motor difficulties and the observation not only of executive, but above all resolute child’s skills in psychokinetic situations which allow the emerging of the relationship between cognition and action (Ausubel, 1978; Novak, 1998).

An example of the most effective integrated methodologies for evaluation of motor difficulties in children between 4 and 12 years is the Movement Assessment Battery for Children (Henderson S.E. & Sugden D., 1999). This evaluation tool has two complementary parts:
- A test for the evaluation of performance which includes 32 items organized into 4 sets of eight tests, each designed to be used with children from four different age groups who must perform, in a standardized manner, a series of motor tests that involve manual skills, skills with the ball and static and dynamic balance.
- A check-list which includes 60 items divided into 5 sections, whose first 4 consider child motor performance in more and more complex situations, while the fifth section detects behaviors related to physical activity. The playful executive characteristics of testing and the simplicity and originality of behaviors marked in the checklists are a model of how an effective investigative tool could become a true recreational activity, which can be harmoniously inserted in the teaching activities of the primary school, ensuring scientific and methodological procedures in the collection and in the processing of data.

HYPOTHESIS OF EMPIRICAL RESEARCH IN ORDER TO INVESTIGATE THE POSSIBLE RELATIONSHIP BETWEEN BODILY EXPERIENCE AND SPATIAL REPRESENTATION

Lipoma, M., Raiola, G., Carlomagno, N., Mango, P., Corona, F., Sibilio, M.

Unisicure, Italy

In recent decades the relationship between movement and space image gave rise to a scientific interest by psychological, neurological, psychological and educational research areas. Howard Gardner, theorizing a spatial and a motor shape of intelligence connected and relatively autonomous, studied in depth the relationship between movement and space image in chess saying that the legendary memory of chess players not be reduced to a simple mechanical reminder memory of a chess player proves more lasting, because it codes plans and ideas, not just a simple list mechanically reminded (Gardner, 1985, p. 214).

The results of the latest neuroscientific research on mirror neurons (Rizzolatti, 2006) and the processes of motor anticipation and control (Berthoz A., 1997 - Schmidt R. A., 2000) have particularly encouraged further investigations on the possible relationship between body and cognition in the process of acquisition of learning space (Piaget, 1952 - Dewey, 1915 - Bruner 1971).

In 1998 in the province of Naples (Italy) the possible correlation between body experience and motor activity has been object of an experimental research designed to check the incidence of motor-sports activities on memorization and mental representation through the graphic sign involving 16 students of the first class of the Secondary School (Junior High School). The experimental survey combining the model of empirical research (Kemmis S. & McTaggart R., 1988), and observational research (Thomas, Nelson & Silverman, 2005), provides for a protocol which included an experimental process characterized by verbal indications concerning the specificity of the test, how to conduct, the time of intervention and the performance of a specific exploration path of places and space and a reproductive process characterized by a motor performance of a prepared path, an observational process aimed at the systematic observation of the motor path made by the researcher and the reproducing of the motor sequence.

The results showed an interesting correlation between the motor executions of a path and its subsequent graphical representations, the observation of a path made by others and its later graphical representation, the observation of a graphic image of the path and its subsequent execution.

SELF-PERCEPTION OF THE PROFESSIONAL COMPETENCE IN TEACHERS OF PHYSICAL EDUCATION WITH DIFFERENT LEVELS OF PROFESSIONAL EXPERIENCE

Batista, P., Pereira, F., Graça, A., Matos, Z.

University of Porto, Portugal

Performance in any professional domain depends not only on the acquired competence level but also on the self-evaluation of performer competences. Hence the perception of one’s own competence becomes a decisive professional competence factor. The purpose of this study was to examine Physical Education teachers’ self-perception of competence on three dimensions: knowledge, skills and attitudes. The likert-type Self-Perception of Professional Competence Scale Specific for the Sport Professional (adapted from Nascimento, 1999; Feitosa, 2002) was administered to a sample of 595 teachers of Physical Education, which were subdivided in three groups: low experienced (0-2 years), high experienced (10-12 years), and most experienced (more than 20 years). Basic descriptive measures and General Linear Model with multivariate tests were used in data analysis. The overall mean value of PE teachers’ self-perception of professional competences was relatively high (3.87). The skills subscale presented the highest mean value (3.94), while the knowledge subscale presented the smallest mean value (3.82). Multiple comparisons put in evidence that the most experienced teachers rank higher in all dimensions of self-perception of competence scale. Yet, in the attitudinal dimension, no statistical differences were found in relation to the low experienced group. In this dimension, both of those groups rank significantly higher than the experienced group (10-12 years). Professional experience emerges as a distinguishing factor of self perception of competence. Results convey that the most experienced PE teachers were more confident in their levels of knowledge and skills. Less experienced PE teachers also rank high in the attitude dimension, which incorporates aspects like investigative attitude, self-criticism spirit, initiative, creativity, at odds with the experienced group (10-12 years), who apparently seems to express signs of professional accommodation, routine and motivational decrease.

THE PEDAGOGICAL CONTENT KNOWLEDGE OF TEACHERS OF EXERCISE PHYSIOLOGY

Melgaço, A., Marcelo Garcia, C.

Faculdade Estácio de Sáo-Brazil and University Presidente Antônio Carlos-Brazil, Brazil

The study on the pedagogical content knowledge (PCK) is in the paradigm of the reasoning and the teachers’ action, considered one of the most important areas of educational investigation at the present time. It represents an appropriate combination among the content and pedagogical knowledge of the teachers. As Exercise Physiology is a fundamental discipline to the Physical Education degree, and there are few researches in this area, it is necessary to investigate it. So, the purpose in this study is to analyze the characteristics of the PCK of the teachers in teaching the Exercise Physiology. The research subjects were ten teachers of this discipline from private and public Physical Education Universities of Belo Horizonte-Brazil. The volunteers were from different gender, title and ages, as well as time experience in teaching. Their teaching plans and structured interviews were the instruments analyzed. The data study had a qualitative approach, therefore, using analytical techniques of the content for description, interpretation and explication of the data. It began by the identification of meaning units and later it was organized in categories. The results indicated that the teachers select the contents prioritizing, above all, which they consider more important for the initial formation. And also, the main contents inserted in their teaching plans, as well as in their reports, were the acute and chronic exercise, being possible to approach any physiologic system in both options. It is remarkable that the contents that are excluded or treaten in a superficial way were: renal, immune and neural system. And this happens...
because the students start the course having a deficient knowledge in many areas, and also because the teachers do not have enough time for teaching the complete content. It was verified the teaching strategies, that the theoretical and practical classes are considered the most relevant, besides the use of some didactic-pedagogic resources. However, they do not explain very well their teaching methodologies and the reasons for the use of such strategies. It is also noticed that there are few innovative practices in the evaluation system. Both demonstrate little association between the pedagogic aspects and the diagnosed problems in the context. Through those results, it is possible to conclude that the selection and organization of contents is originated in the interconnection between the content and the context knowledge, which demonstrates a maturation in the PCK under this prism. However, it is verified a deficit in the PCK when the pedagogic aspects are analyzed, as well as the interrelation to the context. These characteristics demonstrate that the subjects are in PCK development.

PROFESSIONAL BURNOUT OF FEMALE AND MALE PHYSICAL EDUCATION TEACHERS: A FOUR-PHASE TYPΟLOGICAL MODEL

Brudnik, M. 
Bronislaw Czech Academy of Physical Education, Krakow, Poland

INTRODUCTION The best-known professional burnout concept is Maslach’s tri-dimensional model (Maslach & Jackson 1984), where burnout initiates increasing emotional exhaustion (EE), followed by negative sense of personal accomplishment (spPA), and in consequence depersonalization (DP). Progressing in time, the syndrome is manifested differently in various individuals. Recognizing the tri-dimensionality of the phenomenon, Golembiewski suggests a reverse direction of symptom occurrence and proposes an eight-phase model of the phenomenon intensification (Golembiewski & Munzenrider 1988). Two different concepts describing burnout have been termed facing theories (Noworol 2000). The problem of facing theories has been solved by developing a concept based on data clustering. Thus, a typological model emerged, with a special case represented by a four-phase model of professional burnout (Noworol 2000), as well as a typological model based on Golembiewski’s eight-phase model (Noworol & Marek 1994). The premises of the general model include tri-dimensionality of the syndrome, temporal continuity of the process, macro-path specific for the profession (a cluster of individual paths), the effect of external factors (Noworol 2004).

METHOD The experiment was carried out from V 2006 to VI 2007, in PE teachers N=1563: females N=686 (43.9%); males N=877 (56.1%). The Maslach Burnout Inventory (MBI Form Ed.) was employed. Statistical methods included data clustering (K-mean method), U Mann Whitney test.

RESULTS Using the four-phase model, two macro-paths were plotted that illustrated the dynamics of burnout in female and male PE teachers. The different course of burnout paths was indicated by a significantly higher depersonalization (DP) level in men (p<0.001). Initially, women and men react to professional stress (T1 phase) with emotional exhaustion or negative sense of professional achievement - T1 phase (the path bifurcates). At high emotional exhaustion, women begin to depersonalize their pupils (T2 phase) and undergo burnout (F3 phase; N=98, 14.3%). In men, in T2 phase, the path continues to be bifurcated: one branch is identical with the path for females, the other with negative sense of professional achievement at school, illustrates increasing depersonalization, the effect is burnout (N=99; 11.3%).

PROFESSIONAL SOCIALIZATION IN PHYSICAL EDUCATION; TEACHER EDUCATORS AND STUDENTS TEACHER’S PERCEPTIONS IN POLYTECHNIC HIGHER EDUCATION

Sá, C., Carreiro da Costa, F.
Polytechnic Instutut of Viana do Castelo, Portugal

The aim of this study was to describe, analyze and compare the identity and professional perceptions of the teachers educators and last year students, and to understand the conceptual similarities within and between peers on the polytechnical system of physical education teachers curriculum.

The participants were 210 teacher educators, 368 and 326 students (respectively in the first and second moment), belonging to 21 public and private institutions. Two different questionnaires were used. Answers were analyzed by content, using an inductive deductive approach categorization. Comparisons between groups were made using non-parametric statistics.

Results showed differences on biographic, professional, and conceptual characteristics of the teachers educators studied. Similarities were found between PE specialized teachers and final year PE students, suggesting a strong identity and conceptual coherence of the education processes.

Final course year induced changes on the students thinking processes, resulting on significant modifications of their perceptions about the inquired themes. This conclusion suggests that this final stage of the students teachers education plays a positive role and a significant socializing influence.

PREFERENCES AND PERCEPTIONS OF ATHLETES REGARDING THE FEEDBACK PEDAGOGICAL OF FOOTBALL COACH

Crispim-Santos, A., Manuel, R.
SPORT SCIENCES SCHOOL OF RIO MAIOR, RIO MAIOR, Portugal

Introduction

We want to know, the level of satisfaction of athletes about Feedbacks sent by the coach. We study the preference of athletes about the different types of Feedbacks and also the perception that they have of Feedbacks sent by coach. After that, we want checking the relationship between what the athletes prefer and what they understood of what their coach said.

Methods

One football team of Sport Lisboa e Benfica (Under 14) and their coach were observed. The instruments used to collect data were the Questionnaire of satisfaction and perception (Franco and Simões, 2006), shooting for drills and the codification of Feedbacks sent by the
Echocardiographic changes in the development of the heart in young swimmers

Cherouvim, E., Koskolu, M., Vogiatzis, I., Geladas, N.
National and Kapodistrian University of Athens, Greece

Introduction

Breath hold ability has been shown to be affected by many factors such as stimulation of facial cold receptors, lung volume, diving response, breath hold experience, aerobic capacity and age. On the average, females compared to males have smaller lung volume, lower aerobic capacity and lower level of hematocrit (Hct) and haemoglobin concentration ([Hb]) and thus, it is reasonable to hypothesize that breath hold ability would be lower in females than males. The aim of this study was to elucidate the effect of gender on breath hold time.

Methods

A group of 16 healthy subjects, 8 males (M) and 8 females (F), aged 18-30 yrs, without breath hold experience, performed: a) an incremental cycle ergometer test to exhaustion so as to measure aerobic capacity, b) pulmonary function tests for the determination of forced vital capacity (FVC), total lung capacity (TLC) and inspiration capacity (IC), and c) a breath hold protocol which included 8 repeated maximal efforts with a 2-min interval between efforts on two separate condition: without (BHFOI) and with face immersion (BHFI) in cold water (14.8±0.07°C). All apnea efforts were performed at 80% of the individual sitting FVC and upon termination subjects exhaled forcefully where PETO2 and PETCO2 were recorded. Hct and [Hb] were evaluated before the breath hold protocol.

Results

Fitness level was higher in males compared to females (M: 49.7±7.3 ml/kg/min vs. F: 36.4±5.4 ml/kg/min, p<0.05). Similarly, pulmonary capacities were lower (p<0.01) in females than in males. Especially, FVC was 3.53±0.62 l vs. 3.77±0.58 l, TLC was 3.57±1.68 l vs. 3.74±1.08 l and IC was 7.86±0.81 l vs. 5.66±0.33 l for males and females, respectively. Hct and [Hb] were higher (p<0.01) in males (Hct: 44.83±1.83 % and [Hb]: 14.44±0.97 g/dl) compared to females (Hct: 38.81±2.60 % and [Hb]: 12.67±1.41 g/dl). Breath hold time gradually increased (p<0.01) by 31.23±17.50 sec in males and 22.64±23.31 sec in females from the 1st to the 8th apnea without significant differences between genders and between conditions. Maximal breath hold time was attained as average of the last four efforts and no difference was observed between genders (M: 91.45±11.18 sec and F: 100.09±7.27 sec, p>0.05) or between conditions (BHFOI: 94.41±10.45 sec vs. BHFI: 97.12±10.23 sec, p>0.05). PETO2 and PETCO2, did not differ either between genders or between conditions just before apnea. The average values for M and F were 109.45±11.18 mmHg and 100.09±7.27 mmHg and at the breaking point were 78.78±2.09 mmHg, 51.62±1.42 mmHg for PETO2 and PETCO2, respectively.

Conclusion

It appears that despite gender differences in physiological and anthropometrical traits, breath hold ability was not different between males and females, both not experienced in apneas.

Echocardiographic changes in the development of the heart in young swimmers

Olm, T., Baskin, K., Herde, K.
Tallinn University, Estonia

High-level training induces morphologic cardiac adaptations. The effects of training on young athletes’ hearts are not yet clear (Ozer S., Manolás V. M.). The aim of the study was to assess cardiac development in swimmers aged 14 to 21. We studied 125 male swimmers divided in eight subgroups according to their age. Echocardiographic examinations using a Hewlett-Packard Sonos 100 CF echocardiograph were carried out as a part of a complex investigation. Both M-mode and two-dimensional imaging were employed for measurements. All measurements were in accordance with the recommendations of the American Society of Echocardiography. Body surface area was estimated from the Du Bois nomogram.

The effect of gender on maximal breath hold time

Cherouvim, E., Koskolu, M., Vogiatzis, I., Geladas, N.
National and Kapodistrian University of Athens, Greece

Sunday, July 12th, 2008 14:15 - 15:15
Rapid increase of height and body mass measures ended after the age of 17. Most cardiac parameters continued to increase for one more year. After age of 18 we can see slow increase of all echocardiographic characteristics but significant differences among the age groups disappeared after allometric scaling.

The development of the heart in young swimmers is a relatively smooth process. The biggest difference between body and heart measurements appeared in the age groups of 14 and 15. Therefore in those age groups there is a danger of overloading young swimmers having relatively small-sized hearts.

**HEART RATE VARIABILITY DURING HYPERBARIC HYPEROXIA IN ENDURANCE-TRAINED ATHLETES**

Fukusaki, C., Fukaya, K., Kawada, S., Ohtani, M., Kobayashi, K.

The University of Tokyo, Japan

Hyperoxia is known to decrease the heart rate (hyperoxic bradycardia [1]). It is also reported that endurance-trained athletes show a lower resting heart rate [2]. An increase in the parasympathetic nervous activity is thought to contribute to these phenomena [3, 4]. This study aimed to evaluate whether the heart rate of endurance-trained athletes decreases further in response to hyperoxia. In addition, we also examined the change in their heart rate variability under hyperoxic condition.

The study population was comprised of 7 male swimmers (age, 21 ± 1.4 years, mean ± SD) who trained 2 h/d for at least 4 d/w and 7 untrained healthy men (age, 27.3 ± 2.9 years). Written informed consent was obtained from all the subjects. They were seated in the hyperbaric chamber for 60 min; they breathed air at normal pressure (1.0 atmospheres absolute [ATA]) for 10 min (baseline) and 100% O2 at 1.3 ATA for 30 min (hyperbaric hyperoxia [HBHO]). It took 10 min both to increase and decrease the atmospheric pressure. R-R intervals (RRI) were measured for 10 min at the baseline and under HBHO (40 50 min of the experimental protocol). Time domain and frequency domain analyses of the heart rate variability were conducted. The mean RRI and the standard deviation of RRI (SD of RRI) were calculated as the time domain parameters, and low frequency (LF; <0.15 Hz), high frequency (HF, 0.15–0.5 Hz), and total power (TOT) were calculated as the frequency domain parameters. The values obtained during HBHO were compared with those obtained at the baseline by using a paired t test. The alpha level was set at 0.05.

In untrained healthy men, the mean RRI was greater during HBHO than at the baseline. The SD of RRI as well as LF, HF, LF/HF, and HF/TOT remained unchanged. On the other hand, in endurance-trained athletes, the SD of RRI was greater during HBHO than at the baseline, with no difference in the mean RRI. LF and HF tended to increase in response to HBHO. These results suggested that although hyperoxic bradycardia did not occur in the endurance-trained athletes, their SD of RRI increased. It is reported that the SD of RRI is related to the parasympathetic nervous activity: an increase in the SD of RRI correlated with an increase in the parasympathetic nervous activity [5]. In endurance-trained athletes, an increase in the parasympathetic nervous activity in response to HBHO might be reflected in the SD of RRI, a manner different from that observed in untrained individuals.

**EFFECTS OF PASSIVE LEG RAISING DURING RECOVERY PERIOD AFTER HIGH INTENSITY EXERCISE ON CROSS SECTIONAL AREA OF INFERIOR VENA CAVA**

Yoshioka, A., Nishimura, K., Onodera, S.

Graduate school, Kawasaki university of medical welfare, Japan

Introduction. Much blood flow, which is increasing during exercise, is distributed to activity muscles. The muscle inactivity immediately after exercise using lower limb would rapidly decline venous return from lower limb. In general, we obtain venous return from lower limb using muscle pump functions by voluntary muscle contraction or in order to maintain volume of venous return after main exercise. The techniques to increase volume of venous return from lower limb are not only by voluntary muscle contraction but also water immersion and leg raising and so on. We confirm that cross sectional area of inferior vena cava was enlarged by passive leg raising. However, stroke volume during passive leg raising didn’t increase, i.e. enlargement of the cross sectional area of inferior vena cava during passive leg raising represents a pool of venous blood in the abdomen. If cross sectional area of inferior vena cava is enlarged by passive leg raising after exercise, as well as at rest, the passive leg raising after exercise might not relate to the increase in the volume of venous return to heart. We investigated whether the passive leg raising after exercise influenced to cross sectional area of inferior vena cava.

Methods. Seven healthy young males volunteered to participate in this study. All subjects signed the informed consent forms prior to participation in this study. The subjects had a mean age 22 (SD 2) years. Subjects performed high intensity exercise using cycle ergometer for 15 minutes after at rest in supine position. Exercise intensity was 80% peak oxygen uptake of every subject by cycle ergometer. After exercise, subjects maintained recovery period for 15 minutes. At rest and recovery positions were in supine position and in supine position with passive leg raising. The angle of passive leg raising was 30 degrees, and subjects were raising their both legs using gatch bed. We measured the cross sectional area of inferior vena cava using ultrasound at rest, during exercise and during recovery period (at 5, 10 and 15 minutes). We also measured heart rate (HR) throughout the experiment. Data are expressed as the mean [SD]. P<0.05 was considered significant.

Results and discussion. In supine position during recovery period, the cross sectional area of inferior vena cava were significantly less than at rest (P<0.03), but they showed no difference in supine position with passive leg raising during recovery. These data suggested that passive leg raising after high intensity exercise using bicycle ergometer partially contribute to acceleration of venous return from lower limb. Furthermore, the cross sectional area of inferior vena cava in supine position with passive leg raising during recovery period were significantly less than that of a rest with passive leg raising. This implies that inferior vena cava was induced venoconstriction by high intensity exercise.
FASTING DURING RAMADAN DOES NOT AFFECT ISOKINETIC KNEE FLEXOR/EXTENSOR PERFORMANCE

Grantham, J., Racinais, S., Li, C.

ASPETAR, Qatar Orthopaedic and Sports Medicine Centre, Qatar

Background. During the Holy Month of Ramadan Muslim's fast everyday for four weeks between the hours of sunrise and sunset. Based on the 10 month lunar calendar Ramadan starts 10 days earlier each year, which could possibly impact on Muslim athlete's yearly training and competition cycles. Purpose of this study was to determine the effect of Ramadan upon work capacity of the knee extensor in active, injury free middle aged Muslim men. Methods. Following a familiarization session 11 healthy males (aged 30.5 ± 8.8 yrs) undertook four different trials with their dominant leg on an isokinetic dynamometer at speeds of 60, 120, 180, 240 and 300°/sec. The four trials were conducted over a three month period, the first commenced one month before Ramadan (CON1), the second in the days before Ramadan (PRE), the third in the final two days of Ramadan (POST) and the fourth one month after Ramadan (CON2). Subjects were tri-axial accelerometers in the 3 days leading up to each trial. All trials were conducted at the same time of the day and were preceded by anthropometric and body composition measurements. Differences between trials were analyzed with one-way repeated measures ANOVA for the anthropometric and activity data and two-way repeated measures ANOVA for the performance data (Time x Contraction Speed). Significance was set at the P<0.05 level. Results. There were no changes in any variable between the CON1 and PRE trials, attesting the reliability of the PRE recording. No changes were recorded between trials in body mass, body composition, activity and energy expenditure. Furthermore, work capacity was not significantly modified at the end of Ramadan. However, our data showed a significant improvement (P < 0.05) in work capacity one month after the end of the Ramadan (CON2). This effect was independent of contraction velocity with 3.2, 4.9, 4.5, 6.5 and 2.0 % increases in total work between POST and CON2 trials at 60 (214.6 ± 22.7 vs. 221.4 ± 31.7), 120 (192.6 ± 21.1 vs. 202.0 ± 27.8), 180 (175.1 ± 20.3 vs. 183.0 ± 30.3), 240 (155.9 ± 23.5 vs. 166.3 ± 27.6) and 300°/sec (144.5 ± 28.4 vs. 147.5 ± 26.7), respectively. Discussion/Conclusion. Ramadan did not have an effect upon habitual activity of this cohort and consequently, there were no changes in body composition. However, despite isokinetic force production remaining unaltered throughout the testing period, the post Ramadan increase in total work capacity suggests there may be a positive delayed effect upon muscle force production due to Ramadan.

MECHANOMYOGRAPHIC CHANGES TO THE BICEPS BRACHII FOLLOWING HIGH INTENSITY RESISTANCE TRAINING

Groeller, H., Sampson, J., M'cAndrew, D.

University of Wollongong, Australia

The contractile properties of skeletal muscle are tightly coupled with morphological changes that occur with physical training. The purpose of this investigation was to consider the effect of attempted high velocity movement and repetition failure on muscle contractile properties of the biceps brachii as measured by mechanomyography (MMG) in untrained healthy males (N=27). All subjects completed a 4-wk progressive resistance training (control) period prior to the experiment. On the basis of one repetition maximum (IRM) strength gain, subjects were allocated to 1 of 3 elbow flexion (60° - 160°) treatments: (EC) attempted explosive concentric and controlled 2-s eccentric; (SSC) attempted explosive concentric and eccentric; and (C) controlled 2-s eccentric and concentric training. Subjects then exercised a further 3 days per wk for 12 wks at 85% IRM. Group (C) performed four sets to repetition failure, completing 6.1 ±0.1 repetitions per set. The two explosive exercise groups performed four sets of reduced workload. EC (4.2 ±0.1) and SSC (4.2 ±0.0) replications. Percutaneous neuromuscular stimulation electrodes were placed equidistant from the MMG recording site. The MMG laser sensor was positioned 5cm perpendicular to the muscle belly of the long head of the biceps brachii. The subject remained relaxed with the elbow flexed at 90° while a single electrical pulse 100μs in duration was delivered to the muscle (Digitimer, DS-7). To avoid over saturation of the muscle, stimulation current increased gradually from 40 mA until maximal muscle belly displacement (Dmax-v) was observed. The average of 3 MMG waveforms were recorded at 1 kHz prior to storage and analysis utilizing LabVIEW® (Ver7.0) software. IRM strength significantly increased in all groups: (EC) 28.17% (6.28±0.46kg); (SSC) 34.22% (6.28±0.32kg) and (C) 29.43% (5.85 ±0.63kg), no significant difference was observed between groups. Significant training induced increases were observed in Dmax-v: (EC) 45.6% (2.1 ±1.1mm), (SSC) 68.9% (2.9 ±1.3mm) and (C) 65.2% (3.5 ±0.7mm) and normalised contraction time (TC): (EC) 45.7% (0.023 ±0.019mm/ms), (SSC) 88.5% (0.053 ±0.022mm/ms) and (C) 84.9% (0.060 ±0.017mm/ms), however, no significant difference was observed between groups. Our results demonstrate significantly improved contractile properties of the biceps brachii following 12 weeks of high intensity resistance training. Furthermore, the investigation demonstrated repetition failure is not required to induce significant contractile performance changes to the biceps brachii if contractions are performed with explosive intent.

HAEMATOLOGICAL PROFILES OF ELITE EAST AFRICAN ATHLETES OVER A NINE YEAR PERIOD

Ojambo, R., Mohammad, Y., Fudge, B., Kingsmore, D., Parisotto, R., Magnus, L., Pitsiladis, Y.

University of Glasgow, United Kingdom

The World Anti-Doping Agency (WADA) is currently considering use of abnormal blood profiles that can reflect blood manipulation and therefore an anti-doping rule violation. However, chronic altitude exposure also has the potential to influence indirect indices of blood doping. While most Kenyan and Ethiopian athletes live and train in their native east African regions, they must frequently travel to lower altitudes for competitions. There is therefore an urgent need to consider the natural changes in erythropoietic indices from altitude exposure in an attempt to differentiate these responses from blood doping. Methods: 649 blood profiles collected between 1999 and 2007 from 289 (192 males, 97 females) elite athletes from east Africa were screened using the transversal [2nd generation, n=289; [1] and longitudinal (3rd generation, n=33; [2]) approaches to erythropoietin (EPO) screening in athletes. Blood indices were compared at altitude and at sea level. Seasonal variations in haematological parameters and urinary test results for EPO were also considered. Results: Mean haematological indices of elite east African athletes were within published cut-off thresholds for indirect blood markers of doping. The blood profiles of all athletes varied considerably over time (coefficient of variation for haemoglobin, Hb CV. 0.2-11.7%, haematocrit, Hct CV. 2.0-13.9%, Reticulocytes CV. 9.4-74.9%, and OFF-hr CV 3.4-36.5%) and attained peak levels with altitude exposure, peak Hb (range: 170-191 g/L); peak Hct (range: 49-63%). During the assessment period, the Hb cut-off of 160 g/L for females was exceeded at least once (range: 1-4) by 14.2% (n=41) of athletes at altitude, whereas 4.2% (n=12) of athletes exceed the Hb cut-off at sea level. At altitude, 11.1% (n=32) of athletes exceeded the Hct cut-off of 50% for males and 47% for females on at least one occasion compared to 3.5% (n=10) of athletes at sea level. 1.4% (n=4) of athletes exceeded the OFF-hr cut-off of 133 for males and 123 for females at altitude (OFF-hr range: 129-143). No athlete exceeded the OFF-hr cut-off threshold at sea level. For reticulocytes, 4.2% (n=12) of athletes exceeded the > 2.0% cut-off at altitude and 2.1% (n=6) of athletes at sea level. 51.5% (n=33) of the athletes exceed the 1 in 50 cut-off threshold for OFF-hr scores and Hb z scores and would therefore be deemed suspicious. During the study period, 180 urine samples were analysed.
for EPO with 1 positive test for a female athlete. Conclusions: A significant number of elite east African athletes tested had substantially elevated haematological parameters and considerable fluctuations from historical baseline values reflecting numerous confounding factors such as ethnicity and altitude exposure.

EFFECTS OF INTENSITY VARIATION AND MUSCLE FATIGUE DURING KNEE-EXTENSION EXERCISE ON MUSCLE PERFUSION AND OXYGEN UPTAKE

Laaksonen, M., Björklund, G., Heinonen, I., Kemppainen, J., Knutti, J., Kyröläinen, H., Kalliokoski, K.
Mid Sweden University, Sweden

The linear relationship between muscle blood flow (perfusion) and oxygen consumption during incremental exercise has been well established (e.g. Andersen&Saltin 1985). However, the intensity is rarely steady-state or incremental during exercise events. On the other hand, sustained exercise induces muscle fatigue and although the field is well studied (e.g. Amann et al. 2006; Gandevia 2001), there is still missing data about how muscle blood flow and oxygen uptake respond to muscular fatigue during variable intensity exercise.

Thus, quadriceps femoris muscle perfusion and oxygen uptake were measured from healthy male subjects (n=8) during fatigable, intermittent isometric (1-s on, 2-s off) one-legged knee-extension exercise. Resistance during the first 6-min of the experiment was 50% MVC (HI-1), followed by 6-min at 10% MVC (LO), and finishing with 6-min at 50% MVC (HI-2). Muscle perfusion was measured during the last 3-min of each intensity period using positron emission tomography as earlier described (Laaksonen et al 2003). Arterio-venous blood samples, together with muscle perfusion values, were used to determine oxygen uptake and oxygen extraction fraction (OEF). In addition, blood samples for determination of hemoglobin saturation (Hbsat%) were taken. Results are presented as mean (standard deviation).

MVC decreased by 11% during the experiment (before 537(87) N vs after 476(37) N; p=0.04). Muscle perfusion during HI-1 (26(5) mL 100g-1 min-1) and HI-2 (28(4) mL 100g-1 min-1) was higher than during LO (15(3) mL 100g-1 min-1; p<0.01), and no difference between HI-1 and HI-2 was observed (p=0.44). Oxygen uptake was also higher during both HI workloads (HI-1 3.3(0.4), and HI-2 4.1(0.6) mL 100g-1 min-1) compared with LO (45(8)%; p<0.01). Interestingly, oxygen uptake was higher (p<0.01) and OEF tended to be higher (p=0.06) during HI-2 as compared to LO (1.4(0.4) mL 100g-1 min-1; p<0.01). Similarly, OEF was higher during HI workloads (HI-1 62(7) and HI-2 70(7)%) as compared with LO (45(8)%; p<0.01). Interestingly, oxygen uptake was higher (p<0.01) and OEF tended to be higher (p=0.06) during HI-2 as compared with HI-1. Arterial Hbsat% was 98(1)% during the entire experiment. Venous Hbsat% decreased from resting values (70(1)% to 59(6)% during HI-1 (p<0.01), increased to 58(7)% during HI-2 (p<0.01), and decreased again to 31(6)% during HI-2 (p<0.01). No difference was observed between HI-1 and HI-2 (p=0.25).

Decreased MVC after the experiment indicates that the relative work rate during HI-2 was higher than during HI-1 due to muscle fatigue. Since muscle blood flow has been earlier found to be strongly associated with oxygen uptake, the finding of higher oxygen uptake during HI-2 as compared with HI-1 indicates impaired oxygen delivery to working muscles but this is compensated by higher oxygen extraction from blood.

COMPARISON OF VENTILATORY THRESHOLD (VT) MEASUREMENTS TO LEAVE THREE COMMERCIALLY AVAILABLE FACEMASK ON-LINE GAS ANALYSIS SYSTEMS

Barbieri, R., Marcos Roberto Queiroga, M., Barbieri, F., Moura, R., Kokubun, E.
Paulo State University - UNESP, Brazil

The anaerobic threshold (Lan) is considered the gold standard for the prescription of the intensity and physical activity. The indirect calorimetry allows identifying with precision the ventilatory threshold (VT). This method is not invasive and alternative for the determination of the Lan. The VO2000 is a portable metabolic measurement system (MedicalGraphics Corp., St. Paul, MN). It was adapted for Schneider et al. (1993). Computerized method was based on the analysis of the two straight lines determined by linear regression explaining VO2 versus VO2. Thirteen (8 males, 5 females) healthy young subjects (20.8±2.5 yrs, 62.4±10.8 kg, 166.5±9.6 cm) volunteered for the study. The subjects performed three maximal incremental tests, until voluntary fatigue, changing the facemasks in randomly order. Prior to each test, the VO2000 was calibrated according to the manufacturer’s instructions, which consisted of performing an auto-calibration routine to the oxygen and carbon dioxide analyzers. In the incremental test, the subjects pedaling a mechanically braked cycle ergometer (Monark8), throughout multiple stages of increased workloads. At the first stage subjects cycled at 50-60 rpm unloaded during one minute followed by 30 watts with increment in each minute. The one-way ANOVA for repeated measures did not show difference among the facemasks either to VT: mouthpiece (38.4±5.6 mL kg-1 min-1), silicone (30.7±5.1 mL kg-1 min-1) and neoprene facemask (31.5±7.4 mL kg-1 min-1), respectively. In conclusion, the facemasks for this metabolic measurement system used to collect VO2 data did not influence on the VT.

ENERGY EXPENDITURE DURING CANYONING ACTIVITY

Brito, J., Fernandes, R., Gomes, L.
Sport Science School of Rio Maior, Portugal

Aim: The purpose of this study was to determine the intensities and energy expenditure (EE) of the Canyoning practice.

Methodology: Participated voluntarily in this study 10 male adults (age of 25.10 ± 3.57 years old; height: 176 ± 6.29 cm; weight: 71.10 ± 6.81 kg; percent fat: 17.16 ± 3.53%; VO2max: 60.25 ± 7.07 mL kg-1 min-1; HRmax: 189.40 ± 7.17 bpm). The subjects realized a track of River Ancora, and for such was proceeded a description of the vertical and horizontal displacements and manoeuvres, in way to characterize the whole accomplished course. The EE was determined through calculation of the linear regression between the behaviour of HR and of VO2. To calculate the linear regression equation, maximum consumption of oxygen was measured in a situation of continuous sub-maximum progressive incremental test.
Results: It was determined, a heterogeneity in the distribution of the mean values of HR and VO2 during de Canyoning practice. The VO2 mean of the totality of the subjects, in the practice of Canyoning, was of 24.50 ± 6.46 ml.Kg⁻¹.min⁻¹. The analysis of FC and VO2 during the practice of a typical course of Canyoning requests a level of effort of moderate intensity, according to the ACSM (2005). From the VO2 analysis the Canyoning practice could be considered as predominantly aerobic. The mean HR measured was 114 ± 8.32 bpm, correspondents to an intensity 60,54% HRmax. The mean EE verified was 7.45 ± 2.53 Kcal.min⁻¹ corresponds to the recommendations of ACSM (2005). The vertical and horizontal speed of displacement during the 2300m of the river track was 0.142 m.s⁻¹.

Conclusions: The Canyoning practice has characteristics of an intermittent and heterogeneity effort, considering HR and VO2 behaviour. From the VO2 analysis was verified that the practice of Canyoning is predominantly aerobic.

TENDON-MUSCLE PROPERTIES AND PHYSICAL FUNCTION IN RHEUMATOID ARTHRITIS

Matschke, V., Thom, J., Murphy, P., Lemmey, A., Maddison, P.
Bangor University & Gwynedd Hospital, Bangor, United Kingdom

Background: Most research in rheumatoid arthritis (RA) has focussed on the mechanisms and consequences of joint inflammation and the resulting joint damage, with much less emphasis on the metabolic and architectural changes in skeletal muscle which contributes to the disability seen in this disease. Loss of muscle mass occurs in most patients with RA and contributes significantly to reduced strength and function. The elastic characteristics of tendons also influence muscle strength as the force generated by muscle fibres is transmitted via the tendons. Thus the aim of this study was to investigate whether RA leads to qualitative changes of the tendon-muscle complex as a contributor to the reduced physical function.

Methods: Maximal isometric and isokinetic quadriceps muscle torque, and antagonist muscle co-contraction were assessed in 23 patients with stable RA (mean age 60 years, age range 22-72 years) and age- and sex-matched (64% female) sedentary controls (mean age 60 years, age range 25-76 years). Measurements were taken on a Humar Norm isokinetic dynamometer. Antagonist co-contraction was determined by electromyographic activity. Resting fibre fascicle length, pennation angle and muscle volume were measured via ultrasound to determine physiological cross-sectional area (PCSA) of the muscle and muscle quality (defined as force per PCSA). Ultrasound was also used to assess patella tendon (PT) stiffness and Young’s modulus (YM) in a subgroup of 16 matched pairs. Participants also completed lower body physical function tests, and a whole body DXA scan to measure appendicular lean body mass (ALM).

Results: There were significant differences in muscle architecture with 13.5% lower PCSA (p = 0.03), 12.5% smaller pennation angle (p = 0.01) and 12% longer fibre fascicles (p = 0.06) in the RA patients relative to the controls. Despite this, there was no difference in quadriceps isometric torque (144.6 vs 155.6 Nm), isokinetic torque (at 50 and 100 degree.s⁻¹), antagonist co-contraction, nor in muscle quality (24.0 vs 22.0 Ncm⁻²). Maximal PT elongation was similar in the two groups (5.54 vs 5.06 mm), as was PT stiffness and YM (ns). Physical function was significantly lower in the RA patients: 27% in balance (p = 0.01), 20.2% in 50-foot walk (p < 0.001), 14.8% in 8-foot up and go (p = 0.01) and 10.5% in 30-second sit to stand (p = 0.09). Patients had a 4.4% increased body mass index (27.6 vs 26.4) with a 5.8% reduced ALM.(16.3 vs 17.3 kg; p = 0.09).

Conclusion: The quality of the tendon-muscle complex is not compromised in RA patients despite changes in muscle mass and architecture.

A SINGLE BOUT OF MODERATE INTENSITY EXERCISE INCREASES FREE-LIVING PHYSICAL ACTIVITY ENERGY EXPENDITURE OVER THE FOLLOWING THREE DAYS IN SEDENTARY MALES

Silalertdetkul, S., Stokes, K., Thompson, D.
University of Bath, United Kingdom

Introduction: Appropriate physical activity behaviour plays a critical role in weight maintenance. There is a direct increase in thermogenesis during a bout of exercise but it is unclear whether this affects subsequent physical activity behaviour in the following hours and days. The main objective of this study was to investigate whether a single bout of walking in the laboratory leads to changes in subsequent physical activity energy expenditure in free-living conditions.

Methods: Ten sedentary males (Age, 28 ± 2 years; Body Mass Index, 22 ± 1 kgm⁻²; maximum oxygen uptake, 49.8 ± 1.7 mlkg⁻¹min⁻¹) and percent body fat, 18 ± 1%; mean ± SEI participated in this study, which had been approved by the local ethics committee. On one occasion subjects walked on a treadmill at a target exercise intensity of 40%VO2 max for 60 min and on another occasion subjects rested in the laboratory for the same period of time. Fasting venous blood samples were taken at regular intervals before and after rest or exercise. Physical activity energy expenditure was estimated using synchronised measurement of movement and heart rate (Actheart, Cambridge Neurotechnology Ltd., Cambridge). Physical activity energy expenditure (PAEE) represents the energy expended during physical activity recorded in 1 min epochs above rest and not including diet-induced thermogenesis. The data were analyzed using two way repeated measures ANOVA and paired t-test.

Results: The mean daily free-living PAEE over the three days following walking at 40%VO2 max after subtraction of energy expended during the 60 min walk was 35% greater than the rest trial (1065 ± 133 kcal vs. 789 ± 92 kcal, P=0.009). Daily PAEE following exercise was higher than following rest on the main trial day (57%), and the periods 14-38 h (25%) and 38-62 h (26%) after exercise. The increase in daily PAEE was explained by increases in mean light intensity PAEE (between 2.4-4.78 metabolic equivalents or METs) following exercise over the three days (509 ± 65 kcal vs. 356 ± 56 kcal, P=0.0006). Mean PAEE in this MET range following exercise was higher than following rest on the main trial day (71%), and the periods 14-38 h (24%) and 38-62 h (31%) after exercise. There were no changes in circulating concentrations of leptin, adiponectin or acylated ghrelin concentrations in either trial. A single bout of walking at 40%VO2 max induced positive changes in subsequent free-living physical activity energy expenditure over the three days following exercise. This was mostly accounted for by increased low-to-moderate non-exercise behaviour such as standing and walking in the 2.4 to 4.78 METs range.

THE EFFECTS OF EXERCISE-INDUCED MUSCLE DAMAGE ON AGILITY AND SPRINT RUNNING PERFORMANCE

Highton, J., Twist, C.
University of Chester, United Kingdom

Exercise-induced muscle damage (EIMD) has been shown to impair linear sprint running performance (Twist and Eston, 2005). However, the effects of EIMD on the ability to change direction rapidly have not been investigated. Therefore, the purpose of this study was to assess the effects of EIMD on sprint running and agility performance. Twelve healthy adults were randomly allocated to an experimental in
Moreover, a significant speed by time interaction (P<0.05) indicated that peak torque was reduced to a greater extent at the slower (6%, 5%, 9% and 26% respectively) in the experimental group, whilst the control group remained unchanged (P>0.05). Furthermore, there were significant correlations for perceived muscle soreness with agility turn time (r=0.82, P<0.05) and contact time at the agility turn point (r=0.94, P<0.05). These findings indicate that agility and sprint performance is significantly reduced following EIMD, and provides further evidence that following muscle damaging exercise, performance of activities requiring rapid generation of force is impaired. This has implications for athletic performance involving sprint tasks with rapid changes of direction.

**EFFECTS OF ACUTE HYPOXIA ON MOTOR AGILITY**

Pocecco, E., Brunner, F., Jäger, A., Gatterer, H., Faulhaber, M., Burtscher, M.
University of Innsbruck, Austria

**Introduction**
Motor agility, defined as rapid whole-body movement with change of velocity and/or direction in response to a stimulus (Sheppard and Young, 2006), is an important ability for success and safety in alpine sports. Although such activities are performed in high altitudes, there is little information about the effect of hypoxia on motor agility. Thus, effects of acute hypoxia on motor agility have been studied in a controlled, randomized, double blind experiment.

**Methods**
A total of 48 sport students (age: 22±2 yrs) were randomly assigned to the hypoxia group (HG, 10 males, 14 females) or to the control group (CG, 9 males, 15 females). The motor agility test, which measures reaction time, was carried out modifying the protocol of Hamar and Zemková (1998). Subjects reacted to a signal by jumping as fast as possible into the correct area. 20 jumps were performed in each trial. The mean of the best 2 out of 3 consecutive trials was used. Both groups performed normoxic pre-tests (PT) under laboratory conditions. The HG repeated the re-test (RT) in hypoxia (FIO2 = 15.0 %, corresponding to an altitude of about 3500m) and the CG in normoxia 1 week after the PT. All RT were made in the same normobaric hypoxic chamber with no knowledge of FIO2.

**Results**
Motor agility improved in acute hypoxia compared to normoxia and remained unchanged in the CG. Results (means ± sd in ms): HG PT: 858.08 ± 53.23, RT: 841.00 ± 56.49, p < 0.040. CG PT: 838.94 ± 50.92, RT: 843.89 ± 61.61, p < 0.932.

**Discussion**
Acute hypoxia resulted in improved motor agility. This finding could be due to an increased activation of the sympathetic nervous system which in turn increases also physiological tremor (Krause et al., 2000). The mechanisms which produce such a generalized arousal remain unknown. It can be speculated that peripheral chemoreceptor input comprises the afferent limb of a polysynaptic facilitatory pathway, in which the efferent limb includes the muscle spindle-la-afferent reflex pathway (Krause et al., 2000).

**ARE CHANGES IN LOW-FREQUENCY HEART RATE VARIABILITY RELATED TO CHANGES IN ARTERIAL STIFFNESS IN MIDDLE-AGED MEN AFTER EXERCISE TRAINING?**

Perkins, G., Owen, A., Swaine, I.
Canterbury Christ Church University, United Kingdom

**BACKGROUND.** Baroreflex sensitivity (BRS) declines with age and central arterial stiffness increases with age. It has been suggested that stiffening of the carotid artery impedes baroreflex function. Cross-sectional research suggests that baroreflex function is enhanced in older physically active men despite age-related arterial stiffness (Hunt et al. 2001). Exercise training increases BRS and reduces arterial stiffness. The low frequency (LF) component of spectral heart rate variability (HRV) has been proposed as an index of BRS. Stiffness of the central arteries (carotid-femoral) can be measured by pulse wave velocity (PWV). This study investigated whether changes in the LF component of HRV were related to changes in PWV in middle-aged men after 12 weeks of exercise training.

**METHODS.** Participants were healthy sedentary men (n =36), mean (SD) age 51 (7) years (range 40-64 years), stature 1.9 (1.8) m, body mass 89.9 (9.7) kg. Data was collected at baseline and after a 12-week exercise intervention, in which participants performed at least 150 minutes per week of moderate-to-vigorous physical activity (e.g. brisk walking, jogging, cycling). Participants rested supine for 15 minutes before data collection. HRV was derived from a 5-min ECG recording during paced breathing. LF power was calculated within the frequency range 0.04-0.15 Hz. Carotid-femoral PWV was assessed using Complior. Resting blood pressure (BP) and resting heart rate (HR) were also measured. LF data was natural log-transformed for analysis (LFin). Pearson’s correlation was used to test for relationships between LFin and PWV and other measured variables at baseline, and between changes (Δ) in LFin and PWV and other measured variables at follow-up. Significance was accepted at p<0.05

**RESULTS.** At baseline, mean (SD) PWV was 8.4 (1.6) ms-1. Median inter-quartile range LF was 236 [191-369] ms2. Mean (SD) BP was 130 (15)/82 (7) mmHg, and RHR was 61 (8) bpm-1. At baseline, LFin was significantly correlated to PWV (r=-.361, p=0.031), age (r=.347, p=0.038), and systolic BP (r=.384, p=0.021). At follow-up, median (interquartile range) for moderate-vigorous physical activity level was 3.8 (3-1.5-6)
ECCENTRIC CONTRACTIONS OCCUR FREQUENTLY IN EVERYDAY AND SPORTS ACTIVITIES. THIS TYPE OF CONTRACTION HAPPENS WHEN ACTIVATED MUSCLES ARE FORCIBLY LENGTHENED. ECCENTRIC CONTRACTIONS ARE CHARACTERIZED BY THE ABILITY TO ACHIEVE HIGH MUSCLE FORCE WITH LESS ENERGIC COST. THE AIM OF THE PRESENT STUDY WAS TO INVESTIGATE THE CHANGES IN MUSCLE ARCHITECTURE DURING ECCENTRIC CONTRACTIONS IN VIVO. THE BEHAVIOUR OF MUSCLE FASCICLES WAS ANALYSED DURING PASSIVE STRETCHING AND ECCENTRIC CONTRACTIONS AT DIFFERENT INTENSITIES. TWELVE HEALTHY MALE SUBJECTS (AGE: 22.7 ± 3 YEARS) TOOK PART IN THE STUDY. MUSCLE ARCHITECTURE WAS INVESTIGATED NON-INVASIVELY USING ULTRASONOGRAPHY. THE FASCICLE LENGTH AND THE DEEP PENNATION ANGLE OF THE GASTROCNEMIUS MEDIALIS (GM) MUSCLE WERE RECORDED DURING PASSIVE STRETCHING AND ECCENTRIC PLANTARFLEXION AT 20%, 40% AND 60% OF MVC. MUSCLE LENGTHENING WAS INDUCED BY A MOTOR-DRIVEN COMPUTER CONTROLLED ERGOMETER (PASQUET, 2006). THIS DEVICE, EQUIPPED WITH A FOOTPLATE FIXED TO THE ROTATIONAL AXIS OF THE MOTOR, RECORDED THE TORQUE GENERATED BY THE PLANTARFLEXOR MUSCLES UNDER STATIC AND DYNAMIC CONDITIONS. THE ANGULAR DISPLACEMENT OF THE ANKLE RANGED FROM +10° TO -30° DORSIFLEXION AND THE SPEED OF MOVEMENT WAS SET AT 25°/S.

AT REST (+10° DORSIFLEXION), FASCICLES LENGTH WAS 54.5 ± 3.2MM. DURING ECCENTRIC CONTRACTIONS AT 20, 40 AND 60% OF MVC, FASCICLES LENGTH INCREASED PROGRESSIVELY AND REACHED 34.4, 32.7 AND 34.6%, RESPECTIVELY, AT 30° OF ANKLE DORSIFLEXION. DURING PASSIVE LENGTHENING, FASCICLES LENGTH INCREASED BY 44.8% (P<0.001) AT 30° OF ANKLE DORSIFLEXION. FOR THE ANKLE IN NEUTRAL CONDITION, PENNATION ANGLE WAS 20.9 ± 3.1°. DURING ECCENTRIC CONTRACTIONS AT 20, 40 AND 60% OF MVC, PENNATION ANGLE DECREASES BY 11.4% (P<0.001), 13.9% (P<0.001) AND 10.3% (P<0.001), RESPECTIVELY. DURING PASIVE LENGTHENING, PENNATION ANGLE WAS REDUCED BY 32.6% (P<0.001). IN THE LATTER CASE, PASSIVE STRETCHING INDUCED AN EXPONENTIAL INCREASE IN TORQUE THAT REACHED 55.3 Nm AT 30° OF ANKLE DORSIFLEXION. FOR THE SAME ANKLE ANGLE, THE TORQUE DEVELOPED DURING ECCENTRIC CONTRACTIONS AT 20, 40 AND 60% OF MVC REACHED 80.1, 98.5 AND 118.3 Nm, RESPECTIVELY.

THE MAIN FINDING OF THIS STUDY IS THAT ALTHOUGH THE TORQUE DEVELOPED DURING ACTIVE MUSCLE LENGTHENING INCREASES WITH THE INTENSITY OF CONTRACTION, FASCICLES LENGTH CHANGE IS SIMILAR FOR CONTRACTIONS RANGING FROM 20 TO 60% MVC.

CHANGES IN MUSCLE FASCICLES DURING ECCENTRIC CONTRACTIONS FOR DIFFERENT INTENSITIES

Abellaneda, S., Guissard, N., Duchateau, J.

Université Libre de Brussels, Belgium

Eccentric contractions occur frequently in everyday and sports activities. This type of contraction happens when activated muscles are forcibly lengthened. Eccentric contractions are characterized by the ability to achieve high muscle force with less energy cost. The aim of the present study was to investigate the changes in muscle architecture during eccentric contractions in vivo. The behaviour of muscle fascicles was analysed during passive stretching and eccentric contractions at different intensities. Twelve healthy male subjects (age: 22.7 ± 3 years) took part in the study. Muscle architecture was investigated non-invasively using ultrasonography. The fascicle length and the deep pennation angle of the Gastrocnemius Medialis (GM) muscle were recorded during passive stretching and eccentric plantarflexion at 20%, 40% and 60% of MVC. Muscle lengthening was induced by a motor-driven computer controlled ergometer (Pasquet, 2006). This device, equipped with a footplate fixed to the rotational axis of the motor, recorded the torque generated by the plantarflexor muscles under static and dynamic conditions. The angular displacement of the ankle ranged from +10° to -30° dorsiflexion and the speed of movement was set at 25°/s.

At rest (+10° dorsiflexion), fascicles length was 54.5 ± 3.2mm. During eccentric contractions at 20, 40 and 60% of MVC, fascicles length increased progressively and reached 34.4, 32.7 and 34.6%, respectively, at 30° of ankle dorsiflexion. During passive lengthening, fascicles length increased by 44.8% (p<0.001) at 30° of ankle dorsiflexion. For the ankle in neutral condition, pennation angle was 20.9 ± 3.1°. During eccentric contractions at 20, 40 and 60% of MVC, pennation angle decreases by 11.4% (p<0.001), 13.9% (p<0.001) and 10.3% (p<0.001), respectively. During passive lengthening, pennation angle was reduced by 32.6% (p<0.001). In the latter case, passive stretching induced an exponential increase in torque that reached 55.3 Nm at 30° of ankle dorsiflexion. For the same ankle angle, the torque developed during eccentric contractions at 20, 40 and 60% of MVC reached 80.1, 98.5 and 118.3 Nm, respectively.

The main finding of this study is that although the torque developed during active muscle lengthening increases with the intensity of contraction, fascicles length change is similar for contractions ranging from 20 to 60% MVC.

POSITION SENSE AND REACTION ANGLE AFTER ECCENTRIC EXERCISE: THE REPEATED BOUT EFFECT

Jamurtas, A., Paschalis, V., Nikolaidis, M., Giakas, G., Koutedakis, Y.

University of Thessaly, Greece

Unaccustomed exercise, especially when it involves eccentric actions, leads to muscle damage (Nosaka and Sakamoto 2001). When a bout of eccentric exercise is repeated within several months the muscle damage produced is much less than the first bout, a phenomenon known as repeated bout effect (Jamurtas et al. 2000). No studies have investigated the effect of repeated eccentric exercise on position sense or muscle reaction angle of animals or humans. The adaptation to eccentric exercise provides an interesting model to study this relationship because responses to a damaging eccentric exercise (bout 1) can be compared to a relatively non-damaging eccentric exercise (bout 2). Based on our previous finding of disturbed position sense and reaction angle after a single bout of eccentric exercise (Paschalis et al, 2007), the purpose of the present investigation was to examine the effects of a repeated eccentric exercise on position sense and muscle reaction angle. Fourteen healthy women underwent an isokinetic exercise session on their knee flexors in their dominant leg, while the other leg was served as control, which was repeated after four weeks. Muscle damage indices (isometric peak torque, range of movement, delayed onset muscle soreness), position sense (at 30o, 45o and 60o knee flexion) and joint reaction angle (at 20o, 40o, and 60o) of the knee were examined before, immediately after as well as at 1, 2, 3, 4 and 7 days after exercise. Both the first and the second eccentric exercise caused muscle damage and disturbances in position sense and reaction angle to release. However, judging from the less significant differences after the second bout of exercise compared to the first one and the several significant differences at each time-point between the two bouts, the second bout produced lower and smaller alterations in muscle damage indices, position sense and reaction angle to release, compared to the initial one. The main finding of this study is that position sense and joint reaction angle to release of the lower limbs may adapt in response to a repeated bout of eccentric exercise, leading in less disturbances in these motor features after the second bout of exercise. These adaptations may have occurred, at least in part, due to an attenuation of the eccentric exercise-induced muscle damage after the second bout.

RELATIONSHIP BETWEEN THE CARDIAC AUTONOMIC NERVOUS SYSTEM ACTIVITY AND MENSTRUAL CYCLE IN EXERCISE HABIT

Kitamura, M., Seki, K., Kazuki, N., Mayo, K., Kremenik, J., Onodera, S.
Kawasaki University of Medical Welfare, Japan

INTRODUCTION: In previous studies, it had been observed that cardiac autonomic nervous system activity changed during menstrual cycle. Cardiac parasympathetic nervous system activity at rest showed the high values in follicular phase and the low values in early luteal phase. The data of healthy sedentary or recreationally active young women were examined in these studies. Serum oestadiol and progesterone concentrations in the exercise group who habitually performed exercise were lower in luteal phase. It is unknown whether cardiac autonomic nervous system activity is same finding with sedentary during menstrual cycle in the exercise group. The purpose of this study was to prove that relationship between the cardiac autonomic nervous system activity and menstrual cycle in exercise habit.

METHODS: Six healthy young women with exercise habit (age 21.8±0.4 years; height 158.2±3.5 cm; body weight 53.3±2.1 kg; mean±SD) and Two sedentary women (age 23.5±0.7 years; height 162.8±1.8 cm; body weight 59.2±3.1 kg) participated in this study. They were with a normal menstrual cycle. All subjects provided informed consent for their participation with the experimental procedures conducted in conformance. We measured cardiac autonomic nervous system activity at five points in the menstrual cycle (M, menstrual, F, follicular, O, ovulatory, EL, early luteal, and LL, late luteal). Cardiac autonomic nervous system activity and HR were measured using the MemCalc methodology. The frequency domain was divided into two parts: high frequency (HF, 0.15-0.40Hz) and low frequency (LF, 0.04-0.15Hz).

Cardiac autonomic nervous system activity was transformed into logarithmic values to obtain a statistically normal distribution. log HF was an index of cardiac parasympathetic nervous system activity. RESULTS and DISCUSSION: log HF at rest of the sedentary subjects showed the high values in F phase and the low values in EL phase. HR at rest of the sedentary subjects showed the high values in EL phase. It was similar to the previous studies. log HF at rest of six subjects with exercise habit showed no same tendency. Two of six subjects showed the low values in EL phase. Moreover, three of six subjects showed few changes. One of six showed the low values in EL phase as well as the sedentary subjects. HR at rest of subjects with exercise habit showed no same tendency. Three of six subjects showed the high values in LL phase. One of six subjects showed few changes. One of six subjects showed the high values in M phase as well as the sedentary subjects. And one of six subjects showed the high values in M phase. Fluctuations in cardiac parasympathetic nervous system activity at rest of sedentary subjects correlated with the balance between oestadiol and progesterone concentrations.

However, subjects with exercise habit were not an agreement in result. These results suggest that an exercise habit may fluctuate cardiac parasympathetic nervous system activity with menstrual cycle.

INFLUENCE OF ECCENTRIC EXERCISE-INDUCED MUSCLE DAMAGE ON PULMONARY OXYGEN UPTAKE AND MUSCLE DEOXYGENATION KINETICS DURING HIGH-INTENSITY EXERCISE

Davies, R., Eston, R., Poole, D., Rowlands, A., DiMenna, F., Willkerson, D., Twist, C., Jones, A.
University of Exeter, United Kingdom

Unaccustomed eccentric exercise is known to have a profound impact on muscle structure and function and is associated with delayed onset muscle soreness. However it is not known whether associated microvascular dysfunction, including a reduction in microvascular O2 pressure (PO2mv), compromises blood-muscle O2 flux by disrupting the matching of O2 delivery (QO2) to O2 utilisation (VO2). The deoxyhaemoglobin concentration (Hb) signal measured using near-infra-red spectroscopy (NIRS) can be used to provide non-invasive assessments of the muscle QO2/VO2 balance in the microcirculation of the area of skeletal muscle under interrogation. The purpose of this study was therefore to use NIRS to investigate the influence of eccentric exercise on the dynamic balance between QO2 and VO2 following the onset of high-intensity exercise.

Nine physically active men completed ‘step’ tests to high-intensity exercise (70% of the difference between the gas exchange threshold and VO2peak) from an unloaded baseline on a cycle ergometer. These tests were performed both before and 48 h after eccentric exercise which consisted of 100 squats performed as 10 sets of 10 repetitions with a load corresponding to 70% of body mass. Markers of muscle damage (plasma creatine kinase (CK) activity, perceived muscle soreness and isokinetic peak torque) were measured immediately before the pre and post exercise tests and also at 24 h after the eccentric exercise. NIRS and breath-by-breath pulmonary VO2 were measured continuously during the exercise tests and subsequently modelled using standard non-linear regression techniques.

The eccentric exercise was effective in provoking significant changes in all markers of muscle damage: CK activity, pre 172±123, 24 h post 740±666 U/l; soreness, pre 0.6±5.48 h, post 7.1±1.5 (where 0= ‘no soreness’ and 10= ‘worst soreness ever’); peak torque, pre 287±39, 48 h post 227±60 Nm; all P<0.05). There were no changes in phase II pulmonary VO2 kinetics following the onset of exercise (time constant, pre 25±4, post 24±2 s; amplitude, pre 2.36±0.23, post 2.37±0.23 L/min; all P>0.05). However, both the time delay (pre 4.1 s, post 6±1 s) and the mean response time (pre 14±3 s, post 19±3 s) of the (Hb) response were significantly slower following eccentric exercise (P<0.05).

The slower (Hb) kinetics observed following eccentric exercise is consistent with an increased QO2/VO2 ratio during transitions to high-intensity exercise. Since pulmonary VO2 kinetics were not altered by the intervention, the increased QO2/VO2 ratio must reflect an increased local muscle blood flow. It is speculated that an increased QO2 is necessary to compensate for the reduced PO2mv resulting from the eccentric exercise (Kano et al., 2005). In this way, the increased QO2 could act to raise the O2 pressure head and thus preserve muscle VO2 in the transition from rest to exercise.

EFFECT OF FEEDING VERSUS FASTING DURING PROLONGED EXHAUSTIVE EXERCISE ON SALIVARY IMMUNOGLOBULIN A, LYSOZYME AND ALPHA-AMYLASE

Allgrove, J., Oliveira, M., Cheffins, S., Gleeson, M.
Loughborough University, United Kingdom

A decreased level of mucosal immune defence has been implicated as a causal factor for the reported higher incidence of upper respiratory tract infection in athletes (Gleeson et al., 1999). Eating activates both gustatory and mucosal receptors which may stimulate the secretion of proteins into saliva via autonomic mechanisms (Pedersen et al., 2000). Therefore, the aim of the present study was to investigate the effect of feeding versus fasting during prolonged exhaustive exercise on the salivary secretion rates of immunoglobulin A (s-IgA), lysozyme, alpha-amylase and cortisol. Using a randomised cross-over design and following a 10 12 hour overnight fast, 24 fit healthy...
The performance of rapid (ballistic) contractions is influenced by the conditions under which they are performed (Van Cutsem & Duchateau, 2005). For example, we have shown that the rate of isometric torque development was greater when the ballistic contraction was preceded by a rapid contraction of the antagonist muscles compared with a ballistic contraction performed from resting condition (Richartz et al., unpublished observation). In this study, we investigated the time course of change in the activation of the ankle dorsiflexor muscles during a two-hour stay in a snow hole. Six healthy young men participated in this study. Each of them gave us an informed consent. HR, RT and SSTS were measured during two hours. The snow hole was 115cm height, 175cm wide and 200cm interior. RT decreased significantly in all subject (P<0.05). However, the rate of decrease in RT was half as compared to the pre-experiment. On the other hand, HR was not changed. A score of SSTS was significantly increased in all subjects (P<0.05). These data suggest that using a heat insulating material is effective to inhibit a decrease of rectal temperature during a short stay in snow hole. Second experiment; The purpose of this experiment was to examine the effects of HR, RT and SSTS using a heat insulating material during a two-hour stay in a snow hole. Six healthy young men performed a two-hour test in a snow hole. HR showed no significant difference during a two-hour stay. RT significantly decreased in all subjects (P<0.05). However, the rate of these decreases was a quarter as compared to pre-experiment. SSTS was significantly increased in all subjects (P<0.05). These data appear to be associated with factors associated with skin temperature. It was considered that using thermal underwear inhibited the rectal temperature. Third experiment, The purpose of this experiment was to investigate the effects of HR, RT and SSTS using a heat insulating material, thermal underwear and heat-and steam-generating sheets during a two-hour stay in a snow hole. Eight healthy young men performed a two-hour test in a snow hole. HR was no significant difference during a two-hour stay. RT significantly decreased in all subjects (P<0.05). SSTS was significantly increased between the zero minutes of experiment to fifty minutes and after that (P<0.05), it was kept to steady state. It was considered that using the thermal underwear and heat-and steam-generating sheets inhibited a subjective thermal sensation. All the results found that everything is totally effective to prevent the coldness using heat insulating materials, thermal underwear and heat-and steam-generating sheets, during a two-hour stay in a snow hole.

CHARACTERISTIC OF MUSCLE ACTIVATION DURING A BALLISTIC CONTRACTION PRECEDED BY A RAPID ANTAGONIST ACTIVATION

Richartz, C., Duchateau, J.

The performance of rapid (ballistic) contractions is influenced by the conditions under which they are performed (Van Cutsem & Duchateau, 2005). For example, we have shown that the rate of isometric torque development was greater when the ballistic contraction was preceded by a rapid contraction of the antagonist muscles compared with a ballistic contraction performed from resting condition (Richartz et al., unpublished observation). In this study, we investigated the time course of change in the activation of the ankle dorsiflexor muscles when the ballistic action is preceded by a rapid submaximal contraction of their antagonist muscles. Five healthy subjects participated in this investigation. They seated on a chair with their right foot strapped to a footplate with the ankle and knee angles at 90° and 120°, respectively. The task consisted successively: (1) to sustain a submaximal force (20% of MVC) with the dorsiflexors, (2) to perform a rapid contraction at ~50% of the maximal force with the planter flexors (antagonists) and (3) to produce, without transition, a ballistic contraction with the ankle dorsiflexors. The isometric torque developed by the ankle muscles was recorded by a transducer. The EMG activities of both agonist (tibialis anterior) and antagonist (soleus and gastrocnemius) muscles were obtained by means of two surface electrodes placed over each muscle. The motor evoked potential (MEP) induced by transcranial magnetic stimulation (TMS) and the Hoffmann reflex (H-reflex) were also recorded at different times of the task. The EMG responses to both stimulations were normalised to the responses obtained while performing the sustained submaximal contraction at 20% of MVC.

The results show that during the antagonist contraction, the EMG of the tibialis anterior dropped to 70% of that recorded during the sustained contraction of the agonist at 20% of MVC. During the ballistic contraction with the agonist, it raised to nearly 30% of the control value. The activation of the agonist was preceded by a silent period (SP) of 35 ± 5 ms. The changes in MEP and H-reflex followed the same time course throughout the task. They never surpassed 50% of the control values during the antagonist activation, increased progressively during the SP and reached values of 120% and 150% for the MEP and H-reflex, respectively, during the ballistic action.
In conclusion, this study shows the presence of a SP in the activation of the ankle dorsiflexor muscles when a ballistic action is preceded by a rapid submaximal contraction of their antagonist muscles. The SP seems to play a role in the increase in the rate of torque development during a subsequent ballistic contraction (Van Cutsem et al., 2005). Regardless of the exact origin of SP, the similar time course of change for the MEP and H-reflex during the task suggests the contribution of post-synaptic inhibitory mechanisms.

ASSOCIATION OF METABOLISM AND SUBSTRATE SELECTION FOLLOWING HIGH-INTENSITY EXERCISE
Stokes, K., Belts, J.
University of Bath, United Kingdom

Background
Metabolism during sprint exercise has received considerable attention, but a renewed interest in applications for sprint training indicates that a better understanding of metabolism during recovery from this type of exercise is needed. The aim of this study was to examine the effect of a single 30-s sprint on substrate selection during recovery.

Methods
Following ethics committee approval, seven physically active males (mean age (SD), 25.5 (2.9) yr; body mass index, 24.9 (3.5) kg/m²) gave informed consent to participate, before completing two trials in a random order after an overnight fast. In one trial, they performed a single 30-s sprint on a cycle ergometer against a resistance equivalent to 7% of their body mass (EX). In the other trial, they rested in the laboratory (CON). Blood samples were taken at intervals pre- and post-exercise, and at equivalent times in the rest trial. Expired air samples were collected using the Douglas Bag method for calculation of the respiratory exchange ratio (RER). Data were analysed using paired t-tests; statistical significance was accepted at P < 0.05.

Results
Sprint exercise elicited an increase in blood lactate concentrations with highest measured concentrations at 10-min post-exercise (EX vs. CON; 6.5 (0.8) vs. 3.9 (0.9) mmol/L, P < 0.01). Plasma free fatty acids concentrations decreased after exercise with lowest measured concentrations at 5-min post-exercise (EX vs. CON; 0.18 (0.03) vs. 0.33 (0.20) mmol/L, P = 0.08). The RER increased from pre-exercise (EX vs. CON; 0.86 (0.08) vs. 0.85 (0.11), P = 0.72) to 5-min post-exercise (EX vs. CON; 1.12 (0.13) vs. 0.76 (0.02), P < 0.01), before decreasing to lowest measured values at 30-min post-exercise (EX vs. CON; 0.61 (0.04) vs. 0.76 (0.03), P < 0.01).

Discussion
A single 30-s sprint resulted in an RER of less than 0.7 within 30 min of post-exercise recovery. Such a low RER indicates that indirect calorimetry might not be a sensitive tool for the assessment of fat and carbohydrate oxidation after sprinting. Specifically, the occurrence of metabolic processes such as protein oxidation, gluconeogenesis and ketogenesis might reduce RER resulting in over- or underestimation of rates of fat and carbohydrate oxidation. For example, direct oxidation of protein has a respiratory quotient (RQ) of ~0.8, but conversion of glycogenic amino acids into glucose has an RQ of 0.1-0.4, depending on the substrate used to fuel this process. If the glucose derived via gluconeogenesis is subsequently oxidised, the overall RQ will be the same as if the protein had be oxidised directly, however, net storage of this glucose, as might occur following demanding exercise, might result in a low RQ that, in turn, reduces the measured RER. Further work is warranted to improve understanding of the extent and impact of these processes as part of a wider understanding of metabolism and substrate selection following high-intensity short-duration exercise.

EFFECT OF A GROWTH HORMONE RECEPTOR ANTAGONIST (PEGVISOMANT) ON FAT METABOLISM DURING AND AFTER 45-MIN OF CYCLING IN HEALTHY ADULT MALES
Gilbert, K., Thompson, D., Anderton, R., Andrews, R., Hall, G., Stokes, K.
University of Bath, United Kingdom

Background
Exercise stimulates the release of growth hormone (GH), which has a powerful lipolytic effect. GH administration increases fat oxidation in the resting state; however whether GH augments fat oxidation during exercise remains unclear. Previous studies investigating the role of acute GH administration during exercise have failed to show an elevation in whole-body fat oxidation despite substantial increases in lipolysis and fatty acid availability. The aim of this study was to limit the action of GH by administering a GH receptor antagonist (pegvisomant) in order to investigate the role of GH in regulating fat metabolism during, and in recovery from, a bout of moderate intensity exercise.

Methods
Following local Ethics Committee approval, 12 men aged 18-25 years were familiarised before completing two trials in a random order at least 7 days apart. Participants cycled for 45 min at 60% VO₂ max under normal conditions (CON), or 72 h after the administration of pegvisomant (PEG). Expired air and blood samples were taken at intervals pre- and post-exercise, and at equivalent times in the rest trial. Substrate oxidation was estimated from expired air and blood samples for calculation of the respiratory exchange ratio (RER). Data were analysed using paired t-tests; statistical significance was accepted at P < 0.05.

Results
Pegvisomant administration led to a significant reduction in pre-exercise IGF-I (PEG vs. CON; 80 (24) vs. 111 (24) ng/mL, P < 0.01, d = 1.3) and GHBP (150 (155) vs. 596 (291) pmol/L, P < 0.01, d = 1.5) concentrations, suggesting that pegvisomant successfully limited the action of GH in the PEG trial. At rest, there was a significant reduction in fat oxidation in the PEG compared to the CON trial (0.07 (0.03) vs. 0.09 (0.03) g/min, P = 0.043, d = 1.0). During exercise, mean fat oxidation was significantly greater in the PEG than the CON trial (0.48 (0.1) vs. 0.39 (0.1) g/min, P = 0.03, d = 0.8), whilst FFA and glycerol concentrations were consistently, although not significantly, greater during exercise and recovery in PEG than CON. Mean carbohydrate oxidation during exercise was significantly lower during the PEG than the CON trial (1.6 (0.4) vs. 1.9 (0.3) g/min, P = 0.05, d = 0.4). During recovery there were no differences in fat oxidation between trials whilst mean blood glucose concentrations were lower in the PEG trial (4.0 (0.5) vs. 4.2 (0.2) mmol/L, P = 0.21, d = 1.0).

Conclusion
Limiting the action of GH in healthy young men reduced fat oxidation at rest but, in contrast to expectations, increased fat oxidation and decreased carbohydrate oxidation during exercise.
EXHAUSTIVE EXERCISE CAUSES INTESTINAL CONTRACTILITY IMPAIRMENT BY INCREASE OF MAXI-K+ CHANNEL MRNA EXPRESSION

Nouailhetas, V., Goto, E., Pesquero, J., Aboulafia, J., Rosa, E.
Universidade Federal de São Paulo, Brazil

Introduction. The effects of exhaustive exercise (EE) on the intestine are poorly understood. EE is associated with alterations of the expression of genes, like Maxi-K+ channel (KCa 1.1) and CaV1.2 channel, which could interfere with the intestine contractility. We thus investigated the effects of EE on the intestine contractility and the possible relationship with those two gene expression alterations. Methods: C57Bl/6 mice were assigned to control (CT), exercised for 4 (E4), and 10 days (E10) groups. EE program consisted of a daily treadmill running session at 85% of the maximum velocity until exhaustion. Contractility was evaluated by determining Emax and EC50 from non cumulative concentration-isometric contraction curves in response to carbachol (CCh), bradykinin (BK) and KCl. The mRNA of KCa 1.1 and CaV1.2 genes was quantified by real-time RT PCR. Results. The contractility was significantly impaired in E4 animal group, with 50% decrease in the efficacy of KCl, CCh and BK couplings. After 10 days of EE, it was not observed any alteration on the contractile response. The CaV1.2 expression was not significantly affected by 4 or 10 days of EE, while the expression of KCa 1.1 channel increased by 112% only in the E4 animal group. The increase of potassium current could explain the contractility impairment. Thus, we performed concentration-isometric contraction curves in presence of 1mM TEA+, a KCa 1.1 channel blocker. The presence of the blocker restored the efficacy of KCl, CCh and BK couplings to the levels observed in the control group. Conclusion. Altogether these results suggest that EE increases the BK channel mRNA expression, which increases the potassium current. This EE effect is responsible by the intestinal contractility impairment. DIFFERENT FLOW RESPONSES OF RENAL AND SPLANCHNIC ARTERIES DURING DYNAMIC EXERCISE

Sadamoto, T., Sato, K., Hirasawa, A., Yamamoto, Y.
Japan Women’s College of Physical Education, Japan

Purpose.
The blood flow in abdominal viscera has been described as the ‘blood giver of circulation’ and is believed to play a major role in cardiac distribution during exercise. Several investigations have reported that the abdominal blood flow decreases during exercise in proportion to the exercise intensity (Grimby, 1965; Rowell, 1974; Flamm et al, 1999). However, since visceral regions are consisted of functionally different organs such as kidneys and gastrointestinal tracts, it was hypothesized that blood flow regulation during dynamic exercise is different among arteries supplying to specific organs (Eriksen & Waaler, 1994; Perko, 2001). To verify this hypothesis, we studied the blood flow responses in the renal artery (RA) and the superior mesenteric artery (SMA) during dynamic exercise with graded workloads.

Methods.
Nine healthy female volunteers whose mean age was 23 (SD= 3.3) yr participated in the present study. After 10-min resting, the subject performed a 15-min bicycling exercise including three workloads of 30%, 50%, and 70% of peak oxygen uptake for 5 min for each workload. The exercise was done on a recumbent ergometer. Oxygen uptake, carbon dioxide production, minute ventilation, heart rate (HR), ECG, arterial mean blood pressure (MAP), and cardiac output (CO: Finometer) were continuously measured through the experiment. Time-averaged mean blood flow velocity (MBV) in RA and SMA was measured by using Doppler method. The conductance in RA and SMA were calculated as the quotient of MBV values in RA and SMA and the corresponding MAP values.

Results.
During dynamic exercise, the responses in oxygen uptake, minute ventilation, MAP, CO, and HR, respectively, increased linearly with three workloads from rest to 30%, 50%, and 70% of peak oxygen uptake. The conductance in RA, however, demonstrated a significant reduction during three workloads, by 19(5SD=11)% 29(5SD=13)% and 45(5SD=13)% of the value at rest for 30%, 50%, and 70% of the peak oxygen uptake, respectively. In contrast, the conductance in SMA showed no significant decrease from the resting level. The percent reduction of the conductance in SMA during exercise was 5(5SD=15)% 11(5SD=16)% and 19(5SD=16)% for the three workloads, respectively. Thus, the dynamic exercise produced a different response in the conductance between RA and SMA.

Conclusion.
The present data supported the hypothesis that blood flow regulation among visceral arteries is differential during dynamic exercise. The RA appeared to be more sensitive to exercise stimulus than the SMA, whereas the artery supplying to the digesting gastrointestinal tract such as SMA, might be some degree exempt from flow-reducing participation during exercise.

ACUTE EFFECTS OF DIFFERENT TRAINING CLASSES IN GLYCAEMIA LEVELS, IN INDIVIDUALS WITH TYPE 2 DM

Medeiros, L., Félix, R.
Escola Superior de Desporto de Rio Maior - Instituto Politécnico de Santarém, Portugal

Background: Exercise is a key element in the prevention and treatment of type 2 Diabetes mellitus (DM). There are evidences that aerobic, resistance and combined aerobic and resistance training have long term effects over glycaemia levels (Sigal et al 2007). However, it’s also important to know the acute effects of these different types of exercise. Exercise prescription for individuals with diabetes should be oriented to allow a better control of glycaemia as well as to avoid situations of hypoglycaemia/hyperglycaemia during exercise.

Objectives: The purpose of this study was to find out the acute effects of different training classes in glycaemia levels, in individuals with type 2 DM.

Methods: Fifteen, both genders, individuals with type 2 DM aged 68.4 years±7.6 were submitted in different days to 3 different types of classes: Aerobic Training (AT), Resistance Training (RT), Combined Resistance and Aerobic Training (CT), and to a no-exercise control situation (C). Time from last meal and respective content were the same for all individuals in all situations considered. Classes’ duration was 45 minutes, at a moderate intensity (Rate of Perceived Exertion level 12-13). Glycaemia levels were evaluated before and after each class. Paired samples t tests were performed to check for significant differences between pre-post exercise levels of glycaemia.
Results: No significant differences were found between pre-exercise glycaemia values, which confirm situation’s comparability. All conditions showed lower post-exercise glycaemia levels, however, CT was the only condition that that revealed significant differences Mean difference 25,2 mg/dl (CI 95%+9,7 a +40,1) P=0,04. Mean Differences for the other conditions were: C 0,3 mg/dl (CI 95%-12,4 a +13,1) P=0,956, RT 4,3 mg/dl (CI 95%-3,9 a +12,5) P = 0,276, AT 8,3 mg/dl (CI 95%-1,7 a +18,7) P = 0,08 Desert the magnitude of decreases found in CT, there were no cases of individuals with final glycaemia levels below an acceptable level (50 mg/dl). This was the only condition where all individuals reached optimal final levels of glycaemia (<150 mg/dl). It was also the condition that showed the smallest variability (sd=17,8 mg/dl) compared with AT (sd=31,6 mg/dl) and RT(sd=32,3 mg/dl).

Conclusions: Results are in order with Sigal et al (2007) which reached the conclusion that combined aerobic and resistance training was the better condition to achieve the control of glycaemia in individuals with type 2 DM.

CT seems to be an effective and safe prescription for individuals with type 2 DM with a well controlled level of glycaemia, thus it may play an important role in the treatment and control of type 2 DM.

**EFFECTS OF TRAINING IN THE FASTED STATE IN CONJUNCTION WITH FAT-RICH HYPERCALORIC DIET ON MUSCLE METABOLISM AND ENDURANCE PERFORMANCE**

Van Proeyen, K., Nielsens, H., Pelgrim, K., Ramaekers, M., Szulcik, K., Hespel, P.

Catholic University Leuven, Faculty of Kinesiology and Rehabilitation Sciences, Belgium

Introduction: Insulin sensitivity has been shown to be reduced with hypercaloric high-fat diet, which promotes a positive fat balance and an imbalance between lipid storage and fat oxidation(1). A high turnover rate of intramyocellular lipid (IMCL) is proposed to reduce accumulation of toxic lipid intermediates interfering with insulin signalling (2). An acute exercise bout in the fasted state stimulates IMCL breakdown (3), the purpose of this study was to compare the effect of exercise training in the fasted state versus the postprandial state on endurance performance, IMCL content and whole body insulin sensitivity during a period of six weeks of hypercaloric (normal diet + 30% kcal/day) high-fat (50-55%) diet.

Methods: Twenty-eight healthy moderately active males (18-25y) performed training sessions (6wks, 1-1.5h sessions@70-75% VO2peak, 4d/week) either in the fasted (F; n=10) or the carbohydrate-fed state (CHO; n=10), or had no training (ICON; n=8). Before and after the intervention period, subjects performed a 2h constant-load bicycle exercise (~63% of VO2 peak), followed by a 15-minute time trial (TT). Needle biopsies were taken from m. vastus lateralis and blood samples were taken before, and immediately after the 2h exercise and time trial. Glucose tolerance was measured by a 2h oral glucose tolerance test (OGTT). Results: Time to exhaustion during an incremental exercise test similarly increased in both F (+16%) and CHO (+14%). Peak VO2 increased from 60.5 ± 1.5 to 64.7 ± 1.8 ml.min.kg⁻¹ in CHO (p<0.01), but not in F (60.3 ± 2.2 to 61.2 ± 2.6 ml.min.kg⁻¹; p=0.51). TT performance was improved to the same degree (~24%) in both training groups (p<0.0001) but was unchanged in CON. Area under the glucose curve during OGTT decreased after training in F (p<0.01), whilst it was unchanged in CHO and CON. Fiber type-specific IMCL content and insulin data of OGTT are currently being analyzed. Conclusion: Compared with training in the carbohydrate-fed state, training in the fasted state during a period of hypercaloric high-fat does not enhance endurance performance, but could improve glucose tolerance.

**THE RELATIONSHIP BETWEEN BLOOD FLOW AND NITRIC OXIDE EMANATING FROM HUMAN SKIN FOLLOWING THE WRIST FLEXION-EXTENSION EXERCISE**

Itoh, H., Ueda, A., Yoshida, Y., Ohkuwa, T., Yamazaki, Y., Tsuda, T.

Nagoya Institute of Technology, Japan

Introduction. Nitric oxide (NO) is the most important endothelium-derived relaxing factor, which plays a pivotal role in modulating smooth muscle tone in the human conductance and resistance vessels [1]. Jungersten et al. [2] have suggested that NO is increased with increased cyclic wall stress associated with increased pulsatile blood flow during acute exercise. Previously, we [3] have been detected NO emanating from human skin (skin-gas). The purpose of this study was to examine whether increased blood flow during acute exercise would relate human skin-gas NO concentrations or not.

Methods. Ten healthy male students (21.7 ± 2.2 years; mean ± SD) volunteered as the subjects. The subjects performed the repetitive wrist flexion-extension exercise at 25% maximal voluntary contraction at a pace of a time per second until voluntary exhaustion. The skin-gas samples were obtained by the covering index fingertip for 30 sec with a polyfluorovinyl bag (Tedlar bag, GLScience, Tokyo, Japan) in which pure nitrogen gas was introduced, and collected in a sampling bag at rest and after exercise (0-0.5, 2-2.5, 4-4.5, 6-6.5, 8-8.5, 10-10.5 min). Blood flow was measured with a noncontact-type laser-Doppler flowmetry (LDF) probe on the skin surface of the annular fingertip (ALF-21, Advance, Tokyo, Japan).

Results and Discussion. The mean ± SD time to exhaustion of the exercise was 216 ± 50.6 sec. No significant higher levels were found in the index fingertip blood flow levels after the exercise compared to the resting values, however, the peak blood flow levels of each subject significantly increased compared to the resting levels (p<0.01). The skin-gas NO concentrations significantly increased 4-4.5 min after the exercise.
Oxygen uptake kinetics at the onset of heavy intensity exercise have been shown to be faster in young children compared to older children (Fawkner and Armstrong 2004) and in young adults compared to older adults (DeLorey 2004). The exact mechanisms are not known therefore the purpose of this study was to gain further insights by simultaneously examining the relationship between pulmonary oxygen uptake kinetics and muscle deoxygenation at the onset of heavy intensity cycling exercise in 8 girls (aged 9.7 ± 0.4 years) and 8 female adults (aged 22.4 ± 5.2 years).

A single exponential following a time delay was used to analyse both the averaged oxygen uptake (phase 2, time constant) and the Hb response (from exercise onset).

We conclude that increased blood flow during the repetitive low intensity exercise stimulates vascular endothelial NO production and local NO release. The changes in the skin-gas NO concentrations observed in this study have suggest that the repetitive wrist flexion-extension stimulate endothelial NO production by increases in shear stress during the exercise.

Conclusions.

**RELATIONSHIP BETWEEN OXYGEN UPTAKE KINETICS AND MUSCLE DEOXYGENATION IN CHILDREN AND ADULTS AT THE ONSET OF HEAVY INTENSITY CYCLING EXERCISE**

Welford, D., Armstrong, N.

University of Wales Institute Cardiff, United Kingdom

Oxygen uptake kinetics at the onset of heavy intensity exercise have been shown to be faster in young children compared to older children (Fawkner and Armstrong 2004) and in young adults compared to older adults (DeLorey 2004). The exact mechanisms are not known therefore the purpose of this study was to gain further insights by simultaneously examining the relationship between pulmonary oxygen uptake kinetics and muscle deoxygenation at the onset of heavy intensity cycling exercise in 8 girls (aged 9.7 ± 0.4 years) and 8 female adults (aged 22.4 ± 5.2 years).

Each subject performed at least 4 step change transitions from unloaded pedalling to a constant work rate corresponding to 40% difference between their previously determined ventilatory threshold and peak oxygen uptake. Each participant’s breath by breath responses were interpolated to 1s intervals, time aligned and averaged. A near infrared spectroscopy (NIRS) device (Hamamatsu NIRO 300) was used to sample changes in deoxyhaemoglobin (Hb), data were collected at 1s time intervals and individual tests were time aligned and averaged. A single exponential following a time delay was used to analyse both the averaged oxygen uptake (phase 2, time constant) and the Hb response (from exercise onset).

Oxygen uptake kinetics were significantly faster in children at the onset of exercise as shown by the phase 2 time constant (23.5 ± 6.5s in children vs 35.3 ± 6.5s in adults P<0.05). The kinetics of muscle deoxygenation as shown by the MRT for Hb (time delay + time constant) were significantly slower in children compared to adults (28.3 ± 8.1s vs 20.4 ± 8.6s P<0.05). There was no correlation between oxygen uptake and Hb kinetics in either children (23.3s ± 8s vs 28.5s ± 7.7s respectively; P> 0.05) or adults (33.3 ± 9.6s vs 20.4 ± 8.6s respectively; P> 0.05).

The faster pulmonary oxygen uptake kinetics and slower muscle deoxygenation in children compared to adults indicates an age and/or maturational effect on the relationship between oxygen delivery and utilisation at the onset of heavy intensity exercise.

Conclusions.

**CIRCADIAN RHYTHM IN 10-KM LABORATORY RUNNING PERFORMANCE**

Edwards, B., Boyle, B., Doran, D., Waterhouse, J., Reilly, T.

Research Institute for Sport and Exercise Sciences, United Kingdom

ABSTRACT

A wealth of research shows that physiological variables related to gross motor performance follow a time-of-day (TOD) effect. Recently a circadian rhythm in 200m time-trial performance has been reported, with faster times in the evening and worst performances in the early morning. Whether this variation in performance applies also to longer distances is unclear. Therefore, we tested the hypothesis that a circadian rhythm exists for a 10-km time-trial run.

Friday, July 11th, 2008

EXPERIMENTAL PROTOCOL

Ten male sport science students (X±SD: peak = 61.2±9.4 ml.kg.min-1, age = 26±6 years, body mass = 81.2±14.8 kg and height = 179±8 cm) took part in the study. The local Ethics Committee of the University approved the study. The subjects completed two familiarisation trials to the best of their ability at a self-selected pace. The subjects then completed six 10 km time-trials at 06:00, 10:00, 14:00, 18:00, 22:00 and 02:00 h. The design of the study was such that the sessions were counterbalanced in order of administration and a standardised 5-min warm-up at 10 km.h-1 was completed prior to each time-trial. Heart rate, RPE, and split times were measured every 1 km during the time-trial, together with the subjects’ perception of the pacing required to finish as quickly as possible (1-5, too slow/5, too fast). Finger tip blood lactate samples and intra-aural (IA) temperature were taken at rest and immediately after the time-trial. The 95% ratio limits of agreement for the 10 km time-trial performances on these individuals were /= 0.77, assessed in a prior test-retest study. Data were analysed using an analysis of variance model (TOD x distance) for performance times, IA temperature, 916; blood lactate, 916; body mass and 916; osmolarity. A two-way analysis of variance model (TOD x time-trial distance) was used for RPE, heart rate and split times. Group covaraior analysis was employed on resting intra-aural temperature and time taken to complete the trials. Resting IA temperature and finishing time both showed a significant circadian rhythm (P<0.05) with mesor, amplitude and acrophase of 36.58C vs 30.35C, 0.357C vs 0.357C and 19.43 vs 17.41 h, respectively. TOD variations were absent from any pre-post measures. There was a TOD effect in split times, heart rate and perception of optimal pacing, with heart rate and RPE reflecting the faster speeds (hence, lower split times) during the evening, and a perception at this time of having paced too fast to sustain performance to the end of the time-trial.

During the time-trial, split times decreased, and RPE and HR increased, from the first to the last km. There were no interactions in any of the variables for TOD x distance (P>0.05).
EFFECTS OF MENSTRUAL CYCLE IN MUSCLE ACTIVITY: BURST RATE AND RELATIVE TIME SPENT SHIVERING

Maneshi, A., Imbeault, M., Haman, F.
University of Ottawa, Canada

Cold-induced shivering is characterized by two distinct muscle contraction patterns: continuous low-intensity shivering [at ~1 to 5% of maximal voluntary contraction (MVVC)] and bursts of high-intensity shivering [at 10 to 35% MVVC] (Meigal, 2002, Haman et al., 2004). Even though the physiological importance of this dual pattern remains unclear, it is closely linked to observed differences in fuel selection amongst individuals. In this context, Haman et al. (2004) showed that carbohydrate (CHO) oxidation rate is directly related to burst shivering rate which increases the proportional recruitment of glycolytic type II fibers. Because most of these studies have been carried out in men, little is still known on the effects of hormonal fluctuations during the menstrual cycle on the dual shivering pattern and energy metabolism in women. In the only known shivering study focusing on changes in EMG shivering activity in cold women, Hessermeir (1985) have shown that the onset of shivering is delayed in the luteal phase (LP) when compared to the follicular phase (FP) due to an elevated core temperature. However, effects of the menstrual cycle on changes in muscle shivering activity remain to be established. Therefore, the purpose of this study was to quantify differences in muscle recruitment pattern and fuel selection in two phases of the menstrual cycle. Muscle recruitment in eight muscles and whole body fuel selection were monitored in women exposed to 120 min of cold exposure (57°C liquid-perfusion suit) divided into FP and LP. We hypothesized that muscle activity will be reduced in LP due to higher initial core temperature and that this reduction in overall shivering intensity will reduce burst shivering rate during low intensity shivering (~20% of MV2max). Results show that there is no difference in shivering intensity (MV2 and EMG activity) and burst shivering rate between LP and FP during steady state shivering (in last 15 min). However, significant differences in the duration of an average burst are found resulting in a significantly longer time spent burst shivering in LP than FP (18.4±0.9 % vs 16.3±0.4 % total recording time; p = 0.02). Even though exact reasons for this difference remain unknown, this increase in average burst shivering time is associated with a higher reliance on CHO in LP compared to FP. We conclude that burst shivering activity different in LP than FP and that this change is associated with changes in fuel selection during low-intensity shivering.

NEW ELECTROMYOGRAPHIC PARAMETERS FOR SKELETAL MUSCLE PERFORMANCE EVALUATION

Vasilescu, M., Ionescu, A., Rusu, L., Apostol, A.
University of Craiova, UMF Carol Davila, Romania

Authors propose a modern and complex exploration method of muscle fatigue by computerized acquisition and analysis of surface electromyography (SEMG) and mechanomyogram (MMG) during voluntary isometric maximal contraction of flexor hand fingers. The evolution of 12 classical (previously described in literature) SEMG and mechanographic parameters and new parameters and indices were analyzed with dedicated software. This modern exploration method allows precise, quantified, analysis of muscle fatigue phenomenon and, by linear regressions and statistical analysis, permits to differentiate various groups of subjects. The original part of this method consists in the calculation of the Synchronization Ratio (SRa) for the EMGSS, the determination of the percentage of the Synchronization (Syr) between the two EMGSS on the same muscle, the proposal of the Excitation-Contraction Coupling Efficiency Index (ECCEI) who differentiate very well the categories of subjects, the study in time of the parameters through out the I order regression lines, the establishment of the relation between the mechanical and electrical activity of the muscle. With the help of this modern technique, we have studied different athletes categories obtaining very interesting results for the performance and muscle fatigue evaluation.

THE PHYSICAL TRAINING AT THE ANAEROBIC THRESHOLD IS ABLE TO DECREASE THE OBESITY IN RATS

Neiva, C., Campos, P.
(1) FC-UNESP, (2) UNIFRAN, (3) FESP UEMG, (4) UNAERP, Brazil

The obesity and their other associated comorbidities are the main problem of public health on the nowadays. The use of physical training on prevention and treatment of this problem can be many times the best and cheapest way to solve it. Although, many authors have been writing about the incapacity of moderate aerobic training for weight control. The high intensity aerobic training (maximal stead state lactate - MSSL) at the intensity related around of the anaerobic threshold (lactate threshold - LT) were observed on thirty young Wistars rats (3 months aged). All animals were divided in 3 groups with 10 rats each (moderate aerobic trained MAC- n = 10; LT n = 10; and control C group n = 10). All groups were submitted to an hiperlipidic diet for 2 months aiming at developing the obesity, before starting of the training. The LT and MAC groups were submitted to an incremental exercise protocol before 5 weeks of training to determine the LT intensity (the blood lactate breakpoint). The hiperlipidic diet was offerad ad libitum for also all the 5 weeks protocol. The training program was continuously performed from 20 to 25 min. swimming per-day, 4 days a week, loaded with 3% body mass (BM) for the AT group, 1 to 1.5% BM for de MAC group. The C group was not submitted to exercise training. It was observed a significant decrease of weight on the LT group after the 5 weeks (pre 449±35 and post 412±25 g) after 5 weeks of moderate aerobic training. On the other hand, the C group showed an increase of weight (pre 449±35 and post 512±38 g) after the 5 weeks. The lost of weight only by the LT group showed that the moderated aerobic intensity was not efficient for this purpose, but could stop the gain of weight. Still, it was concluded that 5 weeks of swimming at MASSF (LT intensity) was strongly efficient to weight decrease in rats submitted to obesogenic diet.

In summary, the parallelism of temperature and time-trial finishing times agrees with previously published research with a delay in acrophase of 2.02 h in performance. The finding of a circadian rhythm in 10 km time-trial performance (duration 30313s) agrees with that of a shorter di...
**MUSCLE OXYGENATION DURING REPEATED SPRINT RUNNING: ACTIVE VS. PASSIVE RECOVERY**

Buchheit, M., Cornicie, C., Abbiss, C., Ahmadi, S., Nosaka, K., Laursen, P.

Faculty of Sport Sciences, University of Picardie, Jules Verne, 80025, Amiens, France

Active recovery has recently been shown to impair repeated sprint ability (RSA) during cycling. However the effect of active recovery on muscle oxygenation and short repeated run-based sprint performance is not known. Purpose. To investigate the effect of muscle oxygenation on run-based RSA using active (AR) versus passive recovery (PR). Methods: Ten moderately trained male subjects (27.0 ± 3.7y) performed a maximal isometric 10-s contraction (MVC) and 6 repeated all-out 4-s sprints interspersed with 21-s of either AR (2.0m.s-1) or PR on a non-motorized treadmill. Recording was breath-by-breath for oxygen uptake (O2), beat-to-beat for heart rate (H1R), and 6Hz for near-infrared spectroscopy (NIRS) deoxyhemoglobin (HHb). Capillary blood lactate (Lab) was also measured after each exercise.

Mean running speed (AvSpmean) and percentage speed decrement (%Dec) were computed for each recovery condition. Muscular reoxygenation capacity was determined after MVC (T1/2 reoxy). Results: AvSpmean was lower (3.79 ± 0.09 vs. 4.09 ± 0.10m.s-1, P<0.001) and %Dec higher (7.15 ± 1.16 vs. 3.20 ± 0.42%, P<0.001) for AR versus PR. All cardiorespiratory and NIRS values were higher during AR compared to PR: mean O2 (3.64 ± 0.14 vs. 2.91 ± 0.15L, P<0.001). HR (159.9 ± 2.6 vs. 154.7 ± 2.6bpm, P<0.01), HHb (94.4 ± 5.3 vs. 83.4 ± 1.5% of HHb during the first sprint, P<0.05) and Lab (13.5 ± 0.8 vs. 12.7 ± 0.7mmol.l-1, P=0.03). For AR and PR, AvSpmean was negatively correlated with T1/2 reoxy (P<0.01). Conclusion: As with longer duration high-intensity efforts, muscle (reo)xygenation is likely to be modulated by recovery intensity and appears to be an essential determinant of short run-based repeated sprint ability.

**CEREBROVASCULAR RESPONSE DURING BREATH HOLDING, HYPERVENTILATION AND GRADED EXERCISE IN VARSITY HOCKEY PLAYERS SUFFERING MILD TRAUMATIC BRAIN INJURY: A PRELIMINARY TRANSCRANIAL DOPPLER STUDY**

Len, T., Neary, J., Asmundson, G., Goodman, D., Bjornson, B., Duff, W., LaHue, D., Yagesh, B.

University of Regina, Canada

It is theorized that a neuroautonomic cardiovascula r dysfunction (NCD) occurs with mild traumatic brain injury (mTBI) (1). NCD is the disconnection of the autonomic and cardiovascular systems, which together control cerebral autoregulation. We examined the effect of repeated bouts of hypercapnia, hypocapnia and continuous graded exercise on cerebral autoregulation between participants with a previous (<6 months) or current mTBI and a healthy control group using transcranial Doppler ultrasonography. Studies have shown that middle cerebral artery diameter does not change under physiological stress (2), thus mean cerebral blood velocity (vMCA) was used as an indicator of cerebral blood flow.

Thirteen male hockey players participated in the study and were divided into two groups [10 healthy controls, 3 mTBI]. Across both groups, age was 22.2 ± 1.2 years, height was 183.0 ± 6.3 cm and weight was 85.6 ± 7.9 kg. To evaluate the effect of hypercapnia, hypocapnia and graded exercise on cerebral autoregulation, the subjects performed five consecutive breath-holds of 20 sec (BH) with 40 sec of recovery, five consecutive bouts of hyperventilation (HV) for 20 sec followed by 40 sec of recovery and a 20 minute graded exercise protocol (80W, 140W, 200W, recovery). vMCA was monitored using a 1.6 MHz transcranial Doppler probe sampling at 1 Hz.

vMCA differences at rest and in response to BH and HV between groups were not significant. Percentage change of vMCA was significantly different at the end of the fourth BH and at the beginning of the second through fifth HV (p=0.002 0.044). vMCA values during the graded exercise protocol were not significantly different, however vMCA values at the third minute of recovery from exercise were significantly different between groups (61.1 ± 10.9 cm/s vs 49.3 ± 2.3 cm/s, p=0.016). Percentage change of vMCA at the end of exercise showed a significant difference between groups (29.78% ± 18.31% vs -2.33% ± 14.18%, p=0.047). The observed trend, although not significant, during graded exercise showed an increase in vMCA with increasing intensity in healthy participants while injured participants illustrated a decrease at mild to moderate intensities.

These findings suggest that NCD may be present in mTBI when analyzing using vMCA values alone as an index of cerebral autoregulation. A visual trend of response difference between groups was observed, although not significant. Further research examining a larger sample size is necessary to understand the impact of NCD on cerebral blood flow in mTBI patients.

**PHYSIOLOGICAL STRESS IN SKI MOUNTAINEERING**

Voutselas, V., Nikolaidis, G., Jamourtas, Z., Soulas, D., Papanikolaou, Z., Kritikos, A., Stavrou, V.

University of Thessaly, Greece

Introduction

Ski mountaineering is a relatively new competition event that combines elements from the alpine ski (downhill skiing), cross-country ski (uphill skiing) and mountaineering techniques. Athletes cover a long distance, in cold weather and high altitude while carrying their equipment (approximately 12kg). No data have been published concerning the physiological stress occurred in ski mountaineering. The aim of the present study was to examine the physiological stress of a ski mountaineering race.

Methods

Eleven highly trained (nine male and two female) ski mountaineering athletes (table 1) participated in the study. Body Mass, hematocrit (Htc), hemoglobin (Hb), GPT, GOT, Uric Acid (UA), Creatine Kinase (CK), Potassium and Testosterone were measured before, immediately after and 1h after the Greek Ski Mountaineering Championship Race (about 110min mean finish time). One way ANOVA was used to examine the differences between the three measurements. The value of less than 0.05 was considered to be statistically significant for all tests.

INFLUENCE OF CARBOHYDRATE SUPPLEMENTATION DURING TRAINING ON THE DEVELOPMENT OF SPRINT AND ENDURANCE PERFORMANCE

Maassen, N., Kummer, O., Shoushakov, V., Maassen, M.
Medical School Hannover, Germany

Carbohydrate supplementation during training is often used to maintain coordination and performance. This might be detrimental for the development of endurance capacity (EC) as Hansen et al. (2005) have shown that the improvement in endurance capacity correlates with the depletion of the glycogen stores during training. On the other hand carbohydrate supplementation increases the activity of anabolic hormones (Nieman et al. 2003). This might increase sprint performance. The aim was to investigate the effects of carbohydrate supplementation during training on the development of endurance performance and on sprint performance. As a training regimen we choose intermittent training because we recently have shown (Frische et al. 2005) that the improvement in EC is larger compared to continuous training.

20 male athletes were assigned to two groups (CON and CH). 4 subjects in each group were endurance athletes. Mean maximal power (WLmax) reached in incremental tests was 4.1 watt/kg (CON) and 4.2 watt/kg (CH). Tests and trainings were performed on a cycle ergometer (Excalibur sport, Lode).

Training: 10 min warming up at 50 % of WLmax, followed by 55 bouts with WLmax minus 10 Watt for 30sec and 10 watt for 30 sec and a cooling down of 10 min at 50 %. Before training food intake was not allowed for at least 3 hours. Tap water intake before and during training was 26 ml/kg body weight. In CH Maltodextrine was added to reach a 9.1 % solution.

EC was tested at 80 WLmax of the initial incremental test. Sprint performance and the ability to perform repeated sprints was tested in 2 Wingate-tests separated by a 60 s rest. The study was completed by an incremental test. During all tests spirometric data (Metalyzer IIIb), heart rate and lactate were measured.

In CH glucose concentration was higher by about 1.5 mmol/l during the training (p<0.02) compared CON. RER was not affected. In both groups the endurance time at constant load increased by about 60%. Lactate, RER, heart rate and ventilation at the end were not different between the groups and between pre and post tests. The increase in VO2max was about 2% in both groups (n.s.). Maximum heart rate was not altered. However maximum [Lactate] and Ventilation increased significantly in both groups with no differences between the groups.

In CON and CH mean and maximum power (+6 and +12%, 2 and 5% respectively) in the Wingate-tests increased significantly, however the increase was significantly smaller in CH (p<0.05). No significant difference between pre and post or between the groups could be seen in the kinetics and the absolute lactate concentration during the tests and during the following 30 min rest.

The development of EC was not influenced by the carbohydrate ingestion, however the improvement in sprint performance was reduced.

The mechanism remains to be investigated.

PHYSICAL ACTIVITY COMPLIANCE IN SEVERELY OBESE WOMEN

Departamento de Educação Física, Desporto e Lazer, Universidade Lusífona de Humanidades e Tecnologias, Lisboa; Faculdade de Medicina de Lisboa; Hospital de Santa Maria, Lisboa, Portugal

Background: Physical activity (PA) public health recommendations for adults indicate that a minimum of 30 min/d of moderate-intensity PA on 5 d/wk should be achieved (ACSM & AHA, 2007). When this level of activity is accomplished but subjects remain overweight, an increase in PA is advised, attaining 60 min/d of moderate-intensity PA (IOM, 2002). The aim of the present study was to analyze time spent in sedentary activities and different intensity PA levels in severely obese women, and to compare it with actual PA recommendations.

Methods: 9 severely obese women were studied at week 1 of a PA promotion program specially designed for morbibly obese patients (M=39.0y SD=7.2y, M=117.8kg SD=13.6kg, M=1.6m SD=0.1m, M=45.6kg/m2 SD=4.3kg/m2). Daily PA was monitored with accelerometry (Actigraph GT1M), and PA intensity categories were set accordingly to Freedson et al. (1998) cut-points, and expressed in minutes spent in sedentary activities, low-, moderate-, and vigorous-intensity PA. Descriptive analysis was performed, and Wilcoxon’s Signed Ranks Test was used to compare working days and weekend days. Spearman’s test and partial correlations were applied.

Results: Accelerometry revealed a mean result of 170.7 min/d (SD=46.8 min/d) spent in sedentary activities, while low-intensity PA accounted for 304.5 min/d (SD=83.5 min/d), moderate-intensity PA was performed for 511.1 min/d (SD=29.9 min/d), and vigorous-intensity PA was inexist. Time spent in moderate-intensity PA was significantly lower (P<0.05) on weekend days when compared with working
days (63.1 min/d versus 28.3 min/d, respectively). Positive correlations were found between age and daily minutes spent in low-intensity PA (r=0.69, P<0.049). Similar results were observed for BMI (r=0.767, P=0.016), either on weekend days (r=0.817, P<0.007) and marginally on working days (r=0.600, P=0.088). After controlling for age, the relations between BMI and low-intensity PA became marginally significant (r=0.696, P=0.054), and remained significant on weekend days (r=0.730, P=0.040). 77.7% of the subjects met 2007 recommendations, but from these only 33.3% achieved 2002 guidelines for PA. 22.2% of the participants did not accomplish the advised daily PA time.

Conclusion. Although most of severely obese women attained the minimal PA public health recommendations (ACSM & AHA, 2007), this does not seem to be enough in order to reduce or control their weight status. These results may have been influenced by the fact that participants were already on week 1 of a PA promotion program when the data was collected, which might have produced an increase in PA. The decrease of sedentary activities and simultaneously the increase of PA, especially of moderate-intensity, towards 2002 guidelines is advised to impact weight loss reduction and maintenance, contributing to an healthier weight profile and lifestyle.

ARTERIAL BLOOD PRESSURE RESPONSES IN MAXIMAL OXYGEN UPTAKE IN MIDDLE-AGED LONG DISTANCE RUNNERS

Salgado, J., Rocha, J., Biscuola, G., Benjamin, L., Antunes, M., Vilas Boas, D., Silva, J., Chacon-Mikahil, M.
Universidade Estadual de Campinas -Unicamp, Brazil

INTRODUCTION

The run practice has shown an exponential rise in the last decades (1). However, it has been related sudden events with life risk associated to this sport practice. In these events, the whole pathophysiology is unknown. The blood pressure (BP) is a strong prediction of sudden events; so this study serve to verify how the BP behaves in middle-aged long distance runners at rest and a maximal oxygen uptake.

METHODOLOGY

20 long distance runners, male, normotensive and without pathologies, with age 47.45 ± 5.46 years, body mass 67.37 ± 10.55 kg, stature 1.70 ± 0.08 m with approximately 14,10 ± 8.49 years of continuous and uninterrupted training on average 56.14 ± 19.66 km/m day. The maximal oxygen uptake was applied (CPX-Ultima, Medgraphics, EUA), with electrocardiogram monitoring in twelve derivations (Wincardio digital sistem, Micromed, Brasil) in incremental protocol with initial speed of 6 Km/h and increments of 0.5Km/h each 30 seconds. The BP was measured by a column of mercury sphygmomanometer at the periods before, during the effort until exhaustion, each three minutes and at the post effort in the minutes 1, 2, 4, 6. The descriptive statistic analysis was through the SPSS 13.0 software.

This study was approved by the Ethic Committee in Research of the Faculty of Medicine Science from Unicamp.

RESULTS

The average speed peak reached was 16.4 ± 1.46 km/h and the VO2 peak 52.16 ± 6.05mlkg-1min-1. At rest the BP systolic in mmHg (SBP) on average measured standing was 128.4 ± 13.76, the diastolic BP (DBP) was 88.8 ± 9.76, at the effort peak the SBP was 173.8 ± 28.5 and the DBP 81.3 ± 12.45. The delta range between the effort peak and rest to SBP was 45.40 ± 14.74 and to DBP ·7.5 ± 2.69.

DISCUSSION

The BP behavior in exercise reflects homodynamic changes on the heart and vessels (2). In this study in long distance runners the SBP and DBP in the rest situation show normal values and similar to Azvedo et al. We can still observe that at the effort peak the SBP show a variation of 35.36%, and these values were expected for trained person, although well conditioned beings could reach superior values (3). Other studies, evaluating the SBP behavior during the effort, are necessary to elucidate these phenomenons, with the goal to evaluate the risks and provide a safer running practice.

THE RELATIONSHIP BETWEEN PHYSICAL EXERCISE AND SOCIAL STRESS IN METABOLIC AND MORPHOMETRIC PROFILES OF FEMALE WISTAR RATS FEED WITH NORMAL AND CALORIC FOOD

Benite-Ribeiro, S., Santos, J., Mazzola, P., Duarte, J.

Research Centre in Physical Activity, Health and Leisure, Faculty of Sports – University of Porto, Portugal, Universidade Federal de Goiás-Jataí GO - Brasil

Chronic Stress can elicit a stress response characterized by the increased levels of seric glucocorticoid (GC). GC may induce enhanced caloric foods (CF) intake, which may promote an increase of body weight, abdominal fat deposition (AF), and plasmatic insulin levels. On the other hand, CF and AF may reduce the harmful effects of stress response. It is reported that regular physical exercise (PE) can reduce the stress response and, consequently, may decrease CF intake and AF. The aim of this study was to analyse the relationships among the response of stress, the food intake and the PE in females Wistar rats. The animals (n=48) were randomly assigned in 8 groups (CCFPE, CCFS, CNFPE, CNFS, STCFPE, STCFS, STNFPE, STNFS) based on the following experimental conditions for 40 days: a) paired rats without the response of stress, the food intake and the PE in females Wistar rats. The animals (n=48) were randomly assigned in 8 groups.

Conclusion: Although most of severely obese women attained the minimal PA public health recommendations (ACSM & AHA, 2007), this does not seem to be enough in order to reduce or control their weight status. These results may have been influenced by the fact that participants were already on week 1 of a PA promotion program when the data was collected, which might have produced an increase in PA. The decrease of sedentary activities and simultaneously the increase of PA, especially of moderate-intensity, towards 2002 guidelines is advised to impact weight loss reduction and maintenance, contributing to an healthier weight profile and lifestyle.
METABOLIC AND MECHANICAL PARAMETERS DURING A SIMULATED JUDO FIGHT

Carballeira, E., Iglesias, E., Dopico, X.
University of A Coruña, Spain

To date, the analysis of physiological and strength parameters required in fight sports has become important (Carballeira and Iglesias 2007; Kraemer et al. 2001). The purpose of this study was to examine metabolic and mechanical changes induced by a judo fight. It was hypothesised an association between selected parameters.

Eight judo fighters of national level participated in this study. Heart rate (HR) was recorded during each judo fight. Before, and immediately after each bout, the following parameters were measured: blood lactate concentration (LA), countermovement jump (CMJ), isometric handgrip strength (IH), isometric bench press strength at 90° (BP90), prone rawing strength at 90° (PR90), and squatl strength at 160° (S160). Isometric strength peak (ISP), isometric strength average (ISA), rate of force development (RFD), time to reach ISP (TISP) and quantity of force developed (QFD) were measured in the last three isometric exercise.

HR resulted in a mean of 92.65 ± 3.26 % of maximum HR. Pre-Post- mean values of measured parameters were: [LA], 5.39 ± 1.91 and of force developed (QFD) were measured in the last three isometric exercise.

Isometric strength peak (ISP), isometric strength average (ISA), rate of force development (RFD), time to reach ISP (TISP) and quantity of force developed (QFD) were measured in the last three isometric exercise.

6.20 % and ISA= 91.60 ± 9.47 %). %HR correlated significantly with the net loss in strength in PR90 after the match (r = -0.786; p = 0.021). [LA] after fight correlated significantly with the net loss in the time required to reach ISP (TISP) in S160 (r = 0.780; p = 0.022). Average value of isometric strength relative to body weight (ISAR) in S160 correlated with the relative LA increment after match (r = 0.706; p = 0.050). In summary, the acute effect of various simulated judo match resulted in an isometric strength loss of a greater extent in the upper limb compared with lower limb. The absence of relationships between metabolic and mechanical parameters could means that specific judo fatigue is related to local fatigue mechanisms.

THE IMPACT OF A NOVEL ICE SKATING BLADE ON PHYSIOLOGICAL DETERMINANTS OF ICE HOCKEY PLAYERS

Whittom, F., Desmeules-Roy, O., Bouchard, F., Comtois, A.
Université du Québec à Montréal (UQAM), Canada

Goal: To evaluate the skating performance of ice hockey players under conditions closely mimicking game situations while skating with either a heated or non-heated (control) blade. Methods: Two different levels of skating proficiency (1. Long distance [162 m] sustained explosive speed (short and intermediate duration glide sequence) at maximal skating velocity, and 2. Long term sustained speed (long duration glide sequence) at different submaximal skating velocities) were evaluated by measuring various physiological parameters using the latest state of the art technology (VO2 with a K4b2, Cosmed, Accelerometers on skates and shin bone, and lactate measurements). Results: Skating speed was marginally improved while attempting to skate at maximal speed along the outer perimeter of the rink (perimeter ~162 m). In contrast, all physiological parameters measured at submaximal speed showed a marked improvement when the players skated with the hot blade when compared to the cold blade. Physiological data was recorded on all players except for one who was unable to repeat the measurement. For this reason he was left out of the data analysis. In addition, some of the dependant variables for data interpretation were not included in the analysis due to technical difficulties. In conclusion, the results from the present study clearly show that skating with a heated blade has a positive effect on a large array of physiological parameters involved in skating, particularly those associated with fatigue development. This is an important aspect, since the literature reports that fatigue development during ice hockey may lead to several types of serious injuries (concussions, knee ligament strain, ankle sprains, etc.).

COMPARISON OF COMBAT SPORTS WITH OTHER KIND OF SPORTS THROUGH ECHOCARDIOGRAPHIC PARAMETERS

Varga-Pinter, B., Knelfel, Z., Petrekanits, M., Pavlik, G.
Semmelweis University, Faculty of Physical Education and Sport Sciences, Hungary

Martial arts are more and more popular among the population, not only as competitive sport, but also as leisure-time activity. In the literature we can find only two articles about echocardiographic studies of combat sportmen. The first is by Date et al. (2003) who examined judo players, having compared them with marathon runners and healthy controls. They found significantly higher left ventricular mass and left ventricular wall thickness in sportmen than in controls. Vujin et al. (2006) also found increased thickness of the septum and posterior wall, and statistically significant thickness in judo players than in football players. On the other hand, football players had higher left ventricular end-diastolic volume index and ejection fraction. GOALSETTING: Our goal was to check the cardiovascular adaptation in combat sportmen, 196 endurance, 385 ball game, 73 power, 20 artistic, 59 speed-type, 79 leisure-time sportmen and 75 control (total number. 918 males), between age 17-35 were compared with Tukey Honest Significance Difference probe for unequal groups. RESULTS: The cardiac parameters of competitors of dynamic power sports are very similar to endurance and ball game players, but there is a big difference between the branches of power sports, as body builders and weight lifters have higher systolic blood pressure (p<0,001) and their hypertrophy is stronger than the representatives of martial arts. We also found significant differences with the control groups in pulse (p<0,001) and left ventricular muscle mass (p<0,001). SUMMARY: As in martial art practitioner’s main cardiac measurements looks like in other kinds of sports, and show differences compared to controls, we can say that combat sports are good enough for getting fit and tough.
Previous research has shown that the VO2max of boys who train for either speed or endurance sports are comparable. Mero et al. (1991) have shown a positive correlation between power, as measured in the Wingate test, and lactate production in minutes engaged in speed sports, as opposed to endurance events. Other research has indicated that minors show the same relative improvement as adult in comparable sports, when compared within the same competitive sport (Vitasso et al. 1991). The aim of this research was to compare the physiological parameters in anaerobic endurance of hockey players 16 years of age (U16) to those 18 years of age (U18). The participants on the project were training at the U16 level (n=26) or at U18 (n=21) with 7 and 9 years of playing experience, respectively. The U18 group was tested one week before the participation in World Championship and U16 group in similar training period. The players performed 5 minute warm-up exercises on cycle ergometer (Monark 884E, Sweden) at an intensity of 25 W. After a 3 minutes rest they performed a Wingate test. The resistance depended on body mass according to the equation: \( I_g = 80[g/kg-t] x \) body mass (kg) for U16 group and according to: \( 90[g/kg-t] x \) body mass (kg) for U18 group. Blood lactate level was estimated form blood draws from the finger at the 4th and 8th minute after testing. During the test the value of maximal power (Pmax) was calculated in intervals of 3s. Total work (WTOT) and the time of maximal power achievement (Tuz) were also recorded. Pmax obtained in Wingate test for U18 group was 12.53±0.48 W/kg and was statistically greater than the values obtained from U16 (p<0.001). WTOT and Wtot obtained in Wingate test for U18 group were significantly higher than U16 (p=0.001). Lactate concentration was significantly greater in U18 group at the 4th and 8th minutes after the end of the test. The results of the research show that mechanical parameters describing an anaerobic endurance of ice hockey players are improving, but the ability of metabolic acidosis liquidation raised by anaerobic effort do not change. The results of the research show that similarly as non-training children ice hockey players, in ageing process, show an improvement in anaerobic endurance, but the ability of metabolic acidosis liquidation caused by anaerobic effort does not change. The research was to determine the criterion for assessment of starting acceleration phase. After the warm-up and 3-min break, the subject began to work at full load and the power was recorded every 3 seconds. The mean value of speed for each subject was calculated and then the results were subjected to mathematical analysis. Hockey players were divided into groups according to the type of a task they undertake during the game. The dynamics of power during 30-s work performed at maximal intensity during consecutive stages of a training cycle (in the logarithmic co-ordinate system) was divided into 4 linear segments with each segment is defined by: \( I_gW_{log(Pmax-p/t)} \), in which: \( I_g = \) logarithmic value of maximal power at which the change of metabolism character occurs; \( W_{max} = \) logarithmic value of maximal power in specified metabolic sphere, p-index reflecting the tangent of an angle of the segment gradient in specified metabolic sphere. Segments of different gradient verifies the domination of specified sphere of energetic processes in respective time sections. The depletion of metabolic volume of energy source accompanies the elongation of work time and influences the rate of fatigue accumulation, thus providing information concerning the level of work ability in the specified range of intensity. Analysis of the power - time ergonomic correlation established on the basis of parameters recorded in 30-s exercise performed on cycle ergometer allowed to determine specific criteria of assessment of anaerobic capacity levelreaktualy old hockey players. In describing the phase of starting acceleration, in which reaching of maximal power occurs after work resulting from overcoming of inertia external resistance. This is the only phase of a work, during which a gradual increment of power is observed. This phase consists of the segment of dynamic power increase reflecting the real overcoming of inertia external load and the segment representing the achievement of maximal power. The rate of power increment from the 0 to maximal value constitutes the criterion for assessment of starting acceleration phase.

CRITERIA OF ERGOMETRIC DEPENDENCE POWER VS. TIME IN THE ASSESSMENT OF ANAEROBIC POWER AND CAPACITY IN 18-YEAR OLD HOCKEY PLAYERS

Gabrys, T., Fiołkowski, P., Szmłat-Gabrys, U.

University of Physical Education in Warsaw, Poland

Ergometric analysis is based on the determination of characteristic features for the correlation between power value and time this can be maintained. The objective of the present study was to evaluate the assessment criteria of anaerobic capacity in U18 hockey players in 8-month training period. The criteria were based on analysis of power - time correlation during a 30-second work performed at maximal intensity on cycle ergometer. The study group was 26 ice hockey players of Polish National Team (18 years or younger). Anaerobic capacity level was assessed on the 30-s cycle ergometer test was carried out in September (after the training period), in December (after the league play-offs) and in March (prior to World Championship). The protocol for the test was: the load was selected according to index of 10% of body weight and the 5-min warm-up performed at 30% of selected load and at frequency of 60 revolutions per 1 minute before the main exercise. After the warm-up and 3-min break, the subject began to work at full load and the power was recorded every 3 seconds. The mean value of speed for each subject was calculated and then the results were subjected to mathematical analysis. Hockey players were divided into groups according to the type of a task they undertake during the game. The dynamics of power during 30-s work performed at maximal intensity during consecutive stages of a training cycle (in the logarithmic co-ordinate system) was divided into 4 linear segments with each segment is defined by: \( I_gW_{log(Pmax-p/t)} \), in which: \( I_g = \) logarithmic value of maximal power at which the change of metabolism character occurs; \( W_{max} = \) logarithmic value of maximal power in specified metabolic sphere, p-index reflecting the tangent of an angle of the segment gradient in specified metabolic sphere. Segments of different gradient verifies the domination of specified sphere of energetic processes in respective time sections. The depletion of metabolic volume of energy source accompanies the elongation of work time and influences the rate of fatigue accumulation, thus providing information concerning the level of work ability in the specified range of intensity. Analysis of the power - time ergonomic correlation established on the basis of parameters recorded in 30-s exercise performed on cycle ergometer allowed to determine specific criteria of assessment of anaerobic capacity level in 18-year old hockey players. In describing the phase of starting acceleration, in which reaching of maximal power occurs after work resulting from overcoming of inertia external resistance. This is the only phase of a work, during which a gradual increment of power is observed. This phase consists of the segment of dynamic power increase reflecting the real overcoming of inertia external load and the segment representing the achievement of maximal power. The rate of power increment from the 0 to maximal value constitutes the criterion for assessment of starting acceleration phase.

ENERGY EXPENDITURE AT THE GAIT TRANSITION SPEED IN MEN AND WOMEN

Babic, V., Sentija, D., Rakovac, M.

University of Zagreb, Croatia

Background

When increasing or decreasing the speed of locomotion, spontaneous transition occurs (walk-to-run, or run-to-walk) at approximately the same speed for both genders (2 m/s), and this intensity is commonly referred to as the preferred transition speed (PTS) (Hreljac, 1993). There are no data in the literature regarding the relative energy expenditure at the PTS, i.e. expressed in relation to the aerobic capacity, and eventual gender differences.

Purpose

The aim of this study was to relate the energy expenditure for walking and for running at the PTS to the aerobic capacity, and to determine gender differences.

Methods

Previous research has shown that the VO2max and the segment representing the achievement of maximal power. The rate of power increment from the 0 to maximal value constitutes the criterion for assessment of starting acceleration phase.
Twenty-two male (21.4 +/- 2.4 y, 182 +/- 7 cm), and eleven female (19.4 +/- 0.5 y, 169 +/- 6 cm) physical education students performed two incremental treadmill tests with 4-min stages, walking in one and running in the other, in order to determine steady-state VO2 at speeds below and above PTS (5-9 km/h). A treadmill test to volitional exhaustion was performed for VO2max determination, and a fourth treadmill test was also performed at all subjects, in order to determine their individual PTS.

Results
The preferred gait transition speed did not differ between male (7.13 +/- 0.4 km/h) and female (7.21 +/- 0.3 km/h) subjects, as did not the corresponding energy expenditures for walking (24.3 +/- 3.6 and 26.6 +/- 3.7 ml O2/min/kg, p=0.05), and for running (29.5 +/- 2.6 and 31.3 +/- 2.9 ml O2/min/kg, p=0.05). Men had a significantly higher VO2max than women (50.8 +/- 4.7 vs. 44.9 +/- 4.0 ml O2/min/kg, p<0.01), while the oxygen uptake at the PTS expressed as a percentage of VO2max, was significantly higher for women, for walking (59 +/- 6% vs. 48 +/- 6%, p=0.01) as well as for running (70 +/- 6% vs. 58 +/- 6%, p=0.01).

Discussion and conclusions
The average values for the PTS are in close agreement with previous studies. There is no experimental evidence that can explain why women change gait at the same speed as men, no difference between the PTS of male and female subjects probably reflects the pressure of natural selection, that has favored the development of the same average value for the gait transition speed in spite of significant gender differences in stature, mass and aerobic capacity. Anthropometric, morphological and biomechanical variables will be examined in follow-up studies to elucidate how women make better use of the limited energy sources, having a wider relative range of energy expenditure for walking.

RETROSPECTIVE ANALYSIS OF METABOLIC ACTIVITY BY NITROGEN ISOTOPE RATIO ANALYSIS OF HAIR
Huelsemann, F., Flunker, U., Köhler, K., Braun, H., Schänzer, W., Mester, J.
German Research Centre of Elite Sports, Cologne, Germany

Natural abundance stable isotope ratios of organic nitrogen can be used for the determination of metabolic states of any animal organism including humans. Isotopic fractionation during amino acid metabolism in the body results in different stable isotope ratios in dietary, excreted and body nitrogen. Thus, changes in the metabolised proportion of dietary or body protein yield in different isotope ratios in different body compartments. Due to its structure and stability hair is an ideal material for a retrospective analysis. Stable isotope ratio analysis of hair can provide information about an athlete’s protein metabolism up the last twelve months. With knowledge of the athlete’s dietary habits potential catabolic or anabolic conditions of the metabolism can be identified, as physical exercise is associated with an increase in protein synthesis and protein breakdown depending on the amount and sort of exercise.

The retrospective analysis of nitrogen isotope ratios of hair of professional and semi-professional athletes of different sports revealed significant changes of the nitrogen isotope ratios in accordance with the volume and intensity of exercise, documented in the athlete’s training journal. In order to estimate the influence of physical activity on the nitrogen isotope ratios of humans, we examined the nitrogen isotope ratios of urinary urea during and after different types of exercise, in competition and in rest. The nitrogen isotope ratios of urinary urea are strongly negative correlated with the body’s energy balance during exercise. This non-invasive and simple method offers interesting perspectives for the examination of an athlete’s protein metabolism without administration of labelled compounds and a reconstruction of an athlete’s energy balance in the past.

THE EFFECT OF 12 WEEKS AEROBIC TRAINING ON PRE-INFLAMMATORY CYTOKINES, VASCULAR ENDOTHELIAL ACTIVATION AND DECREASE OF ATHEROSCLEROSIS
Moghmarnasi, M., Gaeini, A., Sheikholeslami Vatani, D.
University of Sistan and Baluchestan, University of Tehran, University of Kurdistan, Iran

Abstract
Background Increasing evidences show that pre-inflammatory cytokines and cellular adhesion molecules that lead to increase of vascular endothelial activity and known as new inflammatory markers are more sensitive in anticipating cardiovascular diseases. And they have an important role in atherosclerosis pathogenesis. The purpose was to determine the effect of 12 weeks aerobic training on pre-inflammatory cytokines TNF-α, IL-1 and Inter Cellular Adhesion Molecules sICAM-1 the factor of activity and adhesive vascular endothelial of Wistar rats.

Methods and Materials. This experimental study was performed in animals’ lab of faculty of physical education at Tehran University. Hence, 24 Wistar male rats of 3 months were kept in a controlled place and were divided into two different controlled (n=12, weight=211±3.8G) and experimental (n=12, weight=208±7 G) groups. The training program was performed under certain duration and speed for 12 weeks - 3 sessions a week. The cupping was held after 14 fasting hours in different stages and with the same conditions. For biochemical analysis and sICAM-1 amounts evaluation it is used from Elisa trade kit of R&D company and for TNF-α and IL-1 amounts evaluation it is used from Elisa trade kit of Koma company by Elisa Reader set Spectera model. Resulting data were analyzed by dependent and independent T tests.

Results A significant increase was observed in (p=0.045) IL-1, (p=0.047) TNF-α, and (p=0.028) sICAM-1 amounts of controlled group. While a significant decrease was observed in (p=0.002) IL-1, (p=0.016) TNF-α, and (p=0.000) sICAM-1 amounts of experimental group. And a significant difference was observed in comparison between controlled and experimental groups in (p=0.039) IL-1,(p=0.028)TNF-α, and (p=0.000) sICAM-1 amounts.

Conclusions Generally the results of this study showed that regular aerobic training (Vo2max 55-85%) causes a significant decrease in amounts of novel inflammatory markers of cardiovascular diseases sICAM-1, TNF-α, IL-1. This decrease accompanies body common inflammation. On the other hand, this training method can play an effective role in inclining the activity of vascular endothelial and atherosclerosis with the decrease of these markers.
CHANGES IN METABOLISM AND SERUM HORMONE LEVELS INDUCED BY A NORTH POLE EXPEDITION

Kyröläinen, H., Karinen, H., Pullinen, T.
University of Jyväskylä; University of Tampere, Finland

During an arctic skiing expedition, mean energy expenditure (EE) for 48 days has reportedly been as high as 28.1 and 32.4 MJ/day in two individuals (Stroud et al. 1993). These values are quite close to the EE values during the first 50 days out of 95 days of exercise across Antarctica (29.1 and 35.5 MJ/day). In this study the subjects lost more than 25% of their body mass, although their energy intake (EI) was 21.3 MJ/day (Stroud et al. 1997). In addition to energy deficit, sleep deprivation and cold weather affect the physiological functions during such demanding tasks. The purpose of the present study was to investigate the effects of a prolonged skiing expedition in extreme conditions on plasma lipids, serum hormones and hematocrit. A group of seven healthy men completed a 55-day unsupported ski expedition (over 800 km) to the North Pole. The subjects had all their necessary equipment and food with them in sledges. The daily food rations contained energy of about 23 MJ, of which 60-65% consisted of fat. Despite this high energy intake, mean body mass decreased more than 10 kg in each subject during the expedition. Based on heart rate monitor data, their highest mean energy expenditure was 28.1 MJ/day. In addition to the analyses of EI and EE during the expedition, blood samples were drawn before and several times after it. Triglycerides in plasma did not decrease significantly during the expedition. However, HDL cholesterol (1.28±0.24 vs. 1.86±0.39 mmol/l, p=0.004), LDL cholesterol (3.00±0.42 vs. 4.23±1.26 mmol/l, p=0.045) and total cholesterol (4.77±0.45 vs. 6.40±1.36 mmol/l, p=0.030) all increased. In addition, serum testosterone (26.8±4.5 vs. 11.6±3.5 mmol/l, p<0.001), thyroxine (16.1±2.0 vs. 14.0±2.5 pmol/l, p=0.048) and cortisol (648±193 vs. 327±30 mmol/l, p=0.004) levels decreased, while growth hormone increased from 0.16±0.05 to 9.16±7.31 mlU/l (p=0.017). Across the same time period, serum urea level increased (5.30±0.72 vs. 7.26±1.83 mmol/l, p=0.024), while serum protein levels remained unchanged. Hematological analysis revealed that hemoglobin and hematocrit values decreased (147±6 vs. 135±5 g/l, p=0.009, and 0.44±0.02 vs. 0.42±0.02, p=0.057, respectively). A similar trend was also found for the number of red blood cells (4.93±0.33 vs. 4.52±0.30 U/l, p=0.033), while the respective value of neutrophils remained unchanged (3±0.6 vs. 3.8±0.8 U/l, p=0.140). The strenuous physical loading combined with a great energy deficit caused loss of body mass, despite the high fat intake. It was interesting to notice that the huge fat intake did not increase the triglyceride values but only slightly plasma cholesterol values. Some hormonal changes together with increased urea levels reflect tissue catabolism, but, however, unchanged protein levels suggest that the level of whole-body protein synthesis was maintained constant as Stroud et al (1997) have also suggested.

CUTANEOUS TEMPERATURE MODIFICATION AFTER A TRADITIONAL CHIROPRACTIC ADJUSTMENT

Roy, R., Boucher, JP., Comtois, A.
Université du Québec à Montréal, Canada

Background
The hypothesis that there may be evidence that paraspinal cutaneous temperature (CT) asymmetry is indicative for the need for an adjustment, an indication of somatospinal inconsistencies requiring a chiropractic adjustment was documented and can be measured with accuracy with infrared cameras. Digitized Infrared Segmental Thermometry (DIST) has been demonstrated to be valid and stable when measured under adequate conditions. The goal of the current study was to evaluate the effect of a traditional chiropractic treatment on CT recordings.

Methods
Participants. We elected to have 10 subjects per group.
Subjects were randomly divided into two groups (n=10 per group), a treatment group and a sham group. The technique utilized was a traditional lumbar roll, with a pisiform contact on the ipsilateral mamillary of L-5. CT was measured on six consecutive tests with DIST. Patients rested on a chiropractic table for eight minutes. After the initial recording, the chiropractor began the treatment, of the pre-evulated subjects, for an L-5 subluxation. The total recording session lasted 10 minutes.

Results
There were statistically significant differences between Sides (FI, 18 = 13.363, p= 0.002, P= 0.932) and Time (F5, 90 = 3.238, p= 0.01, P= 0.872). There was a significant interaction between Sides* Time (F5, 90 = 2.970, p= 0.016, P= 0.838). The average CT at L-5 for the treatment group was 92.67 ± 6.0°F and for the sham group was 91.37°F ± 1.42 and was not statistically different. Treatment group, the treated side was cooler by 0.46°F immediately after the adjustment (11) and later warmed by 0.49°F at the 10 mark in relation to t-2 and 0.95°F in relation to 11, while the contralateral side cooled down for the entire recording period and at 110, by 0.17°F in relation to t-2. Sham group, both sides remain parallel to each other.

Discussion
The main finding is a significant change in CT for the following independent variables: Sides-Time. The second important finding, we measured a CT warming on the ipsilateral side at the moment of the adjustment for the treatment, for 10, then a cooling followed by a rewarming from t1 until t3, then we observed a second cooling at 15 followed by a rewarming at 110. The first rewarming could be a vasculocutaneous reaction due to tissue compression, from the compression of the tissues but he chiropractor’s contact. The second rewarming could be apoptosis accompanied by an inflammatory process injury response releasing cytokines and other inflammatory mediators.

Conclusion
Contacting the skin with the hand with or without a sustained pressure without a thrust produced an initial warming immediately after the contact.

RELIABILITY OF DIFFERENT MODELS TO ASSESS HEART RATE RECOVERY AFTER SUBMAXIMAL EXERCISE

Romagnoli, M., Gomez-Cabrera, M., Benito-Beorlegui, A., Fernandez-Flores, E., Martinez-Bello, V., Nascimento, A., Sanchez-Gomar, F., Arduini, A.
Faculty of Medicine, University of Valencia, Valencia, Spain

Introduction
Assessment of HR recovery after exercise is used to monitor cardiac nerves adaptation to increased fitness in healthy subjects and cardiac patients and has been proposed as an independent predictor of all-cause mortality. Various models to assess HR recovery after exercise have been proposed, and several methodological differences, such as exercise intensity and recovery duration, have been
found even in studies that use the same model of analysis. Nevertheless, but poor is the knowledge of their reliability after exercises at the bicycle ergometer. 

**Aim:**
To evaluate the reliability, on a short-term test retest base, of different indexes used to assess HR recovery after 2 levels of submaximal exercise on the bicycle ergometer.

**Methods:** 21 healthy subjects performed 2 exercises at 65% HRmax and 2 at 80% HRmax. Different HR recovery indexes were calculated. Realibility was assessed by ICC and SEM.

**Results and conclusions:**
Our results show that: 1) assessment of HR recovery after 80% HRmax exercise bring more reliable values than after 65% HRmax exercise; 2) reliability increases as a function of recovery time; 3) calculation of recovered HR area (HRRA, percentage HR by time area recovered) is more reliable than other indexes and is robust against minor variations in workload selection; 4) differences in recovery between 65 and 80% HRmax exercise can be assessed by absolute HR decay (delta-HR) at 2 and 3 min recovery and T30-fast (the smallest time constant over a 30 s period); 5) parasympathetic reactivation can be quantified by T30-fast, that showed higher reliability than other methods.

**RISK OF AVOIDING DETECTION OF RHUEPO ALPHA BY APPLICATION OF INTERMITTENT HYPOXIA**
Faculty of Medicine, University of Valencia, Valencia, Spain

**Background and objective:** Intermittent hypoxia has been used as a method to improve the exercise performance. However recent publications reflect the anti-doping authorities concern on the use of altitude training simulators systems. The use of recombinant human erythropoietin (rHuEPO) to enhance athletic performance is prohibited.

The aim of our study was to determine whether intermittent hypoxic treatments could mask the detection of rHuEPO abuse. Our hypothesis is that after the hypoxic treatments there is an increase in endogenous levels of EPO and/or reticulocytes and haemoglobin that may camouflage the rHuEPO abuse when determined using indirect (OFF-Hr Score) or direct methods (isolectric focusing technique).

**Design and methods:**
Eight male young Wistar rats were treated, three times a week during two weeks, with 500 I.U. of rHuEPO-alpha. After the treatments the animals were randomly divided into two groups: one normoxic and one hypoxic. The normoxic group was maintained 24 hours at 21% O2 during 23 days. The hypoxic group was maintained 12 hours at 21% O2 and 12 hours at 12% O2 (~4500 m) for the same time period.

**Results:**
After the HuEPO treatment, the hypoxic group of animals produced a faster recovery in the reticulocyte count, elevated levels of haemoglobin and haematocrit and a significant increase in the endogenous EPO levels when compared with the normoxic group of animals.

**Interpretation and conclusions:**
Intermittent hypoxic treatments after HuEPO administration can be considered a system to avoid the detection of the HuEPO by indirect and perhaps direct methods in an animal model.

**ASSOCIATION WITH SERUM HORMONES, PHYSICAL FITNESS AND SLEEP DURING A 15-DAY MILITARY FIELD TRAINING**
Tyyskä, J., Kokko, J., Salonen, M., Koivu, M., Kyröläinen, H.
National Defence University, Finland

**Military personnel must have a good physical fitness and performance in order to perform his/her duty in all combat environments during different seasons and under varying weather conditions. The present study was planned to investigate association with physical fitness, amount of sleep and hormonal responses during a 15-day military field training (MFT). The main purpose of the MFT was to train offensive manoeuvre of the Brigade in a countryside area. Nine army officers volunteered for the present study, and they conducted different tasks such as leadership and specialist, which were planned for both a war and crisis demands on a company or battalion level. Their daily working routine mainly consisted actions in headquarters that required on-call-duty at all hours. Physical fitness and body composition were measured just before MFT. Serum testosterone (TES) and cortisol (COR) concentrations and sex-hormone-binding globulin (SHBG) were measured before MFT as well as on the days of 8 and 15 after the beginning of MFT. The officers fulfilled daily sleep diaries and, in addition, all events that differed from their normal daily routine were written down. Heart rate (HR) was recorded approximately for 24 hours on the days of 8, 11 and 15 of MFT. The logistics of food and other needed material was arranged by the MFT organization, which then delivered food three times a day to the officers. According to HR responses, there was neither cardiorespiratory strain nor probably energy deficit due to well organized logistics but, however, some hormonal responses and sleep deprivation were observed during MFT. Nevertheless, TES concentrations did not change statistically significantly during MFT (18.0 ± 3.0 nmol/l vs. 17.9 ± 2.2 nmol/l vs. 18.8 ± 4.5 nmol/l) measured before, 8 days and 15 days after the beginning of MFT, respectively. This was also the case for the respective COR levels (45.4 ± 90 nmol/l vs. 485 ± 122 nmol/l vs. 398 ± 101 nmol/l). TES to COR ratio slightly decreased during the first training week (p=0.05), while it increased during the latter week of MFT (p=0.08). Although the hormonal responses were not significant, their strong association with physical fitness (r= -0.67, p=0.03) was observed. Furthermore, TES/SHBG ratio decreased 28% for those subjects whose VO2max was under 44 ml/kg/min. An average of 6 20 h was slept daily but the sleeping rhythm was disturbed due to military tasks. This diurnal sleeping time was strongly associated with TES/COR ratio (r= 0.78, p=0.01). The results indicate that MFT causes stress reactions, which were very individual, even though there was hardly any physical strain and energy deficit. Therefore, we concluded that observed hormonal responses were mainly due to the sleep deprivation and low physical fitness.

**EFFECT OF EXERCISE MODE ORDER ON EXCESS POST-EXERCISE OXYGEN CONSUMPTION**
Oliveira, N., Oliveira, J.
Faculty of Sport Sciences, University of Porto, Portugal

Several studies have previously examined the effects of different exercise intensities, durations and modes on excess post-exercise oxygen consumption (EPOC) (Borsheim & Bohr, 2003, Laforgia et al., 2006). However, to the best of our knowledge only a single study investigated the effect of the exercise mode order (resisted and aerobic exercise) on EPOC (Drummond et al., 2005). Thus, the main
purpose of the present study was to compare the magnitude and duration of EPOC after two exercise sessions with exercise mode order as the single difference between them: in session 1(S1), resisted exercises were followed by aerobic running whereas in session 2(S2) the order was inversed. Seven male voluntary subjects [mean age 19.6 ± 1.4 years] randomly underwent two sessions with duration of approximately one hour each. Running exercise was performed for 30 minutes in a treadmill at an intensity of 80-85% of heart rate reserve. Resistance exercises encompassed 3 sets of 10 maximal repetitions from five different exercises. In the two sessions oxygen uptake (VO2) was measured by spirometry (Cosmed K4b2, Italy) at rest [15 minutes] and during recovery phase from exercise (60 minutes). Respiratory, cardiovascular and metabolic parameters such as ventilation (Ve), heart rate (HR), carbon dioxide volume (VCO2) and respiratory exchange rate (RER) were registered in both moments. The magnitude and duration of EPOC was determined from the values of VO2 registered both at rest and recovery. During recovery in both sessions, similar responses were observed for VO2, Ve and HR, which showed significantly higher values than those registered at rest (p<0.05). The EPOC magnitude was not significantly different between S1 and S2 (5.17 ± 2.26 L vs. 5.23 ± 2.48 L). In the first 10 minutes of the recovery phase, VCO2 and RER declined to pre-exercise levels. Moreover, the values of VCO2 and RER in S2 were lower than those in S1. In conclusion, the results of the present study suggest that the exercise mode order do not affect the EPOC magnitude and duration. References

MAXIMAL INTERMITTENT EXERCISE PERFORMANCE IN RELATION TO RELOADED MUSCLE OXYGENATION DURING RECOVERY

Ichimura, S., Moriguchi, T.
Tokyo University of Science, Japan

Purpose
The purpose of this study was to investigate the relationship between the reloaded oxygen in working muscle during recovery and the performance of maximal intermittent sprint cycling exercise.

Methods
Seven male athletes [age 20.1±1 yrs; height 180.6±7.6 cm; weight 81.4±8.9 kg] performed the ten intermittent maximal sprint cycling exercise of 6 s with 20 s rest. The cycle ergometer resistance load was 7.5% of body weight. During ten intermittent sprint cycling exercise, mean power during each sprint cycling exercise was recorded. In addition, oxygenated hemoglobin/myoglobin (HbO2/MbO2) of the vastus lateralis were measured using near-infrared continuous-wave spectroscopy. To evaluate the HbO2/MbO2 quantitatively, arterial occlusion was performed until the lowest value of HbO2/MbO2 was observed after ten intermittent sprint cycling exercise. During the recovery immediately after each sprint cycling exercise, the recovery rate of HbO2/MbO2 (ReOxyRate) was measured. The amount of reloaded HbO2/MbO2 (AmtOxy) during recovery after each sprint cycling exercise was measured.

Results & Discussion
Mean power was declined gradually for every sprint trial and the decline rate was -0.182±0.031 Watt/trial. In all subjects, the recovery kinetics of HbO2/MbO2 was biphasic shape at the recovery phase after all sprint trials. In this study, thus, all recovery phases were divided into the first [0-1 s] and second [1-5 s] components. ReOxyRate of first component after first sprint trial was -10.6±14.8 %/s, following 10.6±5.7, 7.4±5.0, 10.4±5.5, 8.6±6.1, 8.1±5.4, 8.8±4.9, 9.1±5.7, 7.8±6.1, and 9.7±6.8 %/s, respectively. ReOxyRate of the second component was increased gradually until six sprint trails and subsequent was stable. There tended to be an inverse correlation between the ReOxyRate of first component after 1st sprint trial and the decline rate of mean power (r=0.628, p<0.01). Kime et al. (EurJAP, 2003) found that higher oxidative capacity muscle exhibited slower re-oxygenation after short-term isometric high intensity exercise. In this study, thus, the decline rate of mean power of the subjects with higher oxidative capacity at the vastus lateralis might be smaller during ten intermittent sprint cycling exercise.

The kinetics of AmtOxy showed the similar with that of ReOxyRate. The total of AmtOxy during all recovery phases after sprint cycling exercise related to the decline rate of mean power (r=0.740, p<0.05). The decline rate of mean power was small when the total of Amt-Oxy was larger. In previous study, the reduction in oxygen availability during high intensity intermittent exercise impaired the ability to maintain a high power output | Balsam et al. Acta Physiol. Scand., 1994]. Thus, the amount of reloaded oxygen into the working muscle during the recovery phase between sprint cycling exercises might affect the decline rate of mean power. In conclusion, the muscle oxidative capacity and the amount of reloaded oxygen into the wors

NON-INVASIVE LACTATE MEASUREMENTS IN HUMAN SKIN USING NEAR-INFRARED SPECTROSCOPY

Blomberg von der Geest, K., Suutari, T., Huttunen, H.
University of Oulu, Finland

OBJECTIVES: The goal of this study was to evaluate the potential of near-infrared spectroscopy (NIRS) for continuous lactate concentration monitoring in human skin. Since NIR light penetrates tissue reasonably well, NIRS has emerged as an important tool for non-invasive human physiological studies.

METHODS: The increase of lactate metabolism of five, healthy subjects was induced by performing Wingate 30-s anaerobic bicycle ergometer sprint. Reference blood lactate levels at certain times after the workout were determined from capillary (finger tip) blood samples with an enzymatic lactate concentration analysis method (Pro Lactate, Akray Inc). NIR spectra were measured in vivo from two locations, forearm and thigh, of each subject before and up to 20 minutes after the bicycle sprint using FT-(Fourier-Transform) NIR spectrophotometer (FTPA2000-263, ABB). Wavelengths from 750-1850nm with a resolution 4cm-1 were scanned 17 times for one spectrum. All together, 25 spectra were collected during the 20 minutes. The fibre-optic bundle, stabilised on the skin, consisted of 40 source and 40 detector fibres arranged randomly in the probe of 3mm in diameter. Due to geometry of the fibre bundle the maximum penetration depth of photons at 1600nm was less than 2mm from the skin surface (calculations were made by Monte Carlo simulation technique). Thus, reflection spectra were collected mainly from the skin dermis layer containing the capillary vessels and lactate. The influence of tissue variation among the individuals was minimized by collecting the background spectrum from skin of each subject before the ergometer
sprint. The multivariate spectral analysis method (Unscrambler 9.7, CAMO SA) was used to compare the difference between NIR-reflectance spectra and the reference lactate levels.

RESULTS: Results show that changes in NIR spectra, collected from all the subjects and both the measurement locations, were repeatable, logical and consistent with the reference lactate concentrations. Predominant change in the spectra occurs at the wavelengths 1140nm, 1400nm and 1650-1750nm. It was further indicated that the changes at 1650-1750nm are related to lactate reference concentration over the course of time. In comparison of measurement locations the thigh was preferred over forearm due to more consistent spectral data.

CONCLUSION: The small amount of reference results and location differences for reference lactate assessments (finger tip) and spectra measurements (thigh and forearm) did not provide estimations of correlation between the enzymatic and NIRS method. However, the indicated result of lactate related changes at the wavelengths 1650-1750nm is comparable with the literature (1) and this range of spectral change may be used for further development of lactate monitoring method. The results suggest the potential of NIRS method for in vivo exercise physiology studies.

VALIDITY STUDIES OF A PORTABLE METABOLIC GAS ANALYSING SYSTEM WITH SPECIAL REFERENCE TO A RESPIRATORY GAS DRYING UNIT, LOW TEMPERATURES, HIGH HUMIDITY, EXTERNAL WIND AND STABILITY OVER TIME

Salier-Eriksson, J., Rosdahl, H., Schantz, P.
The Åströdn Laboratory, Sweden

Introduction
Portable gas analysing systems are useful instruments to determine oxygen uptake during sport and other physical activity. Validating such equipment in the outdoor environment in which they are to be used is essential. Most validity studies of the portable system, Oxycon Mobile, have been in controlled laboratory environments and for short periods of time thus not taking into consideration the possible effect on measurements, of cold and humid conditions, external wind or longer periods of time which may be encountered while exercising outdoors. Using the Oxycon Mobile equipment, the aims were a) to test the effect of external wind on VO2 measurements; b) to compare metabolic gas measurements with and without a system for drying the ambient air around the sampling (nafion) tube; c) to investigate the stability of the Oxycon Mobile for measurements of VO2 over a longer period of time during moderate exercise levels performed at low temperatures and high humidity.

Methods
a) Subjects cycled on a cycle ergometer indoors at three different work loads. VO2 uptake was measured via the Oxycon Mobile while wind was applied from three different directions: b) VO2 uptake, carbon dioxide production, the respiratory quotient and ventilation were measured via the Oxycon Mobile at two different loads both with and without a prototype drying system while subjects cycled on an ergometer cycle outdoors in cold and humid ambient conditions: c) VO2 uptake was measured with the criterion Douglas Bag method at the beginning and end of a 45 minute measurement with the Oxycon Mobile so as to allow a comparison of the two methods, taking into consideration the natural physiological drift expected during work over this period of time.

Results
a) External wind directed at a subject from different directions while cycling did not affect the VO2 measurements as compared to no wind: b) There were no significant differences in any of the measured parameters, regardless of whether the drying system was used or not: c) There was a statistical difference in the drift of VO2 between the Oxycon Mobile and the Douglas Bag over the time lapse of the testing. The difference was 1.34 ml/minute, or 60 ml over the 45 minutes testing with the Oxycon Mobile which, physiologically, is minimal.

Conclusion
There were no differences of measurement significance in any of the measured parameters with or without the drying system. External wind from different directions did not either affect VO2 measurements. The ambient conditions tested in this study might not have stressed the system enough to conclude that the Oxycon Mobile gives reliable measurements in colder and more humid conditions, but the tests indicate good stability in measurement values over time.

MAINTAINING EUHYDRATION SUPPRESSES OXYGEN UPTAKE DRIFT DURING MODERATE PROLONGED EXERCISE IN HEAT

Ishiijima, T., Suzuki, K., Usui, C., Hashimoto, H., Sato, K., Okamato, T., Higuchi, M.
Waseda University, Japan

Purpose: This study was examined the effects of maintaining euhydration by ingesting fluids on respiratory response during moderately intense prolonged exercise in heat. A secondary aim was to examine whether maintaining euhydration suppresses the decrease of maximal voluntary contraction (MVC) after prolonged exercise.

Methods: Six healthy young men (age=24.5±2.0yr, VO2max=54.0±9.3ml/kg/min) completed three experimental conditions consisting of a) Subjects cycled on a cycle ergometer indoors at three different work loads. VO2 uptake was measured via the Oxycon Mobile at two different loads both with and without a prototype drying system while subjects cycled on an ergometer cycle outdoors in cold and humid ambient conditions: b) VO2 uptake, carbon dioxide production, the respiratory quotient and ventilation were measured via the Oxycon Mobile at two different loads both with and without a prototype drying system while subjects cycled on an ergometer cycle outdoors in cold and humid ambient conditions: c) VO2 uptake was measured with the criterion Douglas Bag method at the beginning and end of a 45 minute measurement with the Oxycon Mobile so as to allow a comparison of the two methods, taking into consideration the natural physiological drift expected during work over this period of time.

Results
Results: During prolonged exercise, VO2 normalization and heart rate (HR) and BCT were significantly increased. At 90min of DH, VO2 normalization and VE were higher than MW and HF (VO2 normalization: 125±0.03 vs. 115±0.02 vs. 116±0.03 times, P<0.05, VE, 63.7±4.2 vs. 54.0±2.9 vs. 52.3±3.3 L/min, P<0.05 | HR at 90min of DH was higher than HF (173±7 vs. 158±5 bpm, P<0.05), and tended to be higher than MW. BCT at 90min of DH tended to be higher than HF (13.8±0.1 vs. 13.8±0.2, P<0.05): At 90min of DH, RPE-O was higher than W and H (17.7±1.0 vs. 14.3±1.0 vs. 17.3±0.6, P<0.05). RPE-C and RPE-L were higher at 90min of DH than HF (RPE-C; 16.5±1.3 vs. 13.2±0.8, P<0.05, PRE-L; 18.3±0.9 vs. 14.7±0.9, P<0.05). The percentage of pre-value on maximal torque during MVC after prolonged exercise of DH was measured before and after respective prolonged pedaling exercise. During pedaling exercise, VE, VO2, VCO2, RPE, body core temperature (BCT), RPE-Overall (RPE-O), RPE-Cardiovascular (RPE-C) and RPE-Legs (RPE-L) were measured every 15 minutes. VO2 was normalized by converting 1.0 to the VO2 value at 15min.

Discussion: These results demonstrate that maintaining euhydration by fluid ingestion suppresses the elevation of VE and HR, resulted in reducing the increase of VO2. It may be suggested that hypotonic fluid containing carbohydrate (3%) contributes the reduction of fatigue
Military personnel are required to carry heavy combat loads while marching or fighting. The weight of combat gear has increased during the last years and thus it sets higher demands on soldiers' physical performance (Altwells et al. 2006). The purpose of this study was to assess physical performance of soldiers during a simulated training of urban fighting. It was accomplished by carrying either a traditional combat gear (model m/91, mass of 16.8 kg) or a new one (model m/05, mass of 30.3 kg) during a high intensity attacking simulation. Heart rate (HR), blood lactate (BL), RPE, perceived exertion (RPE) and the performance time were measured in 12 healthy male volunteers. The purpose of this study was also to evaluate importance of muscle strength, aerobic capacity and anthropometry on heavy load-carrying performance. Maximal oxygen uptake (VO2max), body composition and muscle strength were measured in laboratory conditions. In the field tests, the length of attacking zone was about 1480 m. All the subjects were instructed to maintain their combat readiness during their action. No statistically significant differences were found either in HR or BL (p>0.05) between the two different combat gear models. The mean ± SD HR values for the subjects with m/91 and m/05 were 159 ± 10 beat/min and 162 ± 8 beat/min, while the respective BL values were 8.6 ± 2.3 and 8.8 ± 3.1 mmol/l. RPE, however, differed slightly but significantly between the actions with different combat gears (p<0.05) being 15 ± 1 mmol/l and 16 ± 1. Thus, the subjects were capable of sensing the higher strain of the heavier combat gear. Therefore, the environmental conditions with combat load of m/05 was longer (1798 ± 333 s) as compared to the respective time with m/91 (1509 ± 126 s, p<0.001). Furthermore, the maximal oxygen uptake (VO2max) was statistically significantly better (p<0.05) for those subjects (3 out of 12) who passed the field test with a heavier combat load (m/05) being 54 ± 2 ml kg⁻¹ min⁻¹ and 50 ± 2 ml kg⁻¹ min⁻¹. The trial time of the field test with m/05 was highly association with maximal strength of lower limbs (r = -0.63, p<0.05) as well as maximal strength of abdominal muscle (r = -0.68, p<0.05) and body mass (r = -0.63, p<0.05). The results suggest that carrying of heavy combat gears during a high intensity attacking sets high physical and physiological demands on body composition, maximal strength of the lower limbs and abdominal muscle of soldiers. Therefore, mobility and load-carryage performance of soldiers should be facilitated. This could be done by selecting soldiers to a certain task according to their physical characteristics and/or by improving their physical training and/or by tailoring a load for specific operations.

MILITARY OPERATIONAL STRESS IN 72-HOUR TRAINING OF RECONNAISSANCE PATROLLING
Salonen, M., Kokko, J., Tyyskä, J., Koivu, M., Kyröläinen, H.
National Defence University, Finland

The main purpose of the present study was to investigate hormonal, haematological and sympathovagal responses during a 72-hour field training (MFT) of reconnaissance foot patrolling. It was hypothesized that soldiers exposed to considerable energy and fluid deficit, sleep deprivation, diminished recovery time and prolonged physical exercise will undergo physiological stress-related changes. A reconnaissance squad, which consisted of ten healthy male soldiers (age 20 ± 1 yr., height 1.79 ± 0.07 m, body mass 74.5 ± 7.9 kg, body fat 12 ± 1.7 %, VO2max 55.9 ± 3.8 ml/kg/min), participated in a 72-hour reconnaissance foot patrolling exercise. Initial measurements were performed a day before the training and the respective daily follow-up ones in the next three days between 08:00 and 09:30 a.m. For studying energy and fluid intake, the subjects kept daily food diaries. They ate only army field rations, of which daily mean energy content was 3426 ± 112 kcal. Heart rate (HR), blood lactate (BL), respiratory (HRV) and heart rate variability (HRV) was continuously recorded, while the distances travelled in terrain were recorded by a GPS-based portable computer. Blood samples for hormones, sex-hormone-binding globulin (SHBG) and creatine kinase (CK) activity were taken from the antecubital vein. During the MFT, the soldiers mean ± SD energy expenditure (EE) was 4646 ± 674, energy intake (EI) 2200 ± 326, and energy deficit (ED) 2405 ± 890 kcal/day. The mean body mass decreased by 2.2 ± 0.8 kg (2.9 ± 1.0 %) being significantly (p<0.001) lower in the mornings of 2, 3 and 4. Serum testosterone (TES) and free testosterone (TESfree) decreased (p<0.01) after 48 and 72 h of the beginning of MFT. During the entire training, the mean TES reduced from 19.0 ± 3.0 to 12.6 ± 6.2 nmol/l and TESfree from 56.0 ± 19.2 to 38.9 ± 21.8 pmol/l. The CK activity started to increase from the beginning of MFT being 167 ± 89 % (p<0.05) higher after 24 h, 227 ± 114 % (p<0.01) after 48 h, and finally 228 ± 88 % (p<0.001) after 72 h. After the first day of the training, blood cell volume and plasma volume decreased 4.0 ± 3.3 % and 4.1 ± 3.4 % (p<0.01), respectively, as compared to the values measured before MFT. The mean HR during MFT was 85 ± 6 bpm, which corresponds to the mean relative HR of 44 ± 4 % from the theoretical strain. On the other hand, ambulatory recording of HRV show changes in cardiac vagal outflow, which may reflect adaptation of the autonomic nervous system to the training.
intermittent exercise period (10min, P2; 15s work/45s rest). The exercise started after the change of the acid base state in P1 by hyperventilation (RAL), CO2-rebreathing (RAC), administration of 0.07 and 0.21g/kgBW (MAC) NH4Cl and 0.2g/kgBW (MAL) NaHCO3 or a 2min bicycle exercise with maximum power reached in an incremental test (EAC). In CON the subjects breathed normal, during PLA 0.12 g/kgBW CACO3 were administered. [K+]i, [Na+]i, pH and [lactate], were measured in venous [ven] and arterialised [art] blood. Mechanical parameters were monitored, m-wave was recorded by surface electrodes. For measurement the motor point of the muscle was stimulated supramaximally with rectangle constant current pulses. The pHven during exercise was significantly different between the groups (p<0.001), the minimum pH ranged from 6.99±0.03 (EAC) to 7.2±0.04 (RAL), CON/PLA (7.17±0.03). Fatigue resistance was highest with RAC (p<0.01) and not different between the other trials. The m-wave in P2 was significant lower with RAC compared with CON and RAL (p<0.001). No differences were found between MAC, PLA and MAL, but with EAC m-wave was elevated compared to CON (p<0.001). In P2 the duration of the m-wave was not different between RAC/PLA/CON, but with MAC it was significantly longer than with PLA/MAL (p<0.001) and with EAC longer than in CON (p<0.001). In the EAC series the lactic acid in P2 was increased due to previous exercise, in the other series it was significantly diminished with AC and elevated elevated with AL (p<0.001, 0.05). The [K+]i in P2 was significantly higher with MAC than with PLA/MAL (p<0.001) and higher with CON than with MAL (p<0.001). In EAC it was significantly lower than in CON (p<0.001), between RAC/CON occurred no difference, but with RAL it was significantly lower than with CON/RAC (p<0.05).

These results lead to the suggestion, that not the acidification per se, but the acidified space and the kind of acidification might explain the differences. Intracellular mechanisms of the excitation-contraction cycle [2,3] and the electrolyte distribution might be affected differently. No correlation was found between m-wave area and performance [4].

CARDIOPULMONARY ADAPTATIONS TO INTENSIVE SWIMMING TRAINING IN CHILDREN

Welman, J., Stoedefalke, K., Winlove, M.
University of Exeter, United Kingdom

Physiological adaptations to training in adults include increased stroke volume ([SV]) and decreased arterio-venous oxygen difference (a-vO2 diff), thus increasing cardiac output (CO) and peak oxygen uptake (peak VO2). Whether such adaptations occur in children remains controversial. Research suggests that training in children has no effect on a-vO2 diff although some studies have shown increased SV, CO and peak VO2. The present study, which represents the baseline data for a longitudinal investigation, explored the influence of intensive swim training on cardiopulmonary function in a group of children classified as pre or early pubertal.

Participants were 18 swimmers aged 9-12 years (7 boys and 11 girls) training for 8.2 and 5 h wk-1 respectively and 13 untrained children (5 boys and 8 girls) of the same age range. All participants completed an incremental cycle ergometer test to exhaustion. CO, SV and heart rate were measured using thoracic bioelectrical impedance (Physioflow). VO2 was measured using online gas analysis (Cortex). Allometric scaling (log-log ANCOVA) was used to calculate appropriate scaling factors for VO2, CO and SV at peak exercise. As a result peak VO2 was divided by 0.82 for boys but data for girls were not correlated with body mass (p>0.05). Scaling factors for CO and SV were significantly different for boys and girls. CO scaled to body surface area BSA1.52 and BSA1.07 in boys and girls respectively. SV scaled to BSA1.39 for boys and BSA0.84 for girls. Within sex group differences were examined using independent samples t-test with significance accepted at (p<0.05).

There were no significant differences in age, stature, mass, BSA and sum of two skinfold thicknesses between the 4 groups. Adjusted mean for body mass adjusted peak VO2 (L min-1) was significantly higher in the trained (5.57 ± 0.05) vs untrained (4.40 ± 0.06) boys and BSA adjusted peak VO2 (2.68 ± 0.04 vs 2.53 ± 0.4 L min-1 m2) and peak SV (4.34 ± 0.04 vs 4.17 ± 0.05 mL m-1 m2) were also significantly higher in the trained boys. In the girls, absolute peak VO2 was significantly higher in the swimmers vs the controls (4.67 ± 0.3 vs 1.33 ± 0.19 L min-1) but there were no significant differences in allometrically scaled peak CO and peak SV. For the girls only, computed a-vO2 diff was significantly (p<0.05) lower in the swimmers (8.1 ± 1.2) vs the untrained group (9.8 ± 0.5 mL).

This preliminary study has noted interesting sex differences in cardiopulmonary responses to peak exercise between swim trained children and similar aged controls. In boys, higher peak VO2 in swimmers reflects their larger stroke volume (central factor) whereas that of the girls reflects a greater extraction of oxygen at the muscle (peripheral factor). Whether or not these differences existed pre training are not known but future longitudinal analyses will clarify the physiological effects of training.

INFLUENCE OF THIGH SURFACE TEMPERATURE DURING ACTIVE RECOVERY ON POST-EXERCISE LACTATE CLEARANCE AND SUBSEQUENT PERFORMANCE CAPACITY

Donne, B., Conroy, J.
Trinity College Dublin, Ireland

Factors influencing post-exercise recovery affect subsequent supra-maximal performance. This study investigated the effects high surface temperature (cold, temperate and warm) during active recovery on post-exercise lactate clearance kinetics and subsequent supra-maximal performance.

Male games players (n=11; mean ± SD, age 22±1 yr, mass 75±8 kg, height 1.8±0.1 m, Pmax 333±27W) performed intermittent sprint sessions separated by three different 30-min randomised recovery interventions. The intermittent sprint protocol was performed on an Excalibur cycle ergometer (Lode Ltd., The Netherlands), the initial sprint session (10 by repetitions of 30s at 40%Pmax followed by 30s at 120%Pmax) increased blood lactate, the post-intervention sprint session to failure (ITT) assessed supra-maximal performance capacity. Blood lactate (BLa) pre-recovery, every 3-min during recovery and post-TTF was recorded from fingertip capillary samples using a YSI1500 products Ltd., USA). Exponential curve fitting of BLa across intervention assessed clearance kinetics and lactate half-life (½) in mL. Lactate clearance and TTF data were analysed using repeated measures ANOVA, post-hoc Tukey tests quantified differences, P<0.05 inferred statistical significance.

Pre-recovery BLa were not significantly different across modality, mean±SD BLa data were 10.8±1.5, 10.9±1.5 and 10.9±1.5 mmol.L-1 pre-recovery at 40, 24 and 0°C, respectively. Active recovery with thigh gel-packs at 0°C facilitated faster lactate kinetics, mean±SD 7% for BLa
Recovery following high-intensity exercise determines an individual’s capacity for subsequent supra-maximal performance. This study investigated the effects of environmental temperature (5 vs. 28°C) and recovery modality (active vs. passive) on post-exercise lactate clearance kinetics and subsequent supra-maximal (>100% VO2 max) performance.

Male club cyclists (n=12, mean ± SD, age 22±2 yr, mass 81±9 kg, height 1.82±0.04 m and Pmax 360±62 W) performed two intermittent sprint sessions separated by four different 30-min randomised recovery interventions (active at 5°C, passive at 28°C, active at 28°C, passive at 5°C). The intermittent sprint protocol was performed on an Excalibur cycle ergometer (Lode Ltd., The Netherlands), the initial intermittent sprint session (10 by repetitions of 30s at 40% Pmax followed by 30s at 120% Pmax) increased blood lactate, the post-intervention intermittent sprint session to failure (TTF) assessed supra-maximal performance capacity. Blood lactate (BLa) pre-recovery, every 3 min during recovery and post-recovery was recorded from finger-tip capillary samples using a YSI1500 sport lactate analyser (YSI Ltd., USA), heart rate was recorded at 1-min intervals and test sessions were separated by 3 to 4 days. Each individual's pre-recovery BLa data were within 0.5 mmol·L⁻¹ across intervention. Recovery was performed in a climatic chamber (Ta=5.0±0.5 or 28±0.5°C, RH 50±5%) on a Monarch cycle ergometer; recovery interventions were cycling (40% Pmax and cadence 60 rev·min⁻¹) or passive seated rest. Exponential curve fitting of BLa data across intervention assessed clearance kinetics and lactate half-life (?½) in min. Lactate clearance and TTF data were analysed using repeated measures ANOVA, post-hoc Tukey tests quantified differences and P<0.05 inferred statistical significance. Pre-recovery BLa were not significantly different across recovery modalities, mean±SEM BLa data were 9.9±0.3 and 9.5±0.4 mmol·L⁻¹ pre-active recovery and 10.0±0.3 and 9.9±0.3 mmol·L⁻¹ pre-passive recovery at 28 and 5°C, respectively. Active compared to passive recovery facilitated faster lactate kinetics, mean % for BLa in active at 28 and 5°C were 13.9 and 11.8 min, significantly shorter (P<0.001) than passive at the same temperatures, 26.2 and 22.1 min, respectively. Mean±SEM % of peak BLa remaining in the circulation at 30 min into recovery were 16.7±1.7 and 22.7±3.3% for active, and 34.9±2.8 and 42.2±2.7 % for passive modalities at 5 and 28°C, respectively. Application of thigh gel-packs at 0°C facilitated greater post-recovery performance, mean±SD cumulative work done (99±13.5 kJ) during intermittent sprint cycling was significantly greater (P<0.001) compared to 24°C (86±8±9.9 kJ) and 40°C (78±3±10.9 kJ), in addition, cumulative work done was significantly (P<0.01) greater post-recovery with thigh gel-packs at 24 compared to 40°C.

In conclusion, active recovery with thigh gel-packs at 0°C was the most efficient at lactate clearance and in maximising subsequent post-recovery performance. As recovery kinetics is determined by lactate efflux from active glycolytic fibres and uptake by oxidative tissues, we speculate that cold possibly increases uptake via MCT channels as inhibited efflux would attenuate post-recovery work capacity.

**EFFECT OF ENVIRONMENTAL TEMPERATURE AND RECOVERY MODALITY ON POST-EXERCISE LACTATE CLEARANCE AND SUBSEQUENT PERFORMANCE**

Donne, B., Hosford, S.
Trinity College Dublin, Ireland

Recovery following high-intensity exercise determines an individual’s capacity for subsequent supra-maximal performance. This study investigated the effects of environmental temperature (5 vs. 28°C) and recovery modality (active vs. passive) on post-exercise lactate clearance kinetics and subsequent supra-maximal (>100% VO2 max) performance.

Male club cyclists (n=12, mean ± SD, age 22±2 yr, mass 81±9 kg, height 1.82±0.04 m and Pmax 360±62 W) performed two intermittent sprint sessions separated by four different 30-min randomised recovery interventions (active at 5°C, passive at 28°C, active at 28°C, passive at 5°C). The intermittent sprint protocol was performed on an Excalibur cycle ergometer (Lode Ltd., The Netherlands), the initial intermittent sprint session (10 by repetitions of 30s at 40% Pmax followed by 30s at 120% Pmax) increased blood lactate, the post-intervention intermittent sprint session to failure (TTF) assessed supra-maximal performance capacity. Blood lactate (BLa) pre-recovery, every 3 min during recovery and post-recovery was recorded from finger-tip capillary samples using a YSI1500 sport lactate analyser (YSI Ltd., USA), heart rate was recorded at 1-min intervals and test sessions were separated by 3 to 4 days. Each individual's pre-recovery BLa data were within 0.5 mmol·L⁻¹ across intervention. Recovery was performed in a climatic chamber (Ta=5.0±0.5 or 28±0.5°C, RH 50±5%) on a Monarch cycle ergometer; recovery interventions were cycling (40% Pmax and cadence 60 rev·min⁻¹) or passive seated rest. Exponential curve fitting of BLa data across intervention assessed clearance kinetics and lactate half-life (?½) in min. Lactate clearance and TTF data were analysed using repeated measures ANOVA, post-hoc Tukey tests quantified differences and P<0.05 inferred statistical significance. Pre-recovery BLa were not significantly different across recovery modalities, mean±SEM BLa data were 9.9±0.3 and 9.5±0.4 mmol·L⁻¹ pre-active recovery and 10.0±0.3 and 9.9±0.3 mmol·L⁻¹ pre-passive recovery at 28 and 5°C, respectively. Active compared to passive recovery facilitated faster lactate kinetics, mean % for BLa in active at 28 and 5°C were 13.9 and 11.8 min, significantly shorter (P<0.001) than passive at the same temperatures, 26.2 and 22.1 min, respectively. Mean±SEM % of peak BLa remaining in the circulation at 30 min into recovery were 16.7±1.7 and 22.7±3.3% for active, and 34.9±2.8 and 42.2±2.7 % for passive modalities at 5 and 28°C, respectively. Active recovery at 5°C facilitated greater post-recovery performance, cyclists’ maintained intermittent supra-maximal performance significantly longer (P<0.001) compared to active recovery at 28°C and passive recovery at 5 and 28°C, mean±SEM TTF data were 477±29 vs. 360±32, 336±24 and 249±27, respectively.

In conclusion, an active recovery at 5°C was the most efficient at lactate clearance and in maintaining post-recovery supra-maximal performance capacity.

**THE EFFECTS OF CYCLE RESISTANCE TRAINING AT PEAK POWER USING DIFFERENT PEDALLING VELOCITIES ON MUSCLE POWER IN OLDER WOMEN**

Duffy, C., Pecoraro, F., Riches, P., Macaluso, A.
1 University of Strathclyde, Glasgow, United Kingdom; 2 Istituto Universitario di Scienze Motorie, Rome, Italy, United Kingdom

Older people crucially rely on their level of explosive muscle power to maintain functional independence. However, the training load that optimally enhances muscle power remains elusive. It has recently been shown that high-intensity training produces greater gains in older peoples’ explosive power than traditional heavy resistance training (Henwood et al., 2008). Nonetheless, these gains in muscle power may be explained through training at a higher power output hence, the optimal training stimulus could be peak power rather than movement velocity per se. Therefore, this study aims to determine the stimulus for optimal gains in older peoples’ muscle power through cycle resistance training. Uniquely, peak power generated from sprint cycling over 8 s against varying loads does not differ significantly (Pearson et al., 2004), enabling the comparison of two different training resistance methods that result in significantly different pedalling velocities, but with participants generating their peak power.

With University Ethical approval, 24 healthy female participants, aged 70-80 yrs, were matched for dynamic strength into 3 training groups; speed (SP), strength (ST) or control (CON). SP and ST performed 3 sets of 8 ‘all-out’ 8 s supervised sprint cycles, with rest periods of 3 min between sets and 1.5 min between each sprint, twice/week for 8 weeks. SP utilised a load 20% of the maximum load pedalled through 2 complete revolutions (2RM), allowing maximum pedal rate to be achieved. Whereas, ST utilised a 60% 2RM load, resulting in a significantly lower pedal rate. Training load was adjusted after the 4th week in accordance with participants’ 2RM. Conversely, CON carried on with their normal daily activities. After a familiarisation period all participants were tested pre and post-training for power output during a 6 s all-out sprint cycle, against loads of 20, 40, 60 and 80% 2RM (Watson et al., 2007). Statistical analysis was performed on the change (load-pre) in peak power (DP) and torque (DT) using one-way ANOVA followed by post-hoc Tukey tests. Significance was set at p < 0.05.

Pre-training peak power for each group was equivalent (p>0.2). The increase in peak power, measured during the first pedal stroke (average of all loads tested), was significantly greater in ST (DP = 106±59 W; mean±SD) compared to the non-significant change in SP (12±45 W) and CON (14±16 W) (p<0.005). ST increase in peak power was accompanied by a significant gain in torque (DT: 7.6±3.7 Nm, SP: 0.08±2.7 Nm and CON: 0.44±2.3 Nm, p<0.001).

As only ST improved explosive muscle power, accompanied by a greater torque, training at peak power cannot be regarded as the optimal training load, whilst the training stimulus appears to be the length of time exercised at higher torques.

BED REST ATTENUATES THE INITIAL VENTILATORY AND CIRCULATORY RESPONSES TO DYNAMIC EXERCISE

Ishida, K., Katayama, K., Akima, H., Takada, H., Watanabe, Y., Iwase, S., Miyamura, M.
Research Center of Health, Physical Fitness and Sports, Japan

It is well known that physical fitness level shows prominent decrease after deconditioning such as in the cases of space flight and bed rest, and that this should be attributed to physiological dysfunction due to inactivity. We previously proved that 20 days of head-down bed rest reduced leg muscle volume (1) and peak oxygen uptake (2). However, few attempts have been made to elucidate the effects of inactivity on cardio-respiratory responses during the transient phase of exercise. We observed that ventilatory and heart rate responses at the onset of exercise within 20 s were slowed in the elderly and this would be caused by aging dysfunction and/or lack of activity (3). Accordingly, we hypothesize that inactivity should induce attenuated initial ventilatory and circulatory responses at the onset of exercise. Therefore, the purpose of this study was to clarify this hypothesis.

11 healthy male subjects participated in -6 degree head-down bed rest (HDBR) for 20 days. Ventilatory and circulatory responses to brief (20 s) and light voluntary exercise (VOL) generated by bilateral legs extension-flexion movements were measured before (PRE) and after (POST) 20 days of HDBR. Similar movements and measurements were performed on the subjects passively by pulling ropes connected to the subject's ankle (PAS) by the experimenters. This method of PAS was utilized because central command, which is assumed to be one of the main mechanisms affecting ventilatory and heart rate increase during exercise, would be reduced to a minimum in PAS. Minute ventilation (VI), tidal volume (TV) and respiratory frequency (RF) were measured by breath-by-breath technique, and heart rate (HR) and blood pressure were also obtained by beat-to-beat.

VI increased rapidly at the start of exercise in both conditions while the rate of increase seemed to be attenuated after HDBR. The averages of the first 10 s value (T10) and that of the second 10 s value (T10) of VI and RF during VOL in POST were significantly lower than in PRE. During PAS, there were no significant differences in VI, RF and VT between PRE and POST, indicating a minor effect of the peripheral neural reflex mechanism for exercise hyperpnea on the attenuated ventilatory response in VOL during HDBR. HR at rest and during exercise (T10 and T10) at POST significantly increased as compared with at PRE. The extent of increase in HR between T10 and the resting value was significantly decreased after HDBR. From these results, we concluded that initial ventilatory and heart rate responses to exercise were attenuated by 20 days of HDBR. It is suggested that these attenuated responses would be derived from changes in the central neural system as a result of HDBR.

EFFECT OF ADDING UPPER BODY MOVEMENT ON ISOMETRICALLY CONTRACTING QUADRICEPS OXYGEN ACCESSIBILITY DURING SIMULATED SAILING

Vasilopoulou, M., Spetsioti, S., Zaroukliotis, G., Beis, L., Athanasopoulos, D., Vogiatzis, I.
National and Kapodistrian University of Athens, Greece

Rationale: It has been documented that the sustained isometric contraction of the lower limb muscles during simulated hiking in sailing significantly reduces quadriceps oxygen accessibility, thereby accelerating the rate of muscle fatigue (Vogiatzis et al. 2008). It is unknown, however, whether the addition of upper body dynamic muscle activity impacts on quadriceps oxygen accessibility during hiking. It was reasoned that competition for oxygenated blood would compromise quadriceps oxygen accessibility during simulated sailing when upper body movement was added to the isometrically contracting quadriceps.

Methods: Six Laser male sailors performed in a balanced ordering sequence two experimental simulated sailing tests with and without upper body movement (hike plus paddle and hike alone, respectively) each lasting for 10 minutes. Paddle was performed on a swimming bench comprising 60 strokes per minute. During each experiment sailors performed five 2-min hiking bouts interspersed with 5-s recovery periods. Quadriceps haemoglobin total volume (HbT) and tissue haemoglobin-myoglobin saturation (SO2) were measured by near-infrared spectroscopy. Oxygen uptake (VO2), heart rate (HR), blood lactate concentration and leg discomfort on the Borg (1-10) scale were also evaluated.

Results: HbT (an index of quadriceps blood flow) was significantly (p<0.05) higher during hike plus paddle compared to hike alone (29.6±6.0% and 26.9±5.0%, respectively). Similarly, quadriceps oxygen accessibility was significantly greater during hike plus paddle compared to hike alone (SO2: 71±15% and 63±20%, respectively). Furthermore, VO2 and oxygen pulse (VO2/HR: an index of stroke volume) were significantly higher during the combination of hiking and arm paddling (VO2: 14.1±2.2 and 9.7±1.42 ml/kg/min, respectively) and (VO2/HR: 9.4±2.5 and 6.6±1.0 ml/beat, respectively). End exercise leg discomfort was significantly higher during hiking alone compared to hiking plus paddle (7.5±1.5 versus 7.5±1.5), whereas blood lactate concentration three minutes into recovery did not differ between the two tests (3.8±0.8 mM in both tests).

Conclusion: Contrary to our original hypothesis, the addition of upper body movement significantly enhanced quadriceps oxygen accessibility during simulated hiking. Possible physiological mechanisms responsible for this finding may include an increase in cardiac output secondary to the increased muscle mass recruited during hiking and to the dynamic nature of the upper body movement. The increase in whole body VO2 and stroke volume during hike plus paddle supports this hypothesis.

INFLUENCE OF BREATH-BY-BREATH DETERMINATION OF ALVEOLAR OXYGEN TRANSFER ON THE ESTIMATION OF THE KINETICS AT THE ONSET OF STEP EXERCISE

Gimenez, P., Busso, T.
Laboratoire de Physiologie de l’Exercice, France

The analysis of the dynamics of oxygen uptake during transients requires breath-by-breath measurements. Breath-by-breath determination includes a correction for the change in lung gas store considering end tidal measurements to assess the composition of alveolar gas and an effective end expiratory volume which was set originally to the functional residual capacity (IAU algorithm from Auchincloss et al. 1966). It has been proposed to neglect the variation in alveolar gas composition, which was mathematically equivalent to set end expira-
In conclusion, it is possible to use the BR algorithm to study the kinetics of oxygen uptake during moderate and heavy exercise.

**ELECTROMYOGRAPHIC ANALYSIS OF MUSCLE RECRUTIMENT PATTERNS DURING THE ‘NORDIC’ HAMSTIRNS EXERCISE**

Fruer, S., Powel, C., Deighan, M., James, D., Iga, J.

University of Gloucestershire, United Kingdom

The ‘Nordic’ hamstrings exercise (NHE) is a simple partner assisted exercise in which, from a knelt position, a trainee attempts to resist a forward fall by engaging their hamstrings. Although training using the NHE has been shown to improve factors that may help prevent hamstring injuries, including the eccentric strength of hamstrings (Mjølsnes et al., 2004) and the muscle groups’ working range of motion relative to its length-tension relation (Brockett et al., 2001), no research has examined the recruitment characteristics of the hamstrings muscles during this exercise. Consequently, the aims of the present investigation were to study the activity of the hamstrings muscles during the NHE. With institutional ethics approval, 6 male professional soccer players (mean ± SD; age, 22.2 ± 4.5 yrs) volunteered to participate. Delays bipolar surface electrodes IDE2 3 MA, Delsys Inc., Boston, MA, USA) were placed on the belly of the medial and lateral hamstrings of the dominant (DOM) and non-dominant limbs (NON-DOM). Participants performed 5 repetitions of the NHE at a standardized velocity. Angle specific (by a single axis electromiometer, DS-X04, Delsys Inc., Boston, MA, USA) Root Mean Square (RMS) amplitudes were recorded (Delsys Inc., Boston, MA, USA). Raw RMS data were normalised against the maximum RMS amplitude recorded in the same muscle over a 500 ms window during the 5 repetitions of the exercise. A paired sample t-test indicated no difference in the normalised RMS amplitude of the hamstrings between the limbs (P = 0.949). Two-way fully repeated measures ANOVA demonstrated the absence of an interaction between muscle region and joint angle for the RMS amplitude of the hamstrings in the DOM limb (P = 0.089; P = 0.912). Although no main effect for muscle region was observed (P = 0.781), main effects for angle on RMS amplitude were demonstrated (P = 0.002). Bonferroni corrected post-hoc tests indicated that the RMS amplitude was significantly higher at the more extended knee positions (90-61º, 60-31º, 30-0º, 51±18%). Results demonstrated the absence of an interaction between muscle region and joint angle for the RMS amplitude of the hamstrings in the DOM limb (P = 0.081). No difference was observed for the second component. But, between-subject variability in d1, d1u2 and G2 was much lower with the AU and BR algorithms than the other methods at PVT+15W. The second component was significant in a greater number of cases when using BR (7 vs 5 for the other methods at PVT+30W and 5 vs 2 or 3 at PVT+15W).

In conclusion, it is possible to use the BR algorithm to study the kinetics of oxygen uptake during moderate and heavy exercise.

**INFLUENCE OF PRIMING EXERCISE ON PULMONARY O2 UPTAKE KINETICS DURING TRANSITIONS TO HIGH-INTENSITY EXERCISE FROM AN ELEVATED BASELINE**

DiMenna, F., Wilkerson, D., Burnley, M., Jones, A.

University of Exeter, United Kingdom

The phase II VO2 kinetics are appreciably slower during a transition to a higher work-rate than when it is initiated from an elevated baseline. In particular, the slow VO2 delivery limitation is presently unclear. ‘Primed’ exercise is known to enhance muscle O2 delivery and to accelerate VO2 kinetics during subsequent high-intensity constant-work-rate exercise, predominantly by reducing the amplitude of the so-called VO2 slow component, possibly as a consequence of changes in muscle fibre recruitment. We therefore hypothesized that the performance of priming exercise would accelerate VO2 kinetics during a subsequent work-work transition by reducing the phase II VO2 time constant and the amplitude of the VO2 slow component, in association with a reduction in the change in VO2 which occurs between 2 and 6 minutes of exercise. Seven healthy men completed exercise transitions to 70% of the difference between gas exchange thresholds (GET) and peak VO2 from a moderate-intensity baseline (90% GET) in each of the ‘unprimed’ and ‘primed’ conditions. Three like-transitions were performed and pulmonary gas exchange, heart rate and the electromyogram of the m. vastus lateralis were measured during all tests. A nonlinear least-square algorithm was used to fit the breath-by-breath VO2 data to a biexponential model. Average iEMG was calculated for 15 s intervals throughout exercise with these values normalized to the average measured during unloaded cycling prior to the initial transition and the change in iEMG between 2 and 6 minutes of exercise was computed.
The phase II VO2 kinetics were slower when severe-intensity exercise was initiated from a baseline of moderate exercise compared to unloaded pedalling (mean ± SD time constant, 42 ± 15 vs. 33 ± 8 s; P<0.05) but these kinetics were not accelerated by priming exercise (42 ± 17 s; P>0.05). However, the VO2 mean response time was reduced from 80 ± 24 to 63 ± 18 s; P<0.05), primarily as a consequence of a reduction in the amplitude of the VO2 slow component (from 0.47 ± 0.09 to 0.27 ± 0.13 L/min·1; P<0.05). The change in EMG between 2 and 6 minutes of exercise was also significantly reduced after priming (from 51 ± 35 to 21 ± 42 % of baseline; P<0.05).

That priming exercise did not accelerate the phase II VO2 kinetics during exercise transitions performed from an elevated baseline indicates that the slow kinetics in this condition are not related to an O2 delivery limitation. However, the VO2 slow component during these work-work transitions is reduced by priming and iEMG data support the role of an altered muscle fibre activation pattern as a facilitator of this effect.

NON-METABOLIC SPECIALISATION IN ELITE YOUTH FOOTBALL PLAYERS
De Ste Croix, M., Mujika, I., Santisteban, J., Iga, J.
University of Gloucestershire, United Kingdom

Previous studies that have examined the concept that young children are non-metabolic specialists have provided conflicting findings (Blockham et al. 2005, Falk and Bar Or, 1993). These data have been derived from laboratory based tests where metabolic cross-over in testing modality occurs, in particular the large aerobic contribution to the Wingate test in children. There are also issues relating to the ecological validity of laboratory tests and to date no studies appear to have examined the concept of metabolic specialisation from field based assessment and with elite performers. Therefore the purpose of this study was to examine the concept of non-metabolic specialisation in elite youth football players using field based tests. 126 participants were recruited for this study, all of who were academy players at a professional Spanish La Liga football club. Players were split into their respective teams consisting of U11 to U18. Fitness testing took place in the middle of the competitive football season (Dec-Jan) and all participants were familiar with the testing procedures. Sessions started with the assessment of players’ body mass, stature and sum of six skinfolds. With adequate rest periods between tests no significant correlations between anaerobic and aerobic parameters for each age group. There were no significant correlations between anaerobic and aerobic tests in any of the age groups. Despite not reaching significance there were more negative correlations in the older age groups 16y+ which could be interpreted as a trend towards metabolic specialisation. There were significant negative correlations (range r = 0.50 to 0.78) between aerobic performance and sum of skinfolds in the U11-U13 age groups that become non-significant after 14y. Significant correlations were found between body size and performance variables, especially in the U11 and U12 age groups. These data suggest that body size and composition play an important role in the ability to perform anaerobic and aerobic work. The lack of significant relationships between anaerobic and aerobic performance in any age group indicates that elite youth football players appear not to be non-metabolic specialists.

This may in part be attributed to the field tests not being discriminative, the use of age groups rather than maturational status and the relatively small sample size.

EFFECT OF ACTIVITY ON MUSCLE FIBER TYPE COMPOSITION AND MYOSIN HEAVY CHAIN MRNA EXPRESSION AFTER MUSCLE INJURY INDUCED BY ECCENTRIC CONTRACTION IN RAT SKELETAL MUSCLE
Nishizawa, T., Tomori, K., Yuki, A., Tamaki, H., Norikatu, K., Takekuro, H.
Chukyo Women’s University Junior College; 2 National Institute of Fitness and Sports; 3 Aichi University of Education, Japan

The purpose of this study was to investigate the effect of muscle damage and activity on muscle fiber type composition and Myosin Heavy Chain/mRNA expression quantity. Our studies so far have reported that the muscle damage causes the temporary denervation in the regeneration processes of the muscle fiber, the innervation form becomes multiple innervation. Then, it removes the surplus nerve terminals from the muscle fiber, and it becomes the single innervation. It is considered that the selection and the elimination of the surplus nerve terminals affect the muscle fiber type. It may be presumed that the activity of the muscle plays pivotal roles in the selection and elimination of the surplus nerve terminals. And it is further estimated that the muscle fiber also interacts with functions and sends signal to the nerve terminal in the process of regeneration.

Female Fischer 344/Jcl rats ( 10 weeks old, body weight, 150–170 g) were used. All procedures in the animal experiments were performed in accordance with the guidelines. The rats were classified into 4 groups: control, endurance training (EL), endurance and downhill training (ED), endurance training addition in ED (EDE). Endurance training ran on the treadmill continuously for 60min at 40min/min, 6days/wk. The training period was 4weeks. Downhill training ran on the treadmill continuously for 5min running with 2min rest interval, 18 bouts at 40min/min and 16 degree decline. Downhill training carried out once. EDE group performed 2weeks endurance training continuously after downhill training. Single muscle fibers were dissected from the extensor digitorum longus and soleus muscles. Using the Real-time polymerase chain reaction, the measurement of the mRNA expression quantity measured expression level of MyHC type I, MyHC type Ila and MyHC type Iib. Three types of fibers were classified based on differences ATPase activity. The muscle fiber composition is shown at muscle fiber for different types the number ratio. The morphological observation of neuromuscular junction by optical microscope used cholinesterase and silver staining.

We observed the muscle damage and denervation in the ED group. In the EDE group, the regeneration muscles fiber such as matrix of the nucleus and small fiber was observed. In the regenerated muscles fibers, multiple innervation and inexperienced neuromuscular junction were observed. In the muscle fiber composition, there was the increase of Type Ila fiber. The relative expression level of MyHCtype Ila and MyHCtype Ila of mRNA were show the high value in the EDE group. The values from the group endurance-downhill-endurance training showed the increase from percentage of Type Ila fiber and MyHC type I and MyHC type Ila as the endurance training group. It is concluded that increase in muscle fiber type transformation promoted by after endurance training programmed after muscle injury. And damage and regeneration may have a role in the nerve conversion of the neuromuscu
OXYGEN DESATURATION AT THE END OF EXHAUSTIVE ROWING TESTS WITH AND WITHOUT WARM-UP: EFFECTS OF GENDER

Riganas, C., Vrabas, I., Kouitidou, C., Papadopoulou, Z., Koidou, I.
Aristotle University of Thessaloniki, Greece

Exercise induced arterial hypoxemia (EIAH) has been reported in various endurance male and female sport specialists, including runners, cyclists, triathletes, swimmers and rowers. When EIAH is present, it usually peaks at or near maximal exercise intensity and during short-term or incremental exercise to exhaustion.

The purpose of the present study was to determine any possible sex differences in the frequency and degree of oxygen desaturation at the end of exhaustive rowing protocols with and without prior warm up.

Twenty male (M; n=20, age: 19.3±.64 years, training age: 5.6±.60 years, weight: 78.19±1.62 kg, height: 181.36±1.49 cm) and twenty female (F; n=20, age: 22.51±3.85 years, training age: 4.29±0.26 years, weight: 66.52±1.21 kg, height: 171.85±1.36 cm) highly-trained rowers, participated in the study. On three separate occasions both groups underwent: a) an incremental rowing ergometer test (Concept IIc, Nottingham, UK) b) a rowing ergometer 2000m all-out effort and c) a rowing ergometer 5 minute all-out effort without prior warm-up.

Rowing drag factor was set in 135 for M and 125 units for F. Arterial oxygen saturation (SaO2) was assessed non-invasively by ear oximetry for all measurement sessions (Nanox2-Medlab, Karsruhe, Germany). The minimum level of % SaO2 was determined using 15-s averages. Data are expressed as means (±SE).

Results showed that SaO2 was significantly lower in female compared to male at the end of the 2000m race (90.69 ± 0.94 vs 87.38 ± 0.84%, p<0.05) and the 5-minute all out without warm up test (90.61 ± 0.77 vs 87.18 ± 0.74%, p<0.001). No significant differences were observed between groups at the end of the incremental test. Severe hypoxemia appeared in 65% of the female and in 15% of the male athletes at the end of the 2000m race. Both male (45%) and female (70%) revealed highest frequency in mild type hypoxemia, at the end of the incremental test. At the end of the 5-min all out test, the highest frequency appeared at the severe (50%) for female and at the mild level hypoxemia for male (50%) athletes.

We conclude that female rowers are more hypoxic compared to male at the end of exhaustive efforts with and without warm-up. Moreover, incremental efforts seem to limit the prevalence of EIAH in female compared to male rowers.

FUNCTIONAL EVALUATION OF OXIDATIVE ENERGY METABOLISM IN MYOPATHIC PATIENTS

Vago, P., Lanfranconi, F., Marzorati, M., Porcelli, S., Morandi, L., Grassi, B.
UNIVERSITY OF MILAN, UNIVERSITY OF UDINE, UNIVERSITA' CATTOLICA, MILAN (ITALY), Italy

Aim of the study

In patients affected by metabolic myopathies, such as mitochondrial myopathies (MM) and myophosphorylase deficiency (McArdle disease, McA), the impairment of aerobic metabolism is responsible of a reduced exercise tolerance, a typical and most relevant clinical observation. The aim of the present study was to evaluate two non-invasive methods of assessment of the aerobic metabolism in MM and McA patients:

1) Indexes of muscle oxygenation state during exercise, representing skeletal muscle O2 extraction capacity, measured by near-infrared spectroscopy (NIRS),

2) Kinetics of O2 uptake (VO2), measured at the lung during transients between rest and exercise.

Methods

Four groups of subjects were assessed: 13 MM, 7 McA, 37 patients with signs and symptoms of metabolic myopathy but with a negative biopptic result (control patients, P-CTRL) and 28 healthy untrained subjects (CTRL). Every subject completed a 5-minute constant-load-cyclogermometer exercise, followed by incremental exercise until exhaustion. The following variables were assessed: 1) heart rate (HR) by ECG,

2) pulmonary ventilation and breath-by-breath gaseous exchange (VO2, CO2 output, VCO2) using an open-circuit metabolograph, 3) peak VO2, Delta[deoxy(Hb+Mb)]peak (peak value of deoxygenated Hb and Mb concentration changes), an index of maximum O2 extraction capacity of the vastus lateralis muscle as assessed by NIRS, and 4) VO2 kinetics.

Results

Delta[deoxy(Hb+Mb)]peak was significantly lower in the MM (25.3 ±12.0%) and McA (18.7±7.3%) compared to the P-CTRL (62.4±3.9%) and to the CTRL (71.3±3.9%) subjects. The peak VO2 values obtained in the MM, McA and P-CTRL patients was significantly lower by ~ 40%, ~50%, and ~15% than in the healthy CTRL group. In the MM and McA patients, VO2 peak and Delta[deoxy(Hb+Mb)]peak were linearly correlated (R2= 0.83), that is to say: those patients with the lowest maximum extraction capacity, showed the lowest peak VO2 values.

The VO2 and HR kinetics of the patients were significantly longer in the MM and McA patients, compared to the P-CTRL and CTRL groups. The time constant of O2 uptake and HR were significantly longer in the MM and McA patients compared to the P-CTRL and CTRL groups.

The VO2 and HR kinetics of the patients were significantly longer in the MM and McA patients compared to the P-CTRL and CTRL groups.

Conclusions

The methods of functional evaluation proposed by this study, enable to identify and quantify the oxidative metabolism impairment of MM and McA patients. The advantage of monitoring this impairment non-invasively seems of considerable medical value when an objective, quantitative and longitudinal evaluation of these patients is needed in the follow-up or in the implementation of therapeutic i

CAN AN INTERRELATIONSHIP BETWEEN LACTATE AND CARBOHYDRATE UTILISATION EXPLAIN THE INTER-INDIVIDUAL VARIATIONS IN FATMAX?

Alkhaltib, A., Beneke, R.
1London Sport Institute, Middlesex University, London, United Kingdom

INTRODUCTION: High inter-individual variations in carbohydrate (CHO) and fat utilisation have frequently been reported during incremental exercise testing. Maximal oxygen uptake (VO2peak) is a determinant of maximal fat oxidation (Fatmax) levels (Venables et al. 2005). However, Fatmax often corresponds to a wide range of exercise intensities of approx. 30-75 %VO2peak and various blood lactate concentration (BLC) levels of 1-2.2 mmol.L-1 (Birch et al. 2005). An interrelationship between BLC and the relative rates of pyruvate combustion (RPY) has previously been proposed based on the idea that lactate may be used to indicate pyruvate availability, and shown to be independent of age and cycling cadence (Beneke et al. 2005, Alkhaltib and Beneke 2006). The latter interrelationship suggests that
RPP changes may be reflected by individual BLC levels, as indicated by a constant (kel) describing RPP as a function of the BLC. The present study investigates whether kel can serve as an independent factor to increase the explanation of the variance of Fatmax.

METHODS: 21 healthy males (Age 26.3 ± 6.0 years, Height 179.4 ± 8.1 cm, Body mass 74.9 ± 12.5 kg) completed an incremental cycling test at 50 rpm. The workload was initiated with 1 W/kg -body mass, and increased by 0.5 W/kg -body mass every 2 min stage. Capillary blood samples were drawn from the hyperaemic earlobe at rest and at the end of each stage. VO2 and carbon dioxide production (VCO2) were measured, and analysed for estimating CHO and fat oxidation using indirect calorimetry. RPP was calculated as a percentage of the full pyruvate combustion (when VO2 equals VCO2). Absolute CHO and fat combustion rates were calculated based on the O2 required to oxidise glycogen and fatty acid, and further used to determine Fatmax. kel was approximated based on the following interrelationship between RPP and BLC: RPP = 100 / (1+kel / BLC2). RESULTS: Fatmax was (Mean ± SD) 0.51 ± 0.14 g.min-1 corresponding to an intensity of 40.2 ± 9.4 % of peak power (293 ± 39.4 W) equivalent to 47.2 ± 9.7 %VO2peak (3885 ± 505 ml.min-1) at a BLC of 1.4 ± 0.04 mmol.l-1. Estimates of kel were 1.75 ± 1.10 mmol.l-1. kel and VO2peak were unrelated (r > 0.05). VO2peak explained 38.7% of the variance in Fatmax (Fatmax = 0.16 + 0.00017 VO2peak, p=0.003). Inclusion of kel as independent explanatory variable increased the explanation of the variance of Fatmax to 55.9% (Fatmax = 0.18 + 0.00015 VO2peak + 0.05 kel, p=0.001). CONCLUSION: Determination of kel increases the predictability of Fatmax. High kel values indicate lower reliance on CHO combustion at given levels of CHO availability, and higher Fatmax.

INFLUENCE OF VO2MAX ON THE %VO2MAX ATTAINED AND VO2 KINETICS IN SHORT DURATION EXHAUSTIVE RUNNING

Draper, S., Hopkinson, Y., Potter, C., James, D.
University of Gloucestershire, United Kingdom

It has been demonstrated that in aerobically trained subjects VO2 does not attain its maximum (IVO2max) during short duration exhaustive running. Rather VO2 reaches a plateau below VO2max, despite the response being fast enough to be complete (Draper and Wood, 2005a). Previous research has suggested that VO2max (ml.kg-1.min-1) is negatively correlated with the percentage (%VO2max) attained during exhaustive running (Draper and Wood, 2005b; James et al., 2007), however neither of these studies utilised a suitably heterogeneous sample for VO2max. The purpose of the present study was to examine the relationship between VO2max and the %VO2max attained in short duration exhaustive running.

Twenty subjects (10 male and 10 female; [mean (SD)] age 30 (7) years, height 1.72 (0.09) m, mass 68.0 (13.0) kg, VO2max 52.6 (11.0) ml.kg-1.min-1) completed the study. Following a familiarisation trial, each completed four exhaustive treadmill tests; two exhaustive ramp tests and two square wave tests of an intensity high enough to exhaust the subject in approximately 2 min. The order that these tests were completed was counterbalanced. Breath-by-breat VO2 was measured throughout each test; this was then interpolated and averaged across both transitions. VO2peak was defined as the highest 15 s moving average from the combined data and VO2peak from the ramp test was considered to be VO2max. Square wave data were modelled using a mono-exponential function having first removed phase-1 data points. Pearson Product Moment correlation was used to investigate the relationship between VO2max and outcome variables. VO2max (ml.kg-1.min-1) was found to be negatively correlated with %VO2max attained in the square wave test (r = -0.539, P = 0.014). There was no relationship however between VO2max (ml.kg-1.min-1) and either the time constant (tau) of the response (r = -0.136, P = 0.568), or mean response time (MRT) (r = -0.218, P = 0.356). This is the first study to examine exercise of this intensity using a sample that was heterogeneous for aerobic capability. Whilst supporting the notion that VO2max (ml.kg-1.min-1) and %VO2peak attained in exhaustive severe intensity running are correlated, the results suggest that VO2max is essentially unattainable in such exercise in any subjects capable of completing a two minute exhaustive run. The results also show that the positive relationship between VO2max and the speed of the VO2 response, which has been reported at lower exercise intensities (Powers et al., 1983), was not found for short duration exhaustive running in the present study.

EFFECT OF TENDON VIBRATION DURING SUBMAXIMAL STATIC ELBOW FLEXION EXERCISE ON MUSCLE OXYGENATION

Ueda, C., Kamo, M., Saijo, M., Kagaya, A., Osada, T., Sato, K., Shibuya, K., Okuyama, S., Sadamoto, T.
Japan Women's College of Physical Education, Japan

Purpose: A recent study has reported that whole limb vibration stimulus induces a lower tissue oxygenation during submaximal dynamic exercise because of a greater recruitment of fast twitch motor units (Mileva et al. 2006). However, it remains unclear whether static exercise with direct vibration on the contracting muscles also produces the lower oxygenation as seen during dynamic exercise (Mileva et al. 2006). The purpose of this study was to investigate the influence of tendon vibration during submaximal static exercise on muscle oxygenation.

Methods: Nine healthy females (mean±SD: 23.8±4.1 years, 162.6±4.4cm, 56.6±4.2kg) participated in this study. All subjects completed two trials, non-vibrated exercise (Ex) and vibrated exercise trials (Vib+Ex). In both trials, the elbow flexion exercise was statically sustained for 2 minutes and the exercise intensity was kept at 30% of maximum voluntary contraction (MVCO) by a visual feedback system. In Vib+Ex, an oscillating stimulation by a vibrator (frequency 100Hz, amplitude 0.8mm) was applied to the distal tendon of the biceps brachii during exercise. Mean arterial pressure (MAP) and cardiac output (CO) were measured using photoplethysmometer. Heart rate (HR) was measured by ECG recordings. The changes in oxygenated hemoglobin (oxyHb), deoxygenated hemoglobin (deoxyHb) and total hemoglobin
MIF was reduced by 54% ± 2% immediately after B1 and stayed depressed for nine days (21% ± 3%; p < 0.01). REA decreased immediately (8° ± 1; p < 0.01) after exercise and returned to pre-exercise values within 96 hours (180° = extended elbow). The reduction in MIF correlates with the decrease in REA (r = 0.8 at 72 hours; p < 0.01). The training program was consisted of four leg-presses, bench-press, pull down curls and leg curls. During the first week, the training was done at 50% 1RM in two sets with 10 repetitions. The intensity of training was increased to 80% 1RM in 3 sets and 6 repetitions, during the 8th week. The training program was three days in a week for 8 weeks. End diastolic and systolic diameter, septum and post wall thickness, left ventricular mass (LVM) and LVM index as structural parameters, pre and post trainings measured by echocardiography with 2D and Doppler methods.

Results: The torque output of elbow flexion was identical between Ex and Vib+Ex. The increases in MAP, CO and HR during exercise were also similar in both trials. However, the decrease in oxyHb during exercise was greater in Vib+Ex than that in Ex whereas there were similar increases in deoxyHb and totalHb in both trials. In addition, the decrease in TOI during exercise was greater in Vib+Ex than that in Ex. Conclusions: This study suggested that the submaximal static exercise with tendon vibration reduces muscle oxygenation as similarly observed during dynamic exercise, probably due to a greater recruitment of fast twitch motor units resulting from the vibration stimulus.

**EFFECT OF THE RESISTANCE TRAINING ON THE HEART MORPHOLOGY IN UNTRAINED FEMALE STUDENTS**

Hosseini, M., Aghaalinejzhad, H., Hajsaadeghi, S.
Islamic Azad University, branch of Qommdast. Tarbiat Modares University. Medical SCI of Iran University, Iran

Through regular and long-term Training, the heart encounters some changes, which make it different from the heart of one who doesn’t take physical Training. These alterations define as physiological adaptation in heart which is in response to Training. Indeed, this process is in contrast with pathological adaptation (2, 4).

These established alterations are different according to type, duration and intensity of training, primary physical fitness, heredity and sex (1).

Pluim (2000) found in (through studying Echocardiography in athletes who take resistance training) that internal diameter, posterior wall thickness of left ventricle, interventricular septum in athletes are more than control group (3).

With due attention to the new style of training among Iranian women is working with weights or lifting them, the aim of this study was to determine the effect of the resistance training on the heart morphology.

**CHANGES IN CALPAIN AND DESMIN AFTER TWO BOUTS OF ECCENTRIC EXERCISE IN HUMANS**

Paulsen, G., HALLÉN, J., RAASTAD, T.
Norwegian School of Sport Sciences, Norway

The calpain system is involved in degradation and remodelling processes in skeletal muscle, and increased calpain-activity is reported in humans after eccentric exercise (1). Because calpains have high affinity for myofibrillar and cytoskeletal proteins, an accumulation of calpains could be expected in this compartment after muscle damaging exercise. Consequently, the aim of this study was to investigate changes in calpain content in the cytosol and the cytoskeleton after high-force eccentric exercise.

Twenty one healthy subjects (26 ± 3 years) performed 70 unilateral maximal eccentric actions with their arm flexors at two occasions (same arm) separated by three weeks. Changes in maximal isometric force (MIF) and resting elbow angle (REA) were monitored for nine days after each bout (B1 and B2). Biopsies were obtained from the exercised and the non-exercised biceps muscles one, 48, 96, 168 hours after B1 and one and 48 hours after B2. The biopsies were homogenized and fractionated to a cytosolic and a cytoskeleton/myofibrillar fraction. Micro-calpain and desmin content in both fractions were measured by western blotting.

MIF was reduced by 54% ± 2% immediately after B1 and stayed depressed for nine days (21% ± 3%; p < 0.01). REA decreased immediately (8° ± 1; p < 0.01) after exercise and returned to pre-exercise values within 96 hours (180° = extended elbow). The reduction in MIF correlated with the decrease in REA (r = 0.8 at 72 hours; p < 0.01). After B2, the MIF recovered within 96 hours, and the REA was slightly decreased immediately after and 24 hours after exercise. The cytosolic calpain content tended to be increased 48 hours after B1, whereas the calpain content in the cytoskeleton was increased after both B1 and B2 (p < 0.05). Desmin was found consistently only in the cytoskeleton fraction and the desmin content was elevated 168 hours after B1 and one and 48 hours after B2 (p < 0.05).

Faster recovery of MIF and the faster normalization of REA after B2 compared to B1, revealed a repeated bout effect. The prolonged depression of the force-generating capacity, especially after B1, was related to disturbances in force-generating and force-transmitting structures, as we have found disruptions of the myofibrillar structure. Ultrastructural changes may in turn be a consequence of increased Ca2+ levels, indicated by the increase in passive tension (decreased REA) and a concomitant activation of the calpain system. The delayed increase in desmin after B1 and elevated levels after B2 suggest that increased desmin expression is part of the adaptation to unaccustomed eccentric exercise. The accumulation of calpain in the cytoskeleton after both B1 and B2 indicates that calpain plays a role in the remodelling of the cytoskeletal structures. In conclusion, the changes observed in both calpain and desmin suggest that these proteins may be involved in the mechanism behind the repeated bout effect.

EXERCISE INTENSITY PROFILE OF TCHOUKBALL MATCH-PLAY

Cereda, F., Peroni Ranchet, F., Basilico, S., Mondoni, M., Impellizzeri, F., Mognoni, P.
University, Italy

BACKGROUND: Tchoukball is a relative new sport developed in 1970 by the Swiss biologist Hermann Brandt. During matches physical contact between players is not allowed to reduce the risk of injuries and limit aggressive behaviors. Tchoukball is played by two teams of nine players on a rectangular field (usually 40x20 m) with one rebound frame placed at each end of the field. To score a player must bounce the ball off the frame such that no defending players can catch it before it falls on the field (rules available on www.tchoukball.org). Each match consists of three periods of 15 min with resting intervals of 5 min between periods. Tchoukball is widely-spread in some countries of Europe, America and Asia. However, to date, there are no studies on this sport. Therefore, to understand the physiological demands imposed by Tchoukball, we examined the exercise intensity by assessing the heart rate and the blood lactate ([BLa-]-) response during a match. METHODS: fourteen players (mean±SD: age 19.5±2.2 years, body mass 75±9 kg, height 1.79±0.07 m) participated to the study. They completed an incremental test for the determination of the lactate threshold (LT, 1 mmol/L above baseline) and that of blood lactate accumulation (OBLA, intensity at 4 mmol/L). Three intensity zones were determined: EASY (<LT), MODERATE (between LT and OBLA) and HIGH (>OBLA). During a friendly match, HR and [BLa-] after each period were measured. Exercise intensity was expressed as percent of individual maximal HR reached in the laboratory and as relative time spent in the three intensity zones. Exercise intensity was analyzed using two-way (period x intensity zones) and one-way (period) repeated measures ANOVAs. RESULTS: Exercise intensity was analyzed using a two-way (period x intensity zones) and one-way (period) repeated measures ANOVAs. RESULTS: players reached a HRmax of 191±8 bpm. The HR at LT and OBLA corresponded to 65±6 and 80±5% of HRmax, respectively. The average intensity during the match was 82±2% of HRmax, while the average HR values during the three periods were 85±5, 83±7, and 81±6% of maximal, respectively. A significant time effect was found for average HR (P=0.024). The time spent in the high, moderate and easy zones was 55±34, 37±27 and 8±13% of total match time. A significant period x intensity zones interaction was found (P=0.047), with the time spent at high intensity decreasing during the match: from 68±33 (first period), to 53±38 (second period) and 45±30% (third period). No differences between periods were found in [BLa-]. DISCUSSION: the average intensity during tchoukball matches is similar to that found in other team sports such as soccer and futsal. The high proportion of time spent in the high zone shows that tchoukball is high demanding sport. The decrease in intensity during the periods suggests the occurrence of fatigue throughout the match. The knowledge of the physiological demands of tchoukball can be useful for coaches and sport scientists attempting to clarify fitness objectives and to ascertain the physiological characteristics that are prerequisites for success.

NO CIRCADIAN RHYTHM OF EXTRACELLULAR HSP72 IN HEALTHY HUMANS

Fortes, M., Whitham, M.
Bangor University, United Kingdom

Stressors such as exercise, trauma, hyperthermia, alterations in blood glucose and infection have all been shown to increase the concentration of extracellular (e) Hsp72 in humans. Research has focused on its potential immuno-stimulatory capability and the possibility that eHsp72 may aid cytoprotection of distal cells particularly with regard to exercise thermodurability. In addition, it has been proposed that eHsp72 may have diagnostic potential in a number of clinical conditions. Clearly, from a methodological and diagnostic perspective, it is important to investigate if concentrations of eHsp72 fluctuate throughout the day. Catecholamines, which have been shown to have a circadian variation of their own, are strong candidates for mediating the release of eHsp72. Therefore, the purpose of the study was to measure resting concentrations of plasma eHsp72 throughout a 24-hour period. With informed consent, 8 healthy recreationally active males were recruited for the study (age: 23.3 ± 3.7 yr, height: 1.83 ± 0.08 m, body mass: 77.9 ± 9.2 kg). Following a standardized breakfast on the morning of the trial, blood samples were taken every hour from an indwelling cannula from 12noon until 9pm and from 7am until 12noon the following day, and analysed for plasma (EDTA) Hsp72 concentration using a commercially available ELISA (Assay Designs, Michigan, USA, intra-assay CV = 1.4%). Participants remained in the laboratory throughout the trial, performed light sedentary activities, and were provided with standardized meals and fluids, which maintained body weight and euhydration. In addition to blood sampling, resting heart rate and blood pressure were recorded every hour. Physical activity was quantified throughout by the use of an accelerometer.

One-way repeated measures ANOVA revealed that heart rate (P = 0.083), systolic (P = 0.664) and diastolic (P = 0.254) blood pressure remained stable throughout the trial. Despite inter-subject variation, physical activity remained sedentary throughout the trial (mean activity energy expenditure above resting metabolic rate: 35.7 ± 10.0 Kcal/hr) and was matched by energy intake. It is therefore unlikely that the subjects were unduly stressed. Plasma Hsp72 concentration did not fluctuate significantly throughout the day and showed no apparent endogenous circadian rhythm in absolute (F = 1.14, P = 0.367) or plasma volume change corrected data (F = 1.04, P = 0.380). Individual-coefficient of variations ranged from 3.8-12.7% (mean 7.6%). Mean Hsp72 concentration across all subjects and time points was 1.85 ± 0.14 ng/ml. These data show that in a rested state, plasma eHsp72 concentrations remain stable throughout the day. However, the mean co-efficient of variation of ~8% suggests researchers and clinicians should be wary when anticipating small changes in response to an intervention.

MUSCLE COORDINATION DURING REPEATED SPRINTS IN WOMAN: A PILOT STUDY

Billaut, F.
University of Lethbridge, Canada

Few data are available on the woman’s neuromuscular function, especially during sprint exercise. The inter-muscle coordination is a primary determinant of power output production, and may therefore constitute a factor limiting the exercise tolerance. The aim of the current study was to examine the effect of fatigue induced by repeated sprints on the activation and deactivation dynamics in the healthy, active woman. Twelve women performed twenty, 5-s all-out sprints on a cycle ergometer, separated by 25-s rest. Surface EMG of the vastus lateralis (VL) and the biceps femoris (BF) was recorded, and two discrete events were computed from the raw-mean-square linear envelope of the raw EMG signal (i.e. onset and offset of EMG bursts) in sprints 1, 5, 10, 15, and 20. The time delay between VL and BF onsets, and the silence period (i.e. time period between BF offset and VL onset in the subsequent burst) were calculated. Results showed a significant mechanical work decrement from sprint 1 to 20 (20.2 ± 8.9%, p<0.05). The mechanical output alteration was accompanied by muscle coordination changes. The time delay between VL and BF onsets was reduced in sprints 15 (135.1 ± 123 ms, p<0.05) and 20 (133 ± 137 ms, p<0.05), compared with sprint 1 (1393 ± 152 ms). Moreover, the silent period within a given pedal stroke was found to increase (p<0.05) during these sprints (sprint 15: 12%, sprint 20: 18%). This study is the first to explore muscle coordination in woman during whole-body exercise. It is demonstrated that the alteration of the coordination timing between agonist and antagonist muscles may contribute
EFFECTS OF AGEING ON SOLEUS-EVOKED H-REFLEX AND V-WAVE RESPONSES
Scaglioni, G., Martin, A.
Equipe INSERM U887 Motricité-Plasticité, France

The Hoffmann (H) reflex and the first volitional wave (V-wave), which is an electrophysiological variant of the H-reflex recorded during maximal voluntary effort, may be used to evaluate the modulation of the spinal loop (Ifton 1971). These two evoked responses are measures of motoneuron excitability and also reflect the magnitude of presynaptic inhibition on the afferent (mainly H-reflex) and the magnitude of the descending neural drive (mainly V-wave). The purpose of the present study was to combine measurements of soleus-evoked V-wave and H-reflex, recorded during maximal plantar-flexor contraction, in order to examine neural adaptive changes induced by ageing.

Experiments were performed on 10 young (25±5 yr) and 8 elderly males (76±2 yr). The maximal H-reflex and M-wave were evoked at rest (Hmax, Mmax) and during maximal voluntary contraction (MVC) (Hsup, Msup). During MVC, supra-maximal stimulus intensity was also used to evoke the V-wave.

No difference between Hsup/Msup and Hmax/Mmax was observed in the young men [0.49±0.16 vs.0.51±0.13], while in the elderly Hsup/Msup was significantly higher than Hmax/Mmax [0.47±0.21 vs.0.31±0.15, P<0.01]. The Hsup/Msup was similar for the young and elderly, whereas Hmax/Mmax was 39% lower in elderly men (n.s., P=0.08). The lack of statistical significance is probably due to the elevated inter-subject variability in Hmax/Mmax showed by the elderly (CV:50%). No difference in V/Msup was found between the young and elderly [0.23±0.17 vs.0.24±0.18].

This study confirms a trend towards a decrease in neural peripheral functionality with senescence. Nevertheless the age-related depression in reflex amplitude observed at rest, disappeared during muscle contraction. The lower reflex amplitude at rest reflects an alteration of the balance between spinal excitatory and inhibitory mechanisms. The similar reflex amplitude during contraction indicates that the depression in excitability and/or the rise in inhibition are compensated or removed during contraction. In other words the spinal excitatory and inhibitory pathways preserved their capacity to adapt to the contraction demands placed on the system. The preservation of the V-wave also suggests that ageing does not affect the central motor drive, as proven by the unchanged voluntary activation (Scaglioni et al. 2001). Collectively these findings support the notion that the age-related neural adaptation mainly occurs at spinal level. In conclusion the modulation in reflex response may be viewed as a compensatory adaptation of the peripheral neural system to preserve its efficiency during contraction despite the age-related impairment of the segmental reflex system observed at rest. These results also suggest that ageing-induced changes in neural function should be evaluated by using H-reflex recorded during muscle contraction and not merely in resting conditions.

ROLE OF WARMING UP ON EXCITABILITY AND PERFORMANCE DURING MAXIMAL ISOMETRIC EXERCISE
Hilbert, M., Wittke, T., Starke, H., Maasssen, N., Shushakov, V.
Medical School Hannover, Germany

The mode of warming up before sport activities has been discussed for several years. A new perspective was added by Pedersen et al. (2005) showing that acidosis or high lactate concentration may be beneficial for the excitability of muscles and may reduce fatigue. Thus we compared 3 different protocols of “warming up” preceding a maximal isometric handgrip contraction lasting until the developed force decreased below 33% of maximum.

11 subjects not especially trained in forearm exercise participated in the study. In the first test a 2 minutes warm up on a cycle ergometer with maximum power reached in an incremental test preceded the isometric test (C). In the 2nd test the subjects had to perform dynamic handgrip exercise for 10 min at 50% of the maximal power reached in an incremental handgrip test as warming up (H). The control trial was performed with no warming up (CON). Maximum force and the time course of the force were recorded. When force dropped below 33 % of maximum the experiment was finished. Blood was taken from a cubital vein of the working arm. Lactate, plasma potassium and sodium concentration and pH were determined. M-wave was recorded via surface electrodes from forearm flexors. Therefore the motor point of the muscle was stimulated supra maximally with rectangle constant current pulses.

The maximum force was not different between the three conditions. However fatigue was greatest after H as performance time was significantly shorter (about 25%) compared to C and CON (p<0.005). The performance times under C and CON did not differ. After warming up on a cycle ergometer, lactate concentration was significantly higher (p<0.001) and the pH remained significantly lower in comparison to the other conditions during the whole experiment (p<0.01). After warming up with dynamically contracting forearm muscles, the isometric contraction started at lower Potassium concentration (P<0.05). At the end of exercise the difference between the conditions had vanished. The M-Wave area increased after H (p<0.01) and remained larger than CON (p<0.05) after the isometric exercise. The decrease in the M-Wave area in comparison with the resting value was most pronounced in CON. Also M-wave duration increased in comparison with other conditions in CON (p<0.05). Under the two other conditions the M-wave duration did not significantly differ from the initial value.

Active warming up did not improve maximal isometric force but reduced performance time. Passive warming up of the forearm muscles by cycling increased lactate concentration and decreased pH. In contrast to Pedersen et al. this did not increase M-wave and performance. Thus a performance enhancing effect on the excitability by lactate or pH seems to be improbable (Shushakov et al. 2007). However in contrast to the traditional view the acidosis did not decrease performance. However, active warming up may decrease muscular performance.

RELATION BETWEEN HEART RATE VARIABILITY AND SUBJECTIVE FEELING OF FATIGUE IN ELITE SPEED SKATERS
Iizuka, T., Maegawa, T., Kon, M., Hashimoto, E., Yuda, J., Aoyanagi, T., Takahashi, H.
Japan Institute of Sports Sciences, Japan

Since it has been considered that fatigue has negative influence on performance in competitive sports, careful monitoring and controlling of the physical fatigue level might be essential for athletes to achieve good performance in competition. Although resting heart rate has
EFFECT OF POSTACTIVATION POTENTIATION ON ENDURANCE TIME IN THE DORSIFLEXORS

Shima, N., Ohta, Y.
National Institute of Fitness and Sports, Japan

Introduction: It is well known that after a brief maximum voluntary contraction (MVC), the force of a twitch contraction is increased as compared with the twitch force preceding the MVC (Shima et al. 2006). This enhancement is called twitch potentiation or postactivation potentiation (PAP) which may offset fatigue of endurance exercise. However, it is unknown whether PAP improves endurance time (the time to task failure) for submaximal contraction. The purpose of the present study was to examine the effect of postactivation potentiation on endurance time in the dorsiflexors. Methods: Nine men (23±1 years) were seated in a custom-built isometric dynamometer with their right ankle positioned at 20° of plantar flexion, and an angle of 90° at both the hip and knee joints, and performed intermittent (6s-on, 4s-off) isometric dorsiflexions at 60% of MVC until exhaustion. Evoked twitch torque (Pt) was obtained during each 4s rest period. With more than 3 days interval, these task performed after 30s later of 10s MVC (PAP condition) and without PAP condition (normal condition). The mechanomyographic (MMG) signal was detected by a uniaxial accelerometer which was 9 mm square with a thickness of 4.5 mm and a mass of 0.75 g. The accelerometer was secured to the skin with double-sided adhesive tape over the portion of the tibialis anterior muscle belly that yielded the minimum rise-time of the evoked MMG signal. The surface EMG signal was recorded using surface bipolar electrodes in the TA. Results: Subjects completed 18.8±2.5 and 15.5±1.8 contractions [means±SEM] before the target torque could no longer be attained at normal condition and PAP condition, respectively. Endurance time of PAP condition was longer than normal condition in 3 subjects, but not other 6 subjects who has smaller Pt at 20% of time-to-fatigue at PAP condition than normal condition. However, evoked MMG were no different between PAP condition and normal condition in 6 subjects. There is significant relationship between magnitude changes in Pt by PAP with 10s MVC and magnitude changes in endurance time from normal condition to PAP condition. Conclusion: The inconsistent effect of PAP on endurance performance in dorsiflexors would not be caused by muscle contractile properties.

EFFECTS OF VIGOROUS LATE-NIGHT EXERCISE ON CARDIOVASCULAR AUTONOMIC CONTROL AND SLEEP QUALITY

Myllymäki, T., Hokka, L., Savolainen, K., Jakonen, R., Martinnmäki, K., Kaartinen, J., Kyröläinen, H., Kinnunen, M., Rusko, H.
University of Jyväskylä, Finland

Background
Physical exercise creates a great need for recovery, and sleep is the most important period for recovery. Heart rate variability (HRV) has been used to measure the autonomic nervous system function, which plays a central role in the recovery process. Previous studies assessing ANS function after exercise have mostly concentrated on acute post-exercise recovery. This study evaluated the effects of a vigorous late-night exercise on autonomic cardiovascular control and sleep quality during the subsequent night's sleep.

Methods
The sleeps of seven young subjects (3 males, 4 females, aged 24±4 yrs, VO2max 45±12 ml/kg/min) were monitored in a sleep laboratory in a counterbalanced order 1) after a day including vigorous late-night exercise and 2) after a control day without exercise. During the exercise day, the subjects performed an incremental cycle ergometer exercise until voluntary exhaustion. The exercise started at 21.19±0.20 hh min and lasted for 28±4 min. The time difference from the test termination to bed time was 2.16±0.21 hh min. During sleep, ECG RR-intervals [Alive Heart Monitor], actigraphy [Actiwatch Activity Monitoring system] and polysomnography [BrainVision Recorder] were recorded. The variables of autonomic cardiovascular control (heart rate [HR], HRV, as well as stress and relaxation vectors based on both HR and HRV) were analyzed with WinBeat PRO Heartbeat Analysis Software. The actigraphic sleep quality was analyzed with Actiwatch Sleep Analysis Software, and polysomnographic sleep quality from the sleep stages determined using a standardized scoring protocol. The analyses were performed for the whole sleep period, and variables of cardiovascular autonomic control were analyzed also hour by hour after being bed time. Statistical differences were examined using Wilcoxon signed ranks test.

Results
During the whole sleep, there was a tendency for higher HR as well as stress vector (p=0.075 and 0.063, respectively) after exercise compared to control condition. HRV as well as actigraphic and polysomnographic sleep quality did not differ between the two sleeps. When looking the cardiac autonomic control during the successive one-hour periods, it was found that HR and stress vector were significantly elevated for the first hour of sleep (p<0.05), and remained elevated (but not significantly) for the next three hours in exercise condition compared to control condition. No changes were found in HRV or relaxation vector during the one-hour periods between different conditions.
Discussion
The study showed that relatively short vigorous exercise 2-2.5 hours before bed time did not influence HRV or objective sleep quality but was sufficient to increase HR as well as stress vector (calculated from HR and HRV) during the first hour of sleep. Thus, our results are consistent with the general view that late-night exercise may impair sleep, and indicate that physiological stress reactions caused by exercise may be reflected in cardiac autonomic control.

IDENTIFYING THE ANGIOTENSIN-CONVERTING ENZYME GENE POLYMORPHISM IN TRAINED SUBJECTS BY CARDIO-RESPIRATORY RESPONSE

España-Romero, V., Ruiz, J., Ortega, F., Artero, E., Jimenez-Pavón, D., Gutierrez, A.
Faculty of Human Kinetics, Portugal

Introduction.
The I allele of the angiotensin-converting enzyme (dipeptidyl carboxipeptidase II) I/D polymorphism has been found with increased frequency in cohorts of elite endurance athletes (I). The role of the I allele in improving endurance ability probably results from higher aerobic power but this relationship has not yet been clearly demonstrated in a group of endurance trained subjects.

Purpose.
To evaluate the effect of I allele in maximal aerobic power and other measures of endurance capacity in a group of endurance trained subjects.

Methods.
In this preliminary study, 42 endurance trained males (34.2±7.2 yrs) performed an incremental maximal exercise on a treadmill after an overnight fast. Respiratory data were recorded breath-by-breath (Quark b, COSMED, II) and averaged over 15 s intervals for measurement of maximal oxygen uptake, maximal rate of expired air, and maximal tidal volume. The anaerobic threshold was identified by the V-slope method and was expressed as percentage of maximal oxygen uptake. Blood pressure was measured at rest. The ACE genotype was determined by PCR amplification of DNA extracted from blood leukocytes.

Results.
The number of subjects of the DD, ID and II genotypes were respectively 25 (59.5%), 16 (38.0 %) and 1 (2.5%) thus deviating from Hardy-Weinberg equilibrium. Maximal oxygen uptake was 55.6±8.2 ml/(kg.min) and 58.6±9.3 ml/(kg.min) for DD and ID/II subjects, respectively (p=0.206). Maximal ventilation, tidal volume and anaerobic threshold were all similar between the ACE genotypes. Systolic blood pressure values were significantly higher in the DD genotype group (p=0.033). Stepwise discriminant analysis correctly classified 76.7% of the subjects on their ACE genotype based on values of systolic and mean blood pressure alone.

Discussion.
The I allele of the ACE gene is associated with lower activity of the respective enzyme and with lower levels of Angiotensin II. This allele has been found with higher frequency in elite endurance athletes and it might contribute to an endurance phenotype through different mechanisms (2). However, in our cohort the presence of the I allele did not mean higher maximal rate of oxygen uptake or differences in the anaerobic threshold an important marker of aerobic capacity. Higher systolic blood pressure was associated to the DD genotype and this is in line to effects of the renin-angiotensin system in the cardiovascular system and particularly with the vasoconstrictor action of Angiotensin II. It is interesting that simple blood pressure measurements quite accurately distinguish the DD genotype from the ID and II ones. A larger cohort of endurance trained subjects is needed to confirm the present results.

This study was funded by grant POCI/DES/60763/2004 from Fundação para a Ciência e a Tecnologia.

BODY FAT IN ELITE ROCK CLIMBERS MEASURED BY ANTHROPOMETRY AND DUAL ENERGY X-RAY ABSORPTIOMETRY

España-Romero, V., Ruiz, J., Ortega, F., Artero, E., Jimenez-Pavón, D., Gutierrez, A.
School of Medicine, University of Granada. Facultad de Ciencias de la Actividad Física y el Deporte, Universidad Politécnica de Madrid, Spain

Body fat mass is an important marker of performance in many sports disciplines, and particularly in climbing. Body fat percentage (BF%) can be either estimated from skinfold thickness by using sex-specific equations, or by using more accurate methods such as dual-energy X-ray absorptiometry (DXA). Nowadays, there is no consensus about which of the 17 published equations (7 in males and 10 in females) is the most appropriate for estimate BF% in elite rock climbers.

PURPOSE: To compare the most commonly used equations to estimate BF% from skinfold thickness, in male and female rock climbers with DXA as a reference method of fatness measurement.

METHODS. A total 19 elite rock climbers (9 females and 10 males) volunteered to participate in the study. Skinfold thicknesses were measured at the triceps, biceps, subscapular, iliac crest, supraespinale, abdominal, front thigh, medial calf according to the criteria described by the ISAK, level 1. BF% was estimated from skinfold thickness using 17 different equations. BF% was also measured with dual-energy X-ray absorptiometry (DXA).

RESULTS. A systematic bias was found for all the equations studied, except for Durnin’s equations in males and females, and for Wilmore’s equation in females. In females, both bias and the limits of agreements were lower when using the Durnin’s equation compared with the Wilmore’s equation (bias: -0.67±1.97 vs -1.81±2.62, respectively, limits of agreements: 3.86 vs 5.13, respectively).

CONCLUSIONS. Out of the 17 equations tested, the Durnin’s equation seems to be the most accurate one, and the can be used in both males and females rock climbers until a more accurate prediction equation or other simple method of body composition estimation are developed.

DEPLETION AND RESYNTHESIS OF GLYCOGEN IN ARM AND LEG MUSCLES AFTER A CLASSICAL 15-K CROSS-COUNTRY SKI RACE

Holmberg, HC., Bonne, T., Örtenblad, N.
Swedish Winter Sports Research Centre, Sweden

Introduction: Bicycle exercise or running has been most often used in studies of glycogen usage during exercise and the replenishment in the recovery afterwards. In cross-country skiing muscle glycogen is probably a dominant factor for maintaining speed and can be crucial in the finish. In this sport the arms may be more critical than the legs both for speed and finish, especially in the classical technique. Thus, in the present study we examined muscle glycogen content in arm and leg muscle in connection with a race and the first 24 hrs after the race with two specific aims. 1) Evaluate whether arm muscles use more glycogen than the leg muscles and whether there is a muscle fibre type specific glycogen depletion pattern for the type 2 fibres, 2) Evaluate whether water intake instead for carbohydrates during the first 4 hrs after the race affect the resynthesis of glycogen acutely and next morning.

Methods: Ten elite male competitive cross-country skiers (Age:22, Body height:182 cm; Body mass:80.8 kg; VO2max:72 ml kg-1 min-1) performed a 15K classical race in varying terrain. The subjects were placed into two groups, a H2O-group and a CHO-group. Directly after the race the H2O-group was only allowed to drink water whereas the CHO-group used a normal post-race strategy to refill CHO with sport drink and gel and thereafter a meal. After 4 hrs both groups had the same carbohydrate enriched food intake. Muscle biopsies were obtained from an arm (triceps brachii) and a leg (v. lateralis) muscle before, directly after, as well as 4 and 20 hrs after the race. Muscles samples were analyzed for fibre types and glycogen as well as glycogen depletion pattern. Results: Muscle glycogen measured directly after the race was reduced by 32 % [484.7 to 331.3 mmol kg-1dw] in the legs and 69 % [from 540.2 to 167.1 mmol kg-1dw] in the arms. Type 1 muscle fibre type depletion was the dominant finding for both arms and legs, with some type 2A fibres being partly depleted in the arms. After 4 hrs with water no elevation in neither arm nor leg muscle glycogen content was observed but with CHO the legs did increase with 80 and the arms with 110 mmol kg-1dw and significantly more in the legs compared to the arms (P<0.05). Next morning regardless of being in H2O- or the CHO group all subjects had returned to close to their pre-race muscle glycogen content in both arms and legs. Conclusion: The main findings were 1) in classical/diagonal skiing is the recruitment pattern of muscle fibre types the typical for prolonged exercise with primarily type 1 fibres being glycogen depleted but equally clear is that the arms are more used than the leg muscle as muscle glycogen stores were more markedly utilized in the arm as compared to the leg muscles 2) Restoration of the muscle glycogen stores are dependant of a carbohydrate intake but of note is that in only 20 hrs of recovery was the pre exercise glycogen level reached regardless of no carbohydrate intake for 4 hrs immediately after the race.

IMMUNOLOGICAL AND HORMONAL RESPONSES TO A FOUR-DAY COMPETITION PERIOD IN FEMALE SWIMMERS

Pessoa, P., Rama, L., Teixeira, A., Alves, F.
Faculty of Human Kinetics, Technical University of Lisbon, Portugal

Introduction. Acute stress has been reported to increase the activity of the hypothalamus-pituitary adrenal (HPA) axis. Near or during competitions, both muscular and metabolic fatigue and anxiety and arousal typical of these situations can influence salivary cortisol (C) and testosterone (T) levels as well as mucosal immunity, reflected by salivary immunoglobulin A (IgA) levels. Conversely, the ratio T/C has been considered as an index of fatigue and readiness to perform.

The main objective of this study was to examine the salivary IgA, testosterone (T) and cortisol (C) and their ratio (T/C) responses to the proximity and participation in season major competitions in a group of national level female swimmers.

Methods. Saliva samples were collected from 9 female swimmers (age: 16.87±2.32 years, height: 168.10±3.25 cm, body mass: 62.40±3.28 kg), in a fast state, between 7:00 and 7:30 am, during the three days preceding the National Championships and the four days of its duration.

Every subject swam at least one event in the morning (heats) and other in the afternoon (finals). Salivary IgA (mg/l) and T (pg/ml) concentration was determined using the BN2 Analyser (Dade Behring, USA). C (g/dl) and T (pg/ml) concentrations were determined using ELISA kits (Salimetrics, USA). Self-ratings questionnaires of well-being were applied every day after breakfast.

Results. IgA concentrations were relatively stable through the days before the competition and then increased significantly to the second day of the competition (66.87%, p<0.01), remaining at high levels until the last day. C showed a pattern of variation similar but with a significant increase the day before the beginning of the championships (61.65%, p<0.05) with highest values in the last day of competitions. T increased gradually during the days of competition, showing no significant variation between the day before and the third day of competition. Psychometric evaluation and T/C showed no significant variations.

Conclusions. The accumulated fatigue induced by consecutive racing days did not hinder the immune response in this group of female swimmers. The increasing levels of C during the competition days may be the effect of both psychological and metabolic stressors. The increase in T, however, means that a functional balance between catabolic and anabolic processes is in place. Nevertheless, pre-competitive psychological stress did not seem to influence the adrenocortical activity of these athletes.

LACTATE CHARACTERISTICS IN CYCLISTS OF DIFFERENT AGE AFTER MAXIMAL CYCLING EFFORT

Zinner, C., Wahl, P., Frese, S., de Maré, M., Häggle, M., Bloch, W., Mester, J.
German Sport University Cologne, Germany

Introduction. Several studies show that, in terms of maximal lactate concentration, children have a lower anaerobic capacity than adolescents and adults. The higher absolute maximal blood lactate values of youth and adults are taken to confirm this statement. Studies investigating athletes of different ages only compared maximal lactate values. In this study the time course of blood lactate after a maximal cycling test was measured, furthermore all subjects had a common training situation, so that they are highly comparable.

Methods. 10 boys (13±0.4years) and 13 male adolescents (17±0.9years) participated in the study. The subjects performed a 30 sec lasting maximal sprint test on a cycle ergometer. The cycle ergometer was adjusted to an isokinetic mode regulating the cadence to 120 rpm. The subjects were instructed to perform the test only in a sitting position on the ergometer.
Blood samples were taken pre, 0min, 1min, until the 10th min, every minute to determine lactate concentrations in whole blood. After the test, the subjects recovered ten minutes passive in a sedentary position, to keep lactate elimination as low as possible.

Results
The adolescent group had a significantly higher mean Peak Power (PP) in the 30 sec trial than the boys (976.1±101.5 Watt [W] vs. 600.3±168.0 W). The relative PP (rePP) reached by the adolescents (14.0±1.4 W/kg) was also significantly higher compared with the boys (rePP 11.4±1.8 W/kg).

During the 30sec a mean power output of 445.4±104.0 W was reached by the boys and 697.4±62.6 W by the adolescents. The relative mean power reached by the adolescents was 10.0±0.7 W/kg bodyweight and the boys reached 8.5±1.2 W/kg bodyweight.

The adolescent group reached a significant higher peak lactate level of 11.5±1.3 mmol/l in the 6th minute of recovery. The boys reached their peak lactate level of 9.4±1.6 mmol/l in the 4th minute. In contrast to the absolute lactate values, rel. lactate values were significantly higher for the boys. The values were 0.18±0.02 mmol/l/kg for the boys and 0.16±0.02 mmol/l/kg for the adolescents.

Discussion
Adolescents reached higher absolute lactate values, but related to the bodyweight, boys even showed significantly higher lactate values, which might be hint for similar anaerobic energy production. Shorter circulation and diffusion distances in boys might be responsible for the earlier peak in absolute lactate values, compared with adolescents. This is in line with findinds from literature (Beneke, R., Hüttler M., Jung M., Leithauser R. M. Modeling the blood lactate kinetics at maximal short-term exercise conditions in children, adolescents, and adults. J. Appl. Physiol. 99:499-504, 2005).

Comparing the PP of the two groups, the adolescents achieved a significantly higher mean PP, a significantly higher relPP and a significantly higher mean power output over the 30sec than the boys. This is likely due to the more limited ability of younger athletes to recruit and use higher-hierarchy motor units.

HARDINESS AND PERFORMANCE-INDUCED EMOTIONS IN FIELD HOCKEY
Neil, R., Mellalieu, S., Copley, B.
University of Wales Institute, Cardiff, United Kingdom

This study examined the influence of hardiness upon the intensity and direction of competitive emotions and performance during critical events in sporting competition. Participants were 40 female field hockey players (M=21.67, SD=2.34) ranging from regional (equivalent to state honors) to national standard. Each performer completed a modified version of the Sport Emotion Questionnaire (SEQ; Jones, Lane, Bray, Uphill, & Catlin, 2005) when undergoing retrospective video-stimulated recall procedures (Sève, Ria, Poizat, Saury, & Durand, 2007) in relation to their performance during critical incidents in field hockey matches (i.e., offensive and defensive short corners). Performance was recorded via objective ratings from expert field hockey coaches and subjective ratings from the participants. Significant differences were observed in the direction and intensity of emotions experienced between high and low hardy groups. Specifically, high hardy individuals reported lower anxiety and greater excitement and happiness symptoms than their low hardy counterparts, which were reported to be more facilitative to performance during the critical incident. The high hardy group also scored higher on both objective and subjective measures of performance than the low hardy performers. Additional qualitative analysis revealed match importance, fatigue, social facilitation and expectation concerns, and previous poor performances during the match as antecedents of the performer’s emotional experiences. High hardy individuals suggested the emotions influenced performance via increases in focus and activation while low hardy performers indicated low self-confidence, concentration disruption, and negative thinking as factors contributing to poor performance. The findings support theory and previous research that suggest high hardy individuals not only appraise the demands encountered as less threatening in high-pressure situations (competitive sport) but interpret the subsequent emotional symptoms experienced as more facilitative to performance and are, consequently, more successful in these situations than their low hardy counterparts (Hanton, Evans, & Neil, 2003). Hardiness training may therefore offer practitioners with a realistic procedure with which to alter the performer’s meaning of the stressor and/or their subsequent emotional response in relation to the stressor, thereby maintaining or enhancing performance.

WHAT REASONS YOUTH INDICATE TO DROPOUT SPORT?
Cañita, L., Brustad, R., Fonseca, A.
Sport Faculty, Oporto University, Portugal

It is consensual that the practice of sports activities by children and youngsters assumes a significant meaning in certain moments of their lives. Therefore it is not at all strange that millions of people around the world join organised sport (Knop, Engstrom, Skirdstad & Weissl. However, paradoxically, many decide to quit sports practice too (Gould, 1987). Due to the lack of investigation in Sport Psychology area, we tried to find out if what Dan Gould designated as Surface Motives to dropout of Sport have remained immutable in the course of time. The sample was composed by 727 young people aged between 12 and 18, athletes from several individual and team sports. 62.6% were male and 37.4% were female. To access the intended information an inventory was built, having as a starting point an exhaustive literature revision on the sport drop-out theme and a pre-study done to individuals with the same characteristics of our sample. They were asked to indicate if they had already quit sport practice and why.

Saturday, July 12th, 2008
In general the results indicated that the main reasons for the dropout were: the lack of family/friends’ support (2.62±1.52), the parents’ pressure towards successful education (2.58±1.45) and the coaches’ lack of ambition (2.53±1.40).

In the gender analyses, boys pointed out the motives referred by the general sample (2.72±1.50, 2.70±1.45; 2.69±1.38) in the same order, whereas girls pointed out the conflict of interests regarding other activities (2.69±1.53) and the lack of family/friends’ support (2.56±1.58), as being the strongest motives to the dropout. Contrarily to boys, girls did not make any reference to the coaches’ lack of ambition, and the allusion to the parents’ pressure towards successful education appeared only in the 8th position (2.41±1.59).

The comparative analyses between the two genders statistically stressed significant differences in 16 of the aimed motives, with boys registering superior medium results in every one of them when compared to girls. The most important were: the parents’ pressure towards successful education (t= 2.03, p<.043), the coaches’ lack of ambition (t= 2.95, p=.003), the coaches’ bad training methods (p=.001), and the bad relationship with the coach (t= 2.64, p<008).

Notwithstanding the fact that some of this results have pointed to previously obtained ones, conflicts regarding education, mentioned in our study through the parents’ pressure towards successful education, levelled with the lack of family/friends’ support, they appear to be, at least, two of the growing motives which lead Portuguese young athletes to quit.

THE EFFECT OF EXPERIMENTALLY PROVIDED SOCIAL SUPPORT ON GOLF-PUTTING PERFORMANCE
Rees, T., Freeman, P.
University of Exeter, United Kingdom

There is considerable evidence to suggest that individuals who perceive their relationships as supportive experience a range of favorable outcomes, and recent studies in sport have demonstrated links between social support and performance in tennis and golf (e.g., Rees & Hardy, 2004; Rees, Hardy, & Freeman, 2007). For researchers and practitioners alike, given this evidence, knowledge is needed about the impact upon performance of providing individuals with social support. Furthermore, it would be important to attempt to elucidate whether the impact of support provision is the same for all individuals, or whether the impact may differ dependent on whether individuals perceive themselves to have high or low levels of support available to them. With this in mind, the present study examined in a laboratory environment the impact of a simple support manipulation on objective task performance. Participants (N = 100) were administered a 20-item measure of perceived support. Of these participants, those with the highest (N = 18) and lowest (N = 18) support scores were subsequently requested to participate in the experimental task. These participants were further sub-divided into the experimental support and control conditions. The task involved 10 golf putts from a 10-foot distance to a target of 10 evenly spaced concentric circles, with the innermost circle denoting a value of 10 points, and the outermost circle denoting a value of 1 point. A 2 (perceived support: high, low) by 2 (manipulation: support, control) ANOVA was performed on the scores in the putting task. There was no difference in the scores of participants rated as high or low on perceived support.

The support manipulation was led to feel more secure and thereby reported less frequent and distracting task-irrelevant thoughts, and this facilitated better performance scores.

WHY DO YOUNG PEOPLE THINK OF DROPPING OUT FROM ORGANIZED SPORT
Catita, L., Brustad, R., Fonseca, A.
Sport Faculty, Oporto University, Portugal

Notwithstanding the range of reasons given by youngsters to justify their drop out of sports, some studies have highlighted the role given to practice intentions as predictors of the real behaviour (Down & Hausenblas, 2005). In this matter we intend with this study to identify the subjacent motives to the dropout intention, so as to try to take action before it really happens.

3178 individuals have participated, aged 12-18 (1749 boys and 784 girls), all of them being organized sports athletes.

In general, the results showed the club change associated to the wish of improving (20.9%), the conflict with other activities/interests (18.2%) and the bad relationship with the coach (27.7%) as the main reasons indicated by youngsters to a possible dropout. Contrarily to boys, girls did not make any reference to the coaches’ lack of ambition, and the allusion to the parents’ pressure towards successful education appeared only in the 6th position (26.1%).

3178 individuals have participated, aged 12-18 (1749 boys and 784 girls), all of them being organized sports athletes.

Regarding the age, we verified that athletes aged 12-14 (749 boys and 784 girls) all of them being organized sports athletes.

Globally, the results showed the club change associated to the wish of improving (20.9%), the conflict with other activities/interests (18.2%) and the bad relationship with the coach (27.7%) as the main reasons indicated by youngsters to a possible dropout. Contrarily to boys, girls did not make any reference to the coaches’ lack of ambition, and the allusion to the parents’ pressure towards successful education appeared only in the 6th position (26.1%).

For the boys, the conflict with other activities (35.4%) was highlighted as the main reason for a possible dropout, followed by the education conflict (27.7%) and the lack of interest/motivation (17.7%).

The boys’ first motive was only pointed out in the 6th position by the girls (3.1%), therefore it is not strange to find statistically significant differences between the two genders (X2=19.07, p=0.001). These differences were also registered in the other two motives in which girls had higher levels: education conflicts (X2=7.86, p=0.005) and conflicts with other activities/interests (X2=17.82, p=0.001).

Regarding the age, we verified that athletes aged 12-14 gave a bigger importance to the conflicts with other activities (32.4%) with education (27.7%) and to the lack of interest/motivation. The ones aged 15-16 mentioned the club change associated to the wish of improving in the first place (26.1%), the conflicts with other activities (13.1%) and education conflicts (8.7%). The older, aged 17-18 also mentioned the club change associated to the wish of improving as the most important one (25.9%), followed by the education conflict (24.1%) and the conflicts with other activities (17.2%). Therefore it is not strange to find statistically significant differences between the 3 groups when the motives related to the education (X2=9.17, p=0.010) and the club change associated to the wish of improving (X2=12.15, p=0.002) are mentioned.

662
13th Annual Congress of the European College of Sport Science
In view of the results, it seems that the motives which are subjacent to the dropout intention are globally coincident to the ones enumerated before the actual dropout. (see Butcher, Johns & Linder, 2002).

THE ANALYSIS OF AUDITORY EVOKED BRAIN POTENTIALS DURING SUCCESSFUL AND UNSUCCESSFUL SHOTS IN RECURVE ARCHERY

Ertan, H., Yagcioglu, S., Korkusuz, F., Ungan, P.
Anadolu University, Turkey

Archery can be described as a static sport requiring strength and endurance of the upper body, in particular the shoulder girdle. The bowstring is released when audible impetus is received from a device called clicker. As the fall of the clicker is an acoustic stimulus, it may evoke a sequence of electrical potentials that can be recorded from the scalp of an archer. These Auditory Evoked Potential (AEP) components occur at different latencies and with various relations to the auditory stimuli. Therefore, the present study aims to investigate the long-latency responses in relation with successful and unsuccessful shots in Recurve archery.

The subjects were 15 archers (9 males) for archery shooting experiments. All subjects reported normal hearing, had medical histories free of significant neurological problems, and were not taking medication known to affect brain activity. The mean age was 22.8 years (range 16 yrs - 31 yrs) and the mean years of archery experience and the highest FITA scores were 5.8 years (range 2 yrs - 14 yrs) and 1120 (range 1050-1313) FITA score, respectively. Each archer shot 72 arrows from 18 m after completing twelve trial shots to acquaint with the measurement conditions. Hits of an archer were recorded by placing the hits on a coordinate system for further analysis. All these hits were matched with the single sweeps of EEG recordings. Finally, hits were grouped as falling into the hit-area and miss-area with their corresponding EEG recordings. Mean amplitude (iV) and latency (msec) values of N100 and P200 components corresponding to hit and miss areas during archery shooting were calculated separately.

Vertex-recorded AEPs consisted of 200 ms pre- and 800 ms post-stimulus (fall of the clicker) periods. EEG was continuously recorded between the earlobe and vertex (Cz) and stored for off-line analysis. AEPs were band pass filtered (112 Hz). The peak amplitudes and latencies of the auditory N100 and P200 waves were measured. Latencies were measured relative to the stimulus onset and amplitudes measured relative to the mean value in the 200 ms preceding stimulus onset. N100 amplitude and latency were measured at the maximum negativity between 50 and 150 ms, and P200 amplitude and latency at the maximum positivity between 150 and 250 ms, respectively. Grand-average waveforms did not reveal consistent components with latencies longer than 200 ms (e.g. N200, P300 etc.).

It was observed that the fall of the clicker in archery shooting increases the amplitude of NI component. However, no difference was noted between successful and unsuccessful shots in terms of NI-P2 amplitude and latency. Thus, both successful and unsuccessful shots have the same effect on the brain evoked potentials in archery shooting.

GOAL STRIVING AND WELL-BEING IN SPORT: A PROSPECTIVE INVESTIGATION OF THE ROLE OF COACH BEHAVIORS

Smith, A., Ntoumanis, N.
University of Birmingham, United Kingdom

In sport, anecdotal and empirical evidence supports the role of goal setting in the mobilization and direction of resources toward desired objectives. Previous cross-sectional research (Smith, Ntoumanis, & Duda, 2007) identified support for the self-concordance model (Sheldon & Elliot, 1999) as a framework for investigating personal goal striving in sport. Grounded in self-determination theory (Deci & Ryan, 1985), the model advocates the benefits of striving for goals with relatively autonomous motives for goal attainment and resultant changes in psychological well-being. In addition, Smith et al. identified coach autonomy-support and social-contextual predictors of athletes’ autonomous goal motives. Developing upon these findings, the present study further examined athletes’ goal striving using a prospective design and assessed the impact of controlling, in addition to autonomy-supportive, coach behaviors.

At the start of the sport season, 108 athletes (63 male, 45 female) nominated personal goals that they would be pursuing during the season and completed self-report measures of coach behaviors and goal motives. At the approximate mid-point of the season participants were reminded of their goals and completed measures of perceived goal progress and relative well-being.

Contrary to our expectations, goal progress mid-way through the season was not predicted by goal motives and did not predict well-being. Structural equation modeling analysis supported a model (scaled 2 (6) = 6.30, p > .05, CFI = .99, NNFI = .98, RMSEA = .02 (CI = .00, .14), SRMR = .07) in which coaches’ autonomy-supportive and controlling behaviors at the start of the season were positively linked to autonomous and controlled goal motives, respectively. In turn, autonomous and controlled motives positively and negatively predicted mid-season relative well-being (created by subtracting summed negative affect and emotional/physical exhaustion from summed positive affect and life satisfaction).

The present study supports the role of the coach in fostering autonomous goal motives and the benefits of such motives for psychological well-being. Furthermore, the study highlights the detrimental implications of controlling coach behaviors. Non-significant links to goal progress may be attributable to the use of mid-season measures which reflect perceived progress relative to future expectations. Future research further examining links to progress and later attainment is warranted.

PERFORMANCE STRATEGIES ON ADAPTED SPORTS IN ELITE AND AMATEUR ATHLETES

Pinho, JP., Fonseca, M.
Faculdade de Desporto da Universidade do Porto, Portugal

Introduction: Lately, the increasing attention given to paralympic sports makes psychological preparation even more important, acquiring a key role in preparing athletes. Psychological preparation includes the performance strategies training (concentration, confidence, motivation, relaxation, activation control, mental preparation, ...) that can be taught, practiced and improved like any other motor skill, and just like the motor skills, psychological skills are closely related to sports performance.

Purpose: The purpose of this study is to compare the performance strategies, during training and competition, on both elite and amateur athletes.

Methods: 14 motor disable adapted swimming athletes served as subjects: 8 amateur athletes members of Futebol Clube do Porto (FCP) and 6 elite athletes members of the Portuguese National Team (PNT). FCP athletes have been participating of official competitions for 4.5 ± 3.7 years, training 2.6 ± 0.7 hours per week and participating of 3 national competitions per year. PNT athletes have been participating of offical competitions for 8.2 ± 3.9 years, training 17 ± 5.9 hours per week and participating of 9 ± 3 national competitions and 3 international competitions per year. TOPS (Test of Performance Strategies) questionnaire was applied in order to measure the psychological skills and strategies used by the athletes in competition and during practice, analysing nine psychological variables: Goal-setting, Emotional Control, Automaticity, Relaxation, Self-talk, Imagery, Activation, Attentional Control and Negative Thinking. Statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS) and was made the following statistical procedures: - Descriptive Statistics: mean, standard deviation; - Statistical Inference: T-test of independent measures.

Results: In practice, only the Emotional Control variable (FCP=3.13 ; PNT=2.54) showed statistically significant differences (p=0.05). In competition the following variables showed statistically significant differences: Goal-setting (FCP=3.47 , PNT=4.58), Emotional Control (FCP=2.69 ; PNT=2.04), Self-Talk (FCP=3.28 , PNT=4.46), Imagery (FCP=3.22 ; PNT=4.33) and Activation (FCP=3.44 ; PNT=4.46).

Conclusions: elite athletes, compared with amateurs, have specific psychological skills that enable them to overcome psychological barriers imposed by the competition stress. The number of hours of training and the participation in competitions has a positive impact on the psychological development of these athletes.

THE SIGNIFICANCE OF MOTIVATIONAL STYLES AND RESISTANCE TRAINING IN ELITE JUNIOR CROSS-COUNTRY SKI PERFORMANCE

Welde, B., Svebak, S.
North-Tromsø University College, Norway

Fifteen females and 13 males, all elite junior cross-country skiers, took part in a resistance training program to test effects on ski performance. They were randomized to a maximal versus endurance resistance program, with half of the participants training for 9 weeks and the rest for 5 month, and all completed survey measures on motivational styles supposed to be of importance for coping with stresses of sport participation. These surveys included the Sport Orientation Questionnaire with measures of goal-, win-, and competition-orientation, as well as the Telic Dominance Scale with measures of planning orientation, serious mindedness, and arousal avoidance. Other measures included negativism, optimism and sensation seeking. Survey results were tested in multiple regression analyses as predictors of racing scores in the season following the training intervention. Results supported the conclusion that optimism and the sport-specific measure of competitiveness predicted excellence when effects of type of resistance training, length of intervention and gender were eliminated.

COHESION, PHYSICAL SELF-PERCEPTION IN A COMMUNITY FITNESS PROGRAM

Borrego, C., Silva, C., Cid, L., Moulojo, J., Granjeia, R.
ESDORM- Sport Sciences School of Rio Maior, Portugal

The postive role exercise can play in promotion physical wellbeing has received a great deal of attention over the last decades. Recent public policy reports such the Portuguese, urge all people to be active on a regular basis. Although the physical benefits of exercise are well document and promoted, evidence for similar relationship between exercise and psychological benefits is less clear.

In the field of sport, more precisely in the area of fitness, the adherence in the first month of the sport season it’s high but as time goes by, in the winter months there is an increase of absenteeism, taken some people to drop-out from exercise. Authors like Spink and Carron (1993) point out that in US they have a 20% to 50% drop-outs in the first 5 to 6 months of exercise fitness program. Since there is a consensus amongst theorist that the self is socially construct, and exercise research by its very nature, has studied groups of individuals exercising together, our propose is to analyse the relation between group cohesion and physical self perception, and how this to concepts behaviour in function to age, time practice and assiduity in context of exercise.

This study was accomplished with 103 individuals, from a community program were assessed for cohesiveness with Portuguese version of the Group Environment Questionnaire -GEG (Widmeyer, Brawley, & Carron, 1985, Mendes, Serpa and Bartolo, 1993)adapted to the context of exercise, and the Portuguese version of the Physical Self Perception Profile PSPP (Fox, 1990, Fonseca, Fox and Almeida, 1995).

The assiduity was analyse by the self perception of the participants in the study

We use the statistical parametric technique, Spearman to analyse the correlations between depended variables, and ANOVA One Way and the test of H.S.D of Tukey, to compare independent variables.

The main conclusions regarding Physical Self Perceptions, were that the middle-aged (19-40 years) persons have highest values in all dimensions, except for global self-esteem (Rosenberg Self-Esteem Scale); the persons with less time to practice (less than 1 year) presented the highest in Body Appearance, Physical Strength, and global Self Esteem, and the lowest values in Sport Competence and Physical Condition. Only in the Sport Competence dimension the persons with more 3 years of practice have the higher values. Examining the self perceptions on the basis of attendance, we verify that are the subject with less assistance (25%), that have higher values in all dimensions. These results can be justified with the fact that more assiduity person has with themselves a degree of demand higher than less assistance. We find significant correlation between ATG-1 dimension of cohesion and global self-esteem

Mental Toughness: The Processes Involved in Its Development and Maintenance

Connaughton, D., Hanton, S.  
University of Wales Institute, Cardiff, United Kingdom

Jones, Hanton, and Connaughton (2002) initiated the process of investigating mental toughness, proposing a definition of mental toughness and twelve characteristics that were perceived essential to its make-up. Jones, Hanton, and Connaughton, (2007) furthered mental toughness research by developing a framework of mental toughness, comprised of thirty attributes which clustered under thirteen subcomponents and four overall dimensions. This study examined the processes involved in the development and maintenance of the thirteen subcomponents of Jones et al’s (2007) framework. Researchers interviewed eleven participants (7 Olympic/World Champions, 2 coaches and 2 sport psychologists), and revealed that subcomponents were developed in the sequence order of belief and focus (attitude/mindset dimension); using long-term goals as the source of motivation, controlling the environment, and pushing yourself to the limit (training dimension); belief, staying focused, regulating performance, handling pressure, awareness and control of thoughts and feelings, and controlling the environment (competition dimension); and, handling failures and handling successes (post-competition dimension). The processes of subcomponents and maintenance evolved through the development and maintenance of the performer’s capabilities in training, with attributions of success in competitions contributing to increased self-belief and focus. Effective goals setting strategies and education programs enhanced motivation levels and the performer’s awareness of what was required to succeed, thereby encouraging greater personal responsibility in training. Once developed, the subcomponents within the attitude/mindset and training dimensions were adopted to increase perceptions of control over thoughts and feelings, and the development of a killer instinct in competition. Reflective practice played a vital role in developing the post-competition subcomponents. Specifically, this provided an understanding as to why successes and failures occurred and how to use this knowledge to further enhance performance. Practical implications indicate the importance of creating the correct mindset in developing mental toughness and challenging performers with difficult but achievable goals. Finally, mental toughness development appears to be assisted by enhancing successful achievements to increase belief, while rationalizing failures to a lack of preparation.

The Experience of International Competition and Its Affect on the Development of Mental Toughness

Connaughton, D., Niccol, D., Hanton, S.  
University of Wales Institute, Cardiff, United Kingdom

Connaughton, Wadey, Hanton, and Jones (2008) identified the underlying mechanisms accountable for the development and maintenance of mental toughness. Findings revealed that the development of mental toughness is a long-term process, influenced by a number of factors. Both, positive and negative, perceived critical incidents were identified as important influences in the development of mental toughness. Examples of negative incidents included: disruptions at school, loss of a peer, and parental divorce; and positive critical incidents such as, being selected for national squads/teams, competing at international competitions/games, and beating respected opponents. This study aimed to explain how one such positive critical incident, namely, the experience of competing at an international competition, affected the development of mental toughness. Six elite male athletes were interviewed regarding their perceptions of competing at their first international competition, and how this experience influenced mental toughness development. Findings revealed that the selection for, and participation in, their first international event resulted in a perceived increase of mental toughness levels. An increase in belief, focus, perceptions of control and personal responsibility, and coach/athlete communication positively impact on the development of mental toughness. Specifically, being surrounded by, and competing against, elite athletes increased the athletes’ belief in their ability and potential to become Olympic/World Champions. This increased belief, in addition to the knowledge gained from the experience of international competition, resulted in a greater focus in training and understanding of what was required to be Olympic Champion. Consequently, this enhanced the athletes’ perception of control and personal responsibility for his actions in training and competition. The resulting increase in personal responsibility required the athlete to form a closer relationship with his coach. This enhanced communication between coach and athlete encouraged a more formalized approach to competitive analysis and reflective practice, resulting in a greater belief in the training program, their coach, and potential to achieve their ultimate goal (i.e., Olympic gold). The practical implications highlight the importance for sport governing bodies to create the correct environment for young talented athletes to develop mental toughness. Specifically, allowing junior athletes to train, compete, and travel with elite performers and to experience international level competition in order to develop mental toughness.

Attributional Reasons for Success and Failure in Different Types of Sports

Sousa, P., Rosado, A., Cabrita, T., Lancho, J.  
Morphofunctional Sciences in Sports Lab. - School of Medicine. University of Córdoba. Faculty of Human Movement. Technical University of Lisbon, Spain

Based on Weiner’s attributitional model of motivation and emotion (1979) and using a sample of several sports activities we have analysed the systematic existence of differences in causal attributions in sporting successes and failures according to the types of sport. A total of 338 athletes, aged from 16 to 38 (M= 23.73, SD= 5.86), took part in this study; all were involved in federated sports competitions, in the Olympic events of football (n=193); athletics (n=100) and fencing (n=46). Causal attributions were evaluated using the Causal Dimension Scale II (CDSII: McAuley, Duncan & Russell, 1992), translated and adapted for the Portuguese population by Fonseca (1993). In general, data suggested that all respondents attributed their successes to more internal, less unstable, personally-controllable causes, whilst there was a marked tendency to attribute sporting failures to less internal, more unstable, externally-controlled causes. The results of the present study suggested a clear tendency among team players to attribute successes to more internal, less unstable and more personally-controllable causes than would
runners. These data on perceptions of sporting success and failure suggest a relationship between the type of sport engaged in and the perceived causality of major positive and negative outcomes.

RELATIONS BETWEEN PERSONALITY DISPOSITIONS AND CAUSAL ATTRIBUTION IN SPORT ContextS

Sousa, P., Rosado, A., Cabrita, T., Lancho, J.

In recent years, there has emerged a limited, but growing, research literature on personality dispositions in relation to causal attributions. In this study it was intended to analyze the influence of personality dispositions (extraversion, anxiety, tough-mindedness, independence and self-control) on causal attributions based on the dimensions of the Weiner’s (1979) attributional model of motivation and emotion (locus of causality, stability, and controllability). Subjects completed the revised Causal Dimension Scale (CDS-II: McAuley, Duncan & Russell, 1992). This scale assesses the causal dimensions of locus of causality, stability, and controllability for the open-ended causal attributions that subjects assign to a particular outcome. Based on a sample of 192 federated football players, this study presents results that show, in sport success situations, a relation between self-control and causal dimensions of the Weiner’s model. In other hand, the dispositional personality dimensions of tough-mindedness and independence seem to be related to the causal dimension of stability. On the contrary, in failure situations, it was verified a total homogeneity in the variation of the causal attributions in function of the personality dispositions. Overall, the results of the present investigation have demonstrated the relationship of selected personality dispositions to the contrary, in failure situations, it was verified a total homogeneity in the variation of the causal attributions in function of the personality dispositions. Overall, the results of the present investigation have demonstrated the relationship of selected personality dispositions to causal attribution. At present, researchers in this area may well choose to study diverse personality dispositions, because different results may emerge in different research contexts and because we need to understanding personality dynamics across a wide range of settings.

SCHOOLYARDS AFFORDANCES

Mourão-Carvalhal, I., Ferreira, I., Larangeiro, H.

Environment should offer experiencing and allow action for children, and playground in the schoolyards must be designed and structured to provide children more possibilities to motion. Children use their environment for physical challenges and play, therefore environmental affordances are what the environment permits or provides for the interaction. Playground equipment affords possibilities for physical activity. It is important to realize that perceived affordances and demands are not universal. The physical outdoor environment and the natural environment in particular, as a play habitat for children, has been a topic of low priority in child research. The aim of this study is to focus on the affordances of schoolyards environment which apply physical activity and versatile play in order to consider as an obesogenic environment. The study included 58 Portuguese elementary schools schoolyards. Data were collected with a checklist in order to check: area, type and the number of playground equipment, as well as the ground surface. The safety of the equipment was evaluated according to the APSI Portuguese norms. In what concerns the area, the results pointed out that 48% of the schoolyards were classified as medium and 35% as good and 17% as bad. According to the ground surface 50% of the schools are made by sandpit. The most popular play structures were the swing (41,38%) and the slide (32,76%). The game equipment, 39,66% of the school yards had a post-goal and 20,69% a basketball table. 50% of the schoolyards don’t have any kind of game equipment or playground structure. 50% of the equipment was considered safe. One challenge in studying the effects of contextual affordances understands the individual’s perception of the object, person or activity. Recess provides a daily opportunity for children to engage in moderate-to-vigorous and vigorous physical activity therefore playground design is very important in order to combat obesity. This study points out that the playground equipment of the schoolyards is poor, not safe, with a very little variety of equipment. Schoolyard as learning environment affords limited possibilities for motion and for physical activity.

THE INDIVIDUALISATION AND MULTI-FACETED NATURE OF PRE-PERFORMANCE ROUTINES IN ELITE TRACK ATHLETES

Swindells, M., Dutton, D., Thombs, M., Lovell, G.

An elite athlete’s capacity to effectively prepare mentally for competition can be seen to be as equally important as their level of physiologic preparation and training. Much of the previous research in the area of pre-performance routines has focused on a unidimensional approach; investigating the individual roles of the mental skills applied within. The aim of the present study was to investigate the multi-faceted nature of pre-performance routines and their effect on the cognitive and emotional states of elite performers.

Participants were four elite track athletes who were interviewed in-depth as to their experiences of the use of pre-performance routines. Participants all competed in the same events at a similar elite level, to factor out inter-sport and inter-skill level differences as identified by previous research, and to highlight how the individual demands of a given sport can influence psychological skill use. Their responses were transcribed verbatim and put through a procedure of thematic analysis, yielding a series of common themes.

Results demonstrated that extensive use was made of pre-performance routines before both training and competitive situations, and the athlete’s individual feelings on the usefulness of routines were highlighted through paraphrased excerpts from their transcriptions. Participants utilised the psychological skills of imagery, self-talk, arousal management, relaxation strategies, and attention cues to varying degrees. Participants also identified a myriad of key factors identified as being distracting to effective preparation and concentration before performance. The actual content of participant’s pre-performance routines was investigated with applied examples being given. The temporal nature of routines were also acknowledged, with any psychological routines that performers carry out during performance examined. Finally, the role of pre-performance routines as an antecedent to consistency of performance and flow state were also investigated.

In conclusion, this investigation highlights the importance of the individualisation of pre-performance routines, and future research directions are suggested. Strategies for applied practitioners and interventions are considered, with a key recommendation being that sport psychologists acknowledge the importance of individualising pre-performance scripts to specific athletes’ requirements. These should be conducive to the athletes’ own prior experience, individual preparation, and sport-specific demands.
THE COMPARISON OF MEMORY IN ACTIVE AND INACTIVE ELDER MEN

Golzar, S., Gholamian, J., Khalaj, H., Gholamian, S.
Islamic Azad University of Abade, Iran

Somayeh golzar, (M.S) Faculty of Islamic Azad University of Abade, Iran
Javad Gholamian, (M.S) In Physical Education & Sport Science of Ferdosi university
Hassan Khalaji,(P.H.D) Assistant professor, Faculty of physical education & sport science, Arak University, Iran.
Samira Gholamian, (B.S) In Physical Education & Sport Science of Ferdosi university

Abstract:
Purpose: The aim of the present study was to investigate and compare the memory quotient of active and inactive elder men (60-75) in Arak.

Methods: This research is Ex post facto type and 76 old men participated in the study. The data was obtained through: Wechsler memory scale (W.M.S) was including 7 subscales. General memory, orientation, Mind control, Logical memory, Repeating the numbers, Visual memory, Associational learning.

Researcher-built personal data and state physical activity questionnaire. The validity was confirmed by experts and its Cornbach alpha reliability was 0.751. For Data gathering, the researcher gave 105 questionnaires to volunteer elder men and 76 questionnaires were completed. Subjects were divided into two active and inactive groups using physical activity questionnaire. To evaluate the memory, W.M.S was used. After gathering and collecting the data, the independent-sample t-test with 0.05 as the level of significance was used to test the hypothesis.

Result: The results showed that with certainty of 95% and p<0/05, the Memory Quotient for the older that are active is more than those who are inactive (T=3/90), also in 4 subscales, that is, orientation, logical memory, mind control and associational learning the active older were better than the inactive older, and in 3 subscales of general memory, repeating the numbers and visual memory, we couldn’t get any result.

Conclusion: The result of the present study suggests that participation in regular physical activity may be due to maintenance of memory performance in aging.

PHYSICAL ACTIVITY, WELL-BEING AND COGNITIVE FUNCTION IN ELDERLY

Mourão-Carvalhal, I., Coelho, E., Lourenço, C., Afonso, E.
Universidade Trás-os-Montes e Alto Douro, Portugal

This investigation had the purpose to compare the levels of psychological well-being and cognitive function between elderly with practice (more than twice/week and at least 30’/day) or not practice physical activity, and male and female.

The sample consisted of 110 elderly residents in Viseu Portugal (51 male and 59 female; age 72,85±5,57 yrs), with 55 with physical activity and 55 without. The instruments used were: Inventory of Psychological Well-Being (Memorial University of Newfoundland Scale of Happiness) and Mini-Mental State Examination. T-test was used to compare groups.

Main results demonstrated differences between elderly who practiced and not practice physical activity in all the variables (p=0,000). Higher values were obtained by elderly with physical activity in cognitive function (27,79±1,84 vrs. 24,47±1,77), positive affects (20,27±2,71 vrs. 15,75±3,57) and positive experiences (26,20±3,79 vrs. 19,67±4,55); whereby in negative affects (13,44±3,57 vrs. 8,75±2,70) and negative experiences (20,55±4,76 vrs. 12,6±2,96), the group without physical activity presented greater scores. No significant differences were found in all the variables when we compared males and females.

The results of the present study are in agreement with the literature; physical activity promotes positive changes in affective states and produces beneficial effects on cognition. In conclusion, physical activity offers one of the greatest opportunities to reduced disability and improves the quality of life for older persons.

Key-Words: physical activity, cognitive function and well-being, elderly

NARRATIVE PATTERNS FOR TEAM’S BEST GAME AND TEAM’S WORST GAME: THE HANDBALL COACHES’ INDIVIDUAL EXPERIENCES

Gonzaga, L., Sequeira, P.
FCHS / Universidade do Algarve, Portugal

It is not linear the correspondence between the objective situation of a victory and the subjective perception of success neither between the objective defeat and the perceived failure (Duda & Allison, 1989). Qualitative research in this domain would give us a better understanding of coaches’ views on their complex experiences and it would help to clarify findings from quantitative studies in the field of achievement motivation in sport competition. Life is a story and every coach has his autobiographical small stories about good and bad games. This study seeks to identify the narrative pattern of handball coaches from their personal experience in non-shared and particular past events: the prototypical narrative for coaches’ Team’s Best Game and Team’s Worst Game. This dichotomised approach in the evaluation of their own team performance suggests our intentional option for the so-called critical incidents approach focussing on coaches’ experiences characterized by high emotional involvement. The sampling and analysis methodology draws on Grounded Theory (Glaser & Strauss, 1967). The sample includes 81 handball coaches aged 23 to 55 (mean +/- SD age; 36 +/- 8 years, 90% men). Each coach was invited to be a story-teller based on his team’s best game and worst game experiences and to post personal statement in the online forum or sending it by email. Participants were grouped according to their current ground reality and life experience (identified and reported by them): 51 as the team coach and 30 as an athlete of the team. Data was coded using MAXQDA2007, software for qualitative analysis, and is currently being analysed and interpreted. The results of the characterization process and construction of the prototypical narratives will be presented and their relevance to psychological practice discussed.
ORDER EFFECTS IN SPORT: THE INFLUENCE OF AN INTERPOLATED ACTIVITY AND DELAY ON JUDGEMENTS OF FOOTBALL PLAYER'S ABILITY

Greenlees, I., Leyland, A.
University of Chichester, United Kingdom

Recently, Greenlees, Dicks, Thelwell & Holder (2007) found that coaches’ judgments concerning the ability of an athlete may be unduly biased by the quality of the initial performance of that athlete (defined by Asch (1946) as a primacy effect). If such biases are a consistent part of sport it is imperative for researchers to examine strategies designed to reduce order effects and promote unbiased information processing. Research in general psychology has shown that asking participants to delay their judgments or perform interpolated activities between viewing targets and providing judgments of them can eliminate order effects (Luchins, 1957). However, no research has examined the influence of delays or interpolated activities when perceivers make attributions of ability. The aim of the present study was thus to examine the impact of the order in which information about a performer is received and the influence of an interpolated activity in judgments of ability. Soccer coaches (N=60) viewed footage of 2 soccer players performing a simple soccer skill 8 times and then rated them on 5 attributes describing the ability of the players. Coaches were randomly allocated to one of 6 groups in a 3 (delay of judgment: no delay, 1 minute delay, 1 minute delay with an interpolated activity) x 2 (order of presentation: poor to good skill execution, good to poor skill execution) between-groups design. A univariate ANOVA conducted on the ratings of the target player demonstrated a significant main effect for order (F(10, 50) = 6.8, p = .011, effect size 2 = .11, estimated power at 5% probability = .73), with higher judgments of ability being made in the good-poor performance condition than in the poor-good condition. This indicated a primacy effect. No significant effect was demonstrated for condition of rating (F(10, 50) = 0.1, p = .941, effect size 2 = .002, estimated power at 5% probability = .06) and no significant interaction effect was observed (F(10, 50) = 2.87, p = .066, effect size 2 = .10, estimated power at 5% probability = .54). Thus, the results indicate that primacy effects are not reduced by the introduction of a delay or an interpolated activity between observing and rating a player.

THE RELATIONSHIP BETWEEN TRANSFORMATIONAL LEADERSHIP BEHAVIOURS AND PERCEPTIONS OF ROLE VALUE IN INTERACTIVE SPORTS TEAMS

Bell, J., Clark, C., Hardy, J., Hardy, L., Callow, N., Arthur, C.
Bangor University, Wales, United Kingdom

Recently leadership research has identified a new type of leader, described as transformational, who is capable of transforming followers’ attitudes, beliefs and values as opposed to simply gaining compliance (Bass, 1985). Transformational leadership (TL) behaviours have been shown to impact a wide range of individual and organisational outcomes including self efficacy, commitment, satisfaction, group cohesion, and performance. However, currently there is very little evidence of the effect of TL behaviours in a sporting context. Furthermore, TL research has typically examined main effect relationships between the sub-dimensions of TL behaviours and the outcome variables of choice. As such the present study aimed to investigate main and interactive relationships between coaches’ TL behaviours and team members’ perceptions of the value of their interdependent role responsibilities. Male and female collegiate athletes (N=155) completed a TL measure developed by Hardy et al. (in press) and a measure of perceived role value constructed specifically for this investigation. Regression analyses revealed that only one leadership behaviour, High Performance Expectations (HPE), R2 = 0.13, p = 0.000, positively predicted perceived role value, such that increases in HPE were associated with increases in perceptions of role value. Moderated hierarchical regression analyses examined the interactive effects of challenge behaviours such as HPE and Intellectual Stimulation (IS) with the supportive behaviours Individual Consideration (IC), Contingent Reward (CR), Appropriate Role Model (ARM) and Creating and Articulating a Positive Vision (PV). All but two of these hypothesised interactions were found to be significant. The significant interactions between HPE and ARM, R2 change = 0.063; p = 0.007, and between IS and CR, R2 change = 0.063; p = 0.009, typified the general trend whereby a reduction in HPE or IS was associated with a reduction in perceptions of role value with low levels of support behaviours. In contrast, when support behaviours were higher perceptions of role value were mostly maintained. From an applied perspective results suggest that some TL behaviours can affect team members’ perceptions of their role related responsibilities in both a positive and a negative manner. Furthermore, coaches who do not express high performance expectations or do not encourage athletes to solve problems independently should anticipate that this could reduce perceptions of role value if not accompanied by supportive behaviours.

ELITE RUGBY COACHES’ COMMUNICATIONS IN MATCH

Mouchet, A.
Paris 12 University and CRR of French Federation in Rugby, France

This research is organised with the National Technical Direction of the French Union in Rugby. The problematic consists in informing the private and public facets of the coaches’ communications with players during the match. We try to characterize communications by different aspects: intention, frequency, object, modalities, and their impact on the game production. The theoretical frame aims to encircle the implicit and tacit competences constituents. Coaching process is complex, dynamic and depending from the context (Lyle, 2002).

The methodology has for ambition to supply a detailed and ecologically valid portrait about coaches and about the coaching process (Gilbert & Trudel, 2004). We study all the technical staff members involved in the coaching process, using case studies with methods triangulation (Mouchet, 2005). We articulate:
- interviews before the match about coaches conceptions,
- behaviors and communications recording during contest,
- explicitation interviews (Vermersch, 2002) after the match about coaches' subjective lived,
- analysis of game evolution. We use for this last aspect the video of the game and an observation tool.
Results are in the course of treatment. The first elements about coaches’ conceptions put in evidence:
- The main addressees of orders: numbers 9 and 10 for the strategic aspects; the captain if he’s a different player, for aspects relative to
  the group management;
- The variety of used distribution channels, according to the opportunities of meeting with the players during the game, or the use of
  persons authorized to enter on the ground (for example medical staff).
On the other hand it is surprising to notice the absence of elements strongly shared in coach’s’s conceptions about the nature of com-
munications. The only element quoted explicitly by 50 % of the coaches concerns ‘ strategy ’. But the optimal use of these strategic regula-
tions seems to require from coaches a fine analysis of events and the necessity of developing two aspects:
- functional modalities of communications distribution in the course of contest,
- Players’ responsibility and self-sufficiency in the management of the game.
Data treatment of the communications in game is in course at this moment. The first elements seem to indicate preferential modes used
by coaches depending on their own experiences and characteristics as coach or player. But also depending from the local context of the
match.

AVOIDANCE MOTIVATION AND CHOKING UNDER PRESSURE IN SOCCER PENALTY SHOOTOUTS

Jordet, G., Hartman, E.
Norwegian School of Sport Sciences, Norway

Choking under pressure can be defined as performing worse than expected in situations with a high degree of perceived importance (Baumeister, 1984). Although previously not directly tested, researchers (e.g., Wallace, Baumeister, & Vohs, 2005) have argued that moti-
vation to avoid failure may predict choking under pressure. In achievement motivation theories, avoidance motivation refers to behavior
directed by negatively valenced events, while approach motivation refers to behavior directed by positively valenced events (Elliot, 1999).
The purpose of our study was to examine the relationships between shot valence, avoidance behavior, and performance in a high-
pressure real world sport task.

Video analyses were conducted with all penalty shootouts ever held in the World Cup, the European Championships and the UEFA
Champions League (n = 36 shootouts/359 kicks). Shot valence was assessed from the potential consequences of a shot outcome: shots
where a goal instantly leads to victory were classified as positive valence shots and shots where a miss instantly leads to loss as negative
valence shots. Avoidance behavior was defined as looking away from the goalkeeper or preparing the shot quickly (thus speeding up the
wait, possibly to get it over with). We used logistic regression analyses (for avoidance looking and performance) and ANOVA (for prepara-
tion speed).

The results showed that the players did more avoidance looking on negative valence shots (44%, OR = 4.7, p = .029) than on positive
shots (14%, OR = 1, reference category) and prepared their shots quicker on negative shots (M = 1.1 s) compared to the positive shots (M =
2.0 s) (F = 4.13, p = .017). Moreover, performance was significantly better on the positive valence shots (92% goals, OR = 1, reference
category) than on the negative shots (62%, OR = 7.1, p <= .016).
In conclusion, the results provide direct-observation support for theories of valence based achievement motivation in real world high-
pressure sport tasks. The study also gives an alternative explanation for the previous finding that soccer penalty shooters perform worse
with higher kick-importance (Jordet, Hartman, Visscher, & Lemmink, 2007). In general, we suggest that avoidance motivation may help
explain why professional athletes occasionally choke under pressure.

THE DEVELOPMENT OF A QUALITY DECISIONAL INDEX FOR THE MATCH ANALYSIS OF OFFENSIVE ONE-ON-ONE
SITUATIONS IN BASKETBALL

Esteves, P., Araújo, D., Correia, V., Travassos, B., Barreto, H.
Technical University of Lisbon, Portugal

INTRODUCTION: In order to reach a better understanding of the game dynamics, sport performance analysis, is nowadays branded by a
multidisciplinary nature of contributes (Reilly & Gilbourne, 2003). However, much of the match analysis does not explain the continuous
interaction between the player and the competition environment. Decision-making behaviour is usually not included in these match anal-
yses. In this work we consider the 1 vs 1 situations that finished with an attempt to shot. In order to analyze the dyad we considered
the interaction between players as a symmetric relation defined for the distance between the basket and both players and their interper-
sonal distance (Araújo et al., 2006). The aim of this paper is to provide a match analysis tool for decision-making behaviour in basketball.
To achieve this goal, we present a quality decisional index (QDI) (Esteves, Araújo & Barreto, in press) which allows the measuring of the
temporal course of this behaviour in a one-on-one situation in basketball.

METHOD: In order to show that it is an accurate and reliable tool for analyzing information regarding players’ behaviour in the game, we
used notational analysis data from one-on-one situations that occurred in a basketball game (Portuguese main league). This notational
procedure allowed us to gather the needed variables for the quality decisional index [QDI = 0.7 (SS/SA) 0.1 LB/nLtv) + 0.2 (IF? nLtv), where
SA is the number of shots attempts, SS is the number of shots scored, LB is the number of lost balls, nLtv is the number of occurrences of
Identifying talent for sports at an early age has become one of the major issues in many highly competitive sports. The talent identification process is largely based on systematic expert observation that raises an important question: what is if that coaches and scouts see as early talent? The present study examined the contribution of one important characteristic that may relate to the process of talent identification and selection, that is, the role of physical precocity associated with the relative age effect. The study focused on the relation of the month of birth to sustained participation in youth ice hockey. It was hypothesized that the players with a greater relative age would be more likely to be identified as talented, and consequently, they were expected to sustain their participation in competitive ice hockey. In the first phase of data collection, a questionnaire, including items on date of birth, height, and weight, was administered to 2,806 Finnish male ice hockey players whose fifteenth birthday fell during the year 1987. The number of respondents was 1,712, representing 61 percent of the Finnish youth players in that age group. Data of the licence holders was obtained one, two and three years later. The month of birth distribution of the respondents differed statistically significantly from that of the general Finnish male population for the year 1987 (Chi square = 21.087, df = 11, p = .032). The data concerning the first five months (January to May) highlighted an over-presentation of the players, whereas a decreasing number of players were born in the subsequent months except December. In the following phase of data analysis, the month of birth variable (MB) was recoded in two categories: January to June and July to December (MB2). The MB2 variable appeared to be statistically significantly associated with continued participation one year (p = .003) and two years later (p = .003). Finally, as the month of birth was correlated with height and weight, forward stepwise logistic regression analyses were carried out with participation as dependent variable and MB2, height and weight as independent variables. When predicting participation one or two years later, regression coefficients for MB2 and weight at the age of 15 had statistically significant regression weights. When predicting participation three years later, only weight had statistically significant regression coefficient. The fit of model was statistically significant for all three regression models. Taken together, the data suggested that much of what coaches see as early talent may be explained by physical maturation associated with a relative age advantage. The present study addresses an important issue concerning the role of physical precocity in the talent identification and selection process in highly competitive sports like ice hockey.

THE EMOTIONAL ASPECTS OF COACHING CHILDREN IN TENNIS

Huguet, S., Antonini-Philippe, R.

University of Bedfordshire, United Kingdom

Introduction

The coach-athlete relationship plays a significant role in the player’s development at the early stages of practice (Côtè et al, 1995) but few researches investigated the emotional aspects involved in this relationship at a very young age. The psychodynamic approach introduces the concept of transference to explain that an athlete may direct affection, feelings to a coach (Strean & Strean, 1998), thus transferring experiences lived with significant others (parents, siblings) from the past.

Methods

14 tennis players were interviewed 3-4 times. All interviews were transcribed verbatim and direct interpretation was used to create case studies. We cannot develop all but we can comment on 3 aspects: the inner drive, narcissistic play and emotional bonds with the coach.

Results - Discussion

The child’s inner drive family often imposed on the player to practice tennis because somebody was already involved in tennis. Tennis becomes a narcissistic transaction between parents and players as winning increases parent’s self-esteem and thus there is an unconscious demand of being loved by parents through their success. This inner drive is important as a child who has not been able to achieve his parent’s expectations will have difficulties to take ownership of his/her professional career. The narcissist practice Enjoyment is a distinctive factor of sport participation (Scanlan et al., 1993). Players demonstrated a need to experience enjoyment in their practice at an early age. There are no thoughts of the future and tennis remains a pleasing activity. Emotional bonds with the coach and parents. There is a difference between conscious and unconscious wishes made towards the coach. If the inner drive is based upon the parent’s wishes, the coach does not play a major role in the emotional affects on the player. But if the parents fails to fill out these emotional aspects, then it is transferred to the coach. Communication is important as children seek out a coach that is able to discuss and listen to their needs.

Conclusion

This research shows that coaching a child is specific regarding the emotional aspects and needs. Playing tennis at an early age is essentially based on pleasure to play and compete and coaches encourage these aspects at early age and not focusing on performance.

WHEN BODY TALKS: AN EXPLORATORY CASE STUDY ON PSYCHOSOMATIC ASPECTS OF INJURIES

Huguet, S.
University of Bedfordshire, United Kingdom

Introduction
Injury is a complex phenomenon a lot more than physical. While individual factors such as age, previous injury, body type, fitness level, personality have often been discussed (Andersen & Williams, 1998), there are few in-depth researches on the meaning of injury and psychosomatics aspects that would explain why some athlete get repetitive injuries. The psychodynamic approach considers injury as a symptom, which acts as evidence that unacceptable wishes, thoughts and fantasies will reach consciousness (Freud, 1961). McDougall (1989) presented psychosomatic illness as a deflection in the development, especially in the bodily representation, and a failure of emotional and physical pain to gain mental representation.

Methods
Participant is a 19 years old female tennis player. Four interviews were carried out with a clinical method and were transcribed verbatim.

Data were analysed inductively using direct interpretation to create the case study. Interpretations were discussed with a fellow researcher who acted as a peer reviewer.

Results
Elisa has started tennis at 5 years old and became quickly one the best of her age. She started questioning her interest for tennis at 14 years old. Describing an ambivalent relationship with a mother, she had to face strong parent’s expectations towards tennis. Every time she had to take a decision, she found a way to escape and being injured to express doubt about a tennis career. Then, she became anorexic. It was a way to express to her parent’s that she no longer wanted to be trained and be a tennis player.

Discussion
Injury occurs when the athlete’s failed to find expression in the language, there are directed to bodily action. This can be seen as somatization, which is explained by discharged affects diversified inadequately into somatic channels without any psychic processing. Injury often occurs when an athlete realises that playing sport was to fulfill parental expectations.

Conclusion
Investigating somatic aspects of injury could help to provide insight about the meaning of an injury. There is a need to develop this research further to understand injury and help preventing them by dealing with the unconscious process behind.

RECORDING EYE MOVEMENTS DURING FENCING BOUTS: PILOT STUDY ON REFEREES’ BEHAVIOUR

Taddei, F., Bultrini, A., Di Russo, F., Spinelli, D.
University of Sport and Movement Sciences, Rome, Italy

The aim of this study was to highlight the characteristics of visual exploration strategies in referees during fencing competition, comparing them to fencers and non-experts. In this study both conventional (foil) and non-conventional (épée) weapons were used.

Three groups of subjects were studied. Seven fencing referees (2 females, mean age 31.4, SD=7.9), 7 fencers (5 females, mean age 21.8, SD=1.9) and 7 non-experts (5 females, mean age 23.0, SD=2.5).

Eye-track 6000 instruments at the Applied Science Laboratories (ASL) were used. Participants wore a helmet with a camera and an infra-red apparatus attached and sat on chairs 3 metres from the screen. The apparatus was regulated to record the pupil’s movements in relation to the corneal reflex and videos of foil and épée bouts were projected onto the screen, while participants were requested to register each hit assigning it to one of the fencers, using a remote-control button provided.

We used Gaze-Tracker software for data analysis identifying the specific areas of interest of each video, defining the ‘look zone’ (the rectangular area of variable dimensions that defines the video zone from which the desired information is recorded). The electronic equipment that recorded the hits and the central zone (the space between the fencers including the fencers’ armed limbs) only fixations lasting more than 100 ms were considered.

ANOVA were performed for each condition (‘look zones’ focused on: hit recording equipment, the central zone between the fencers; the remainder of the observed area) while the group (referees, fencers, and non-experts) was employed as independent factor, and the fixation number percentage related to the weapon (foil and épée) as dependent variable. We included age and gender as covariate.

The weapon factor [F(1,18)=9.88, p<0.01] was significant in relation to the fixations recorded by the equipment for the hits. During foil bouts, the equipment was more frequently observed (18.5) than it was during épée bouts (13.2).

Considering the fixations relative to the remainder of the observed area, the weapon factor [F(1,18)=6.20, p<0.05, foil=29.53 épée=37.47] and the interaction group x weapon [F(2,18)=4.17, p<0.05] proved significant. While fencers [foil=29.1; épée=34.9] and non-experts [foil=31.2; épée=29.1] showed a similar fixation percentage irrespective of the weapon observed, the referees [foil=28.3; épée=48.8] showed a significantly greater fixation number outside the central zone area during the observation of épée bouts. This behaviour can be explained by the fact that the épée, being a so-called non-conventional weapon, does not require interpretation in order for a hit to be assigned - the visual strategies referees use are less action focused compared to the ones they use for the foil.

THE DEVELOPMENT OF A QUESTIONNAIRE SPECIFICALLY FOR EXERCISE INTERVENTIONS

Hilton, C., Minnili, A.
Nottingham Trent University, United Kingdom

Purpose of the Research
Qualitative data has been used to develop an initial pool of questions for an exercise referral specific test questionnaire. It is intended that a series of reliability and validation procedures will give rise to an instrument suitable for use by exercise and health professionals working within exercise referral.

Participants
23 participants (F=15, M=8) attended the initial pilot and four subsequent focus groups between the ages of 33 and 78 (M = 60, SD = 10). Health difficulties for which participants were referred were typical of exercise referral populations.

Procedure
Focus group data was transcribed verbatim and the interview scripts were coded with QSR NVIVO software. The value of enhancing data auditing and transparency of analysis via the use of QSR NVIVO has been recognised (Bringer, Johnston, & Brackenridge, 2004, 2006).

Instrument Analysis (Phase Two)
Necessary amendments will be made to the instrument. This process will continue until revisions are no longer necessary.

Instrument Pre-Testing (Phase One)
Item-analytic methods of test construction will be used to reduce the number of test items that will be included in the final measure. Internal consistency of items (item-total correlations, inter-item correlations, and Cronbach’s Alpha), and test-retest reliability of items and item groups (kappa values, intraclass correlation coefficients, and mean difference in scores), will be examined.

Results
The qualitative data has given rise to nine common themes that are subject to consensus validation. An initial pool of items will be tested. The questionnaire will be subject to Phase one (cognitive pre-testing) of validation procedures and Phase two (instrument analysis) will follow.

Conclusions
The availability of a validated evaluation tool for use by exercise professionals will provide an important opportunity to assess the wider outcomes of exercise referral, and in particular beyond those that fall within physiological parameters, thus enabling a greater understanding of the contribution of exercise interventions to holistic health improvement.

KNEE INJURIES IN FORMER FEMALE HANDBALL PLAYERS
Lima, D., Espanha, M.
Faculty of Human Kinetics, Technical University of Lisbon, Portugal

Introduction.
The knee joint is an anatomic region with a high injury incidence in handball players (1). The female handball players have a higher risk for knee injuries than males (2). Previous knee joint injury has been pointed out like risk factor for developing knee osteoarthritis (OA) (3). The most typical OA symptoms are pain and stiffness leading to a decline in physical function (4). This retrospective study analysed sports injuries during practice and competition, namely, type of injury, injury severity, mechanism of injury and treatment after surgery in former female handball players, who had suffered knee injury for at least 4 years. Relation between injury severity and handball exposure with pain, joint stiffness and physical function was also investigated.

Methods.
The sample was composed by 27 former handball players that played in the highest handball Portuguese league. Data was obtained by using two types of questionnaires. The first was designed especially for this study and the second was Western Ontario and McMaster Universities Osteoarthritis (WOMAC®). Injury definition used was adapted from Baltzer et al. (5). Chi-Square test and Spearman’s correlation coefficient were used to assess statistical significance level, p<0,05.

Results.
Handball players had mean age of 38.7 years (24-48 yrs.), mean weight of 64.6 kg (53-85 kg), mean height of 1.67 m (1.52-1.80 m) and mean body mass index 23.1 kg/m2 (19.03-28.4 kg/m2) and played during an average of 15.7 years (4-25 yrs.). The former players suffered a total of 45 knee injuries; six were classified as minor, nineteen has severe and twenty has catastrophic injury. The most common injury situation was competition and the offensive phase (48.9% and 84.4% respectively), and most typical game situation at the point of injury was side-cutting maneuver (28.9%). Surgical treatment of knee injuries was predominant (64.4%) to the conservative one. Association between the severity of knee injury pain (r=0.310), joint stiffness (r=0.083), physical funcion (r=0.176) and Womac index (r=0.174) were not found, neither between handball exposure and pain (r=-0.205), joint stiffness (r=-0.020), physical function (r=-0.103) and Womac index (r=-0.100).

Conclusion.
Although this study is limited by the low number of former injured players, and the lack of a control group the results are nevertheless similar to aetiology studies with knee injured handball players. Besides clinical criteria for knee OA radiological criteria should be considered as well as better understanding the influence previous injury for developing knee OA.

STRENGTH AND BALANCE CHANGES IN FEMALE SOCCER PLAYER MEASURES BETWEEN PRE AND OFF-SEASON

Thomas, K., Onate, J., Cortes, N., Kollock, R., VanLunen, B.
Old Dominion University Norfolk VA, United States

Physical changes that occur to athletes in balance and strength following completion of a sport season are of interest to sports medicine clinicians. Purpose: The purpose of this study was to determine if there were any differences in strength and balance measures in female National Collegiate Athletic Association (NCAA) soccer athletes following a season of play. We hypothesize that a significant loss of strength and balance will occur following a season of play. Methods: Participants consisted of eighteen female (19.67 ± 8.85 yrs, 63.97 ± 8.24 kg). 1.69 ± 0.04 m) NCAA soccer players that attended both pre- and off-season assessment sessions. Static balance was assessed using a modified Balance Error Scoring System (BESS) consisting of one trial for each of the 4 stances (double leg, single [R/L], tandem) using two surfaces (firm and foam). BESS error scores were recorded and total error score for 8 conditions was used for analysis. Dynamic balance was assessed using the Star Excursion Balance Test (SEBT) in three directions anterior (ANT), posterior medial (PM), and posterior lateral (PL). All subjects performed 3 trials of each SEBT assessment measure. Average of 3 reach distances were normalized to percent leg length (reach distance/leg length *100) to determine SEBT scores used for analysis. Strength measures consisted of a 5 second maximal effort with a 10 second rest period between trials. Movements assessed were hip abduction (AB), hip adduction (AD), hip internal rotation (IR), hip external rotation (ER), hip flexion (HF), hip extension (HE), knee extension (KE), and knee flexion (KF) using a portable fixed dynamometer (Evaluator, BTE, Hanover, MD). Strength measures were normalized to percent bodyweight [(F[N]/BW[N]) * 100]. A 10% coefficient of variance (CV) was set to ensure a consistent effort by subjects across each trial. Paired samples t-tests (p<0.05) were performed on all variables pre vs. off measurement scores. Results: There was a significant reduction in [177] 7.25, p< 0.01] between pre (29.89 ± 4.88) vs. off (17 83 ± 4.80) season BESS scores and all SEBT reach directions, ANF [177]= 4.32, p<0.01], pre (69.48 ± 5.30) vs. off (78.97 ± 5.77), PM, PM [17]= 8.41, p= 0.00], pret (105.40 ± 5.39) vs. off (122.59 ± 7.23) and PL, PL [17]= 7.64, p<0.01], pre (98.01 ± 6.54) vs. off (115.52 ± 8.64). There were no significant differences found between any of the eight strength dependent variables (hip AB, AD, IR, ER, HF, HE, KE, and KE, p<0.05). Conclusions: The results of this study indicate that there was an improvement in both static and dynamic balance measures between pre-season and off-season assessments in female collegiate soccer athletes as measured by the BESS and SEBT. There were no changes in lower extremity strength measures. Future studies are necessary to evaluate balance and strength across different time frames (e.g. mid-season and immediate post-season).

INTEGRATED COMPRESSION ZONE SOCK THERAPY IN PATIENTS WITH NON-INSERTIONAL ACHILLES TENDINOPATHY - RESULTS OF A FOUR WEEKS PILOT STUDY

Langberg, H., Boesen, M.
Parker Institute, Frederiksberg Hospital, Denmark and Department of Orthopedic Surgery, Copenhagen University Hospital, Herlev, Denmark; Institute for Sports medicine, Denmark

BACKGROUND: In patients with chronic Achilles tendinopathy (AT) pain is usually the limiting factor for returning to sports. High resolution color Doppler ultrasound shows intratendinous edema and hyperemia in the painful area. Treatment of the condition is difficult and a multi orientated approach is often necessary. Eccentric rehabilitation and therapies aiming of reducing the edema and hyperemia has demonstrated good results on pain relief (Alfredson 1998, Ohberg L 2004, Boesen 2007). Hypothesis: It was hypothesized that increased peri tendinous pressure around the Achilles tendon induced by a specially designed integrated compression zone sock (Csock®) in patients with chronic tendinopathy could reduced symptoms and reduce hyperemia.

METHODS: Color Doppler ultrasound was performed on 11 patients (nine men, two women, mean age 37 years) with painful chronic mid-portion Achilles tendinosis. The mean length of problems was 17 month (range 1 to 48 month). The mean weight and height were 85.5 kg (range 71 to 108 kg) and 180 cm. (range 164 to 193 cm), respectively. Five of the patients were professional athletes (three soccer players and two long distance runners). All patients were given a Csock® and ask to wear it all time during the day for a period of at least 3 weeks. Pain was measured on a visual analog scale (VAS-score) before and after the period.

RESULTS: All patients had grey scale changes (thickening and irregular fiber structure) and intratendinous Doppler activity (vascularisation) in the mid-tendon area before treatment. The patients used the sock for a mean of 4.3 weeks (range X to X). All patients were satisfied with the sock and had no discomfort using it. There was a significant reduction in pain during activity, from a mean VAS of 33.8 (SD ± 19.6) at baseline to 20.4 (SD ± 19.6) at follow up (P =0.04). One patient had no effect on pain in the 4 weeks period but found it comfortable and wore it through out the study. In all patients, vascularisation and grey scale findings were unchanged at 4 weeks follow up, with no significant change in semi quantitative or quantitative color scoring.

CONCLUSIONS: Use of a specially designed compression zone sock (Csock) reduces pain in patients with chronic Achilles tendinopathy determined by VAS. Thus use of local compression (Csock) during normal daily activities seems to be an effective supplement in the treatment for painful chronic mid-Achilles tendinopathy. No effect on the intratendinous Doppler activity or grey scale changes could be detected, suggesting that the effect is independent of structural changes in the tendon. Localization of hyperemia appears to be the key to the pathology and the target for the compression treatment. Csock is an excellent supplement in combination of multiorientated treatment in chronic Achilles tendinopathy.

SERUM CARTILAGE OLIGOMERIC MATRIX PROTEIN (COMP) AND INFLAMMATORY RESPONSE DURING AND AFTER A MARATHON RACE

Lee, YH., Kim, HJ., Ho, Jr., Eo, SJ., Son, HJ., Park, YS., Koh, YG., Lee, YW., Cho, JY., Oh, JG., Kim, CK.
Human Physiology, Korea National Sport University, Seoul, Korea; Yongsesaran Hospital, Seoul, Korea, South

Background
Numerous studies have been reported that long distance running is associated with muscle fiber damage but, little information is available on exercise-mediated prolonged impact-stress on cartilage integrity. Marathon running is increasingly popular with the general population but as an exercise imposes high levels of stress on the musculo-skeletal system, causing numerous cellular changes. These include deterioration in the structure and function of muscle, in particular sarcomeric Z-disc stripuation, as well as damage to cartilage and liver. Whilst the effects on muscle have been extensively investigated, little or no information is currently available on the effects of exercise-mediated prolonged impact-stress on cartilage integrity.
Purpose
This study was performed to evaluate the biochemical responses related to muscle and cartilage damage during and after a marathon race. We considered that damage to both muscle and cartilage would be related to the distance of the race.

Methods
Blood samples were obtained before, midway (i.e., after 10, 20, 30 km) and at the end of a 42.195 km race, as well as after 1 h recovery and on every day following the marathon race until the 7th day. However, the full compliment of twelve blood samples was obtained from only 7 subjects due to the difficulties of contacting subjects during the post-race period. Mean body weight and height were 70 kg (64-84) and 170 cm (164-175) and all subjects had been training for more than 2 years (2.4-7.0). The mean running-time of the runners was 4:02 (ranging from 3:10-4:55).

Plasma CPK and hs-CRP activities were measured as markers of muscle damage. The serum level of cartilage oligomeric matrix protein (COMP) was measured as a marker of joint metabolism and/or damage.

Results
The COMP concentration was increased 30-35% by the end of 10K running, but showed no further change in this by end of the race or after 1h recovery. The COMP concentration had declined back to the pre-race level within 24h. At the end of 10K running serum CPK was increased significantly 120% in subjects running at 70-80% of VO2 max, and 400% in those running at 80-90% of VO2 max. Plasma CPK activity had returned to pre-race levels after 4 to 5 days of recovery. No alteration occurred in hs-CRP throughout the race but this markedly increased during the first day of recovery. Hs-CRP returned to the pre-race level after 5 days of rest.

Discussion and Conclusion
The present study demonstrated that marathon running has a major impact on muscle and cartilage structures. Despite this the COMP concentration had fallen to the pre-race level within 24h of recovery (and CPK within 4 to 5 days).

INCIDENCE OF INJURIES IN LADIES GAEIC FOOTBALL OVER TWO COMPETITIVE SEASONS

Beades, M., Clarke, C., O’Rourke, H.
Ladies Gaelic Football Association, Ireland

The Ladies Gaelic Football Association was founded in 1974 and since then has progressed to being one of the fastest growing female sports in Europe with approximately 1,000 clubs registered in Ireland alone. The high participation rates and the competitive nature of Ladies Gaelic Football results in numerous competitive injuries in similarity with other female field-based sports. The present observational study assessed the incidence of injuries in amateur Ladies Gaelic Football over 2 competitive seasons.

The data presented relates to all injuries reported and processed in the injury scheme for players, mentors and referees. All reported injuries were collated and categorised according to age: Adult or Juvenile (under 18) and site of injury.

In 2007, in total 837 injuries were reported: comprising of 544 adult (A) and 303 juvenile (J), this equated to an increase of 31 injuries (1%) compared to the previous season. The frequency of injuries at the different sites was unaffected by age. The greatest number of injuries occurred at the leg (207; 138A, 69J), knee (194; 134A, 70J), ankle (113; 72A, 41J), hand (97; 58A, 39J) and back (85; 53A, 30J). As a percentage of the total number of injuries reported these sites represent 25, 23, 14, 11 and 10%, respectively. Hamstring injuries represent 43% of the total number of leg injuries reported while injuries to the finger account for 47% of all hand injuries. In relation to the costs associated with the treatment of these injuries, hospital treatment was highest followed by physiotherapy and doctors expenses. In total, 21 Cruciate ligament injuries were reported in 2007 (11% of total knee injuries), however this equated to 36% of the cost associated with knee injuries in the same year. In total 286,000 (A) and 98,000 (J) was reimbursed to players to cover treatment of injuries sustained during Ladies Gaelic Football activities. Incidence of injuries is highly correlated with regional areas with the greatest playing population. In comparison with 2006 the total number of registered players has increased by approximately 5-10,000, however, the incidence of injuries has not changed significantly (Chi squared test, P>0.05) across the two playing seasons despite increased participation.

In conclusion the incidence of injuries sustained in Ladies Gaelic Football across two playing seasons are representative of those expected for a highly competitive field-based sport. However the increase in the number of players from one season to the next is not reflected in the number of injuries reported.

This study was funded by the Ladies Gaelic Football Association, Ireland.

THE EFFECT OF HONEY DRINK WITH ROSE WATER FLAVOURS AND GLUCOSE DRINK AND DURING ENDURANCE CYCLING ON PERFORMANCE, RPE, HR AND BLOOD (GLU), (INS), (COR) OF TRAINED YOUNG MEN

Matinhamoee, H.
Islamic Azad university central branch of Tehran, Iran

Purpose: Determine the effect honey and Glucose drinks ingestion before and during endurance cycling on performance, rate of perceived exertion (RPE), heart rate, Glucose (Glu), insulin (Ins), Cortisol (Cort).

Methods: 16 trained men (Age 23 ± 2, weight 68 ± 3) 3 phase per week every 48h, cycling 50km. At first phase 13 ml/kg drink with %10 honey a %3 rose water, 40c was given to athletes. was given to subjects during 120 min, 100 min, 80 min before race and other half of total drink was given during 20 min, 40 min and 60 min after start of race. Honey composition %35 glucose, %38 fructose, %3%15 water, %8g wax) was determined in laboratory. In second phase %10 glucose drink was given, at third phase, placebo drink that was sweet but has not any energy been given. Blood glucose 2h before race measured that was normal 60 ±1 mmol/dL. 5h before drinking any drinks a standard meal %55 CHO, %20 Pro, % 25 fats and 80 Kcal/kg was given to subjects. During race temperature was 25-27oc, humidity %50, and % 52. Total time average speed, heart rate was taking with polar watch. A questionnaire was given about metabolic, gastro intestinal and heart disease and use drugs.

Result: Was shown that in honey drink. Group glucose was higher and performance (total time, average speed, RPE, HR) was significantly better than glucose drink group and water group insulin was higher in Glucose drink group.

Conclusion: Honey drink has fructose and lower glycaemic index and desirable taste for Iranian athletes and cause lower insulin and high blood glucose during exercise. These can preserve liver and muscle glycogen and delay fatigue and improve performance.
THE EFFECT OF A DEEP WATER RUNNING TRAINING AND APPLE VINEGAR INGESTION ON SOME BLOOD COAGULATION FACTORS, BLOOD PRESSURE AND HR AMONG 58-68 YEARS OLD MEN

Matinhamomoe, H.
Islamic Azad university central branch of Tehran, Iran

Increasing blood homocysteine and coagulation speed increasing lead to arteries blockages and heart stroke in old men. Positive effects of exercise and apple vinegar on prevention of arteries blockages and decrease blood pressure is reported but effects of these factors altogether are unknown.

Purpose: To determined the effect of a deep water running training and apple vinegar ingestion on some blood coagulation factors, Blood pressure and HR among 58 + 68 years old men.

Methods: 24 men age = 63 ± 4y ± SD, weight = 10 ± 4kg body fat, %30 ± 5.5 with out acute heart and cardiovascular or gastro-intestinal problem, no smoking and no use alcoholic dink and any drugs randomly divided to low experimental and control groups. 16 week, 3 sessions per week and 1h per session water running training was done %45 to %55 from max heart rat. Apple Vinegar (5 ml/kg). Bw was ingested every day. Before and 24h after last session homocysteine, RBC, Hb, Hct, Fibrinogen, Plt, PT, PTT, BP and HR was measured.

Results: Was shown that after 16 week in experimental group fibrinogen, homocysteine, Hp, HR was significantly decreased but PT, PTT, was significantly increased and other factors have no significant change. (Table 1)

Table 1. Comparison between mean values of experimental and control groups before and after 16 week training and apple vinegar was ingested every day. Before and 24h after last session homocysteine, RBC, Hb, Hct, Fibrinogen, Plt, PT, PTT, BP and HR was measured.

Conclusion: Deep water training and apple vinegar ingestion can reduce homocysteine and decrease blood coagulation speed. These may be prevent arteries blockages and improve BP and cardiovascular system function in old men.

DIFFERENTIAL ADAPTATION OF MOLECULAR SIGNALING IN MITOCHONDRIAL BIOGENESIS UNDER EXTENSIVE ENDURANCE TRAINING WORKLOAD

Frese, S., Gehlert, S., Brixius, K., Heinzelmann, I., Bloch, W.
German Sport University Cologne, Institute of Cardiovascular Research and Sport Medicine, Germany

Exercise-induced adaptation of mitochondrial density depends on various molecular signaling pathways, which are singularly well described. A multifactorial investigation in a practical training regimen, however, is rarely seen. Therefore, we investigated parameters involved in skeletal muscle mitochondrial adaptation in two extensive cycling training groups with a constant but different workload determined as higher and lower percentual usage of VO2max. Before and at the end as well as after 9 days during the training, VO2max was determined and a muscle biopsy was taken (M. vastus lateralis). Mitochondrial adaptation was determined by immunohistochemical measurement of the protein expression of NRF-1, PGC-1alpha and superoxide dismutase 2 (SOD). Functional mitochondrial adaptation was determined by measuring cytochrome C oxidase (COX)-activity. VO2max increased over the time period slightly but not significantly in the high intensity group but not in the low intensity group. There could be seen a significant relationship between SOD2 and PGC-1alpha. NRF-1 expression did not change significant during the training intervention in both groups. Skeletal mitochondrial COX activity increased in all participants however at different time points during the training intervention.

Conclusions: This study provides evidence for a differential molecular mitochondrial adaptation towards training stimuli which also is dependent on the respective individual. Moreover it was suspected that altered adaptational sensitivity might occur over the time course. An alteration of VO2max seems not to be a representative marker of mitochondrial adaptations in skeletal muscle. To date, defined adaptations as result of practical training approaches are difficult to forecast. However, further gathering of relevant data might contribute in creating future, highly effective training stimuli in clinical and sports applications.

COMBINING TWO HYALURONIC ACIDS IN OSTEOARTHRITIS OF THE KNEE. A RANDOMIZED, DOUBLE-BLIND, PLACEBO CONTROLLED TRIAL

Petrella, R., Cogliano, A., Decaria, J.
University of Western Ontario, Canada

Background: Synovial fluid in patients may differ in molecular weight depending on the presence and degree of osteoarthritis. Treatment is not directed at this relationship.

Participants: Patients with osteoarthritis of the knee with resting visual analogue scale (VAS) pain of >45 mm.

Design: Randomized, prospective, double blind cohort followed for 16 weeks.

Intervention: Patients were randomised at baseline to receive a three intra-articular injection series with one of: DMW (Dual molecular weight 580-780kDa + 1.2 to 2.0 million); LMW (Low molecular weight) (500-730kDa); HMW (High molecular weight) (6 million); or saline placebo over 3 weeks.

Methods: Patients completed baseline assessment of rest and walking VAS pain (primary efficacy variable), collection of a 5-point categorical global satisfaction score and record of adverse events.

Results: Two-hundred and twenty-five patients (age 68±8y) were screened and two hundred were randomized to one of the four groups. There were no differences at baseline between groups. At 4, 12 and 16 weeks respectively, walking VAS pain was significantly improved in all treatment groups vs Placebo. DMW (79.6%, p<0.001; 85.6, p<0.001; 89.3%, p<0.001), LMW (73.6%, p<0.001; 76.4, p<0.001; 81.3%, p<0.001) and HMW (69.1%, p<0.001, 81.0, p<0.001; 79.1%, p<0.001). Patients in the DMW group had significantly greater improvement.
ankles (2) and feet (4). Ground reaction forces (GRFs) were recorded by means of two Kistler® force platforms working at 960Hz. Each test session consisted in 3 different tests: a static test (to measure the GRFs distribution between the two legs), a gait test (to study kinematics and kinetics of the stride cycle during the rehabilitation steps) and squat tests with/without overload (to quantify differences between athletic groups). Kinetics data allowed to quantitatively describe GRFs with specific attention to vertical force. In this way it was possible to control the player’s condition during the rehabilitation program in order to refine the rehabilitation activities and to reduce the time of recovery. Results showed an increase of the injured leg ankle vertical excursion of 30% after 3 weeks and a progressive recovery of symmetry between the two legs in squat exercise.

Results: About 30% of the ankle sprains were first events and no differences in clinical assessments with those presenting but not volunteering for the study (N=341) was observed. Time to intervention was 39 ± 4 hours with no difference between groups. A significant reduction in VAS pain on both weight bearing and walking was observed at Day 8 for HA compared to PL (p<0.05). There was a significant difference in VAS pain on weight bearing at 18 months favoring the HA group (p<0.05). No serious adverse events were recorded during the 8-day treatment period to 90 days followup. At 18 months, in the PL versus HA group, there were 2 versus 0 lower limb fractures, 16 versus 8 second ankle sprains (p<0.05), 3 versus 1 third ankle sprains, and a significantly greater number of days missing primary sport activity. Differences between groups were determined using an intent-to-treat ANOVA.

Conclusions: Greater improvement in patients who received the DMW product was achieved by the second injection persistent at 16 weeks.

Key words: Hyaluronic acid, knee osteoarthritis, molecular weight composition, activity concentrations

Registered Clinical trial number: ISRCTN98630331

PERI-ARTICULAR HYALURONIC ACID IN ACUTE ANKLE SPRAIN: 18 MONTHS FOLLOWUP

Petrella, R., Cagliano, A.
University of Western Ontario, Canada

Objectives: To determine the long-term efficacy and safety of peri-articular hyaluronic acid injections in acute lateral ankle sprain.

Design: Randomized controlled prospective trial.

Setting: Primary sport medicine and emergency practice.

Patients: One hundred and fifty-eight consecutive competitive athletes who suffered an acute Grade 1 or 2 lateral ankle sprain were randomized within 48 hours of injury.

Interventions: Patients were randomized at baseline to peri-articular injection with hyaluronic acid (HA) + standard of care (RICE) or placebo injection (PL) + standard of care (RICE) treatment at baseline assessment and Day 4 post injury. This report describes the 18 month followup results of this cohort.

Outcomes measures: Assessments at baseline and Days 4, 8, 30, 90 and 18 months included VAS (0-10 cm) pain on weight bearing and walking 20 m, patient global assessment of ankle injury (5-point categorical scale), patient satisfaction with treatment (5-point categorical scale), time to return to pain-free and disability-free sport, adverse events; recurrent ankle sprain and total number of days missing primary sport activity. Differences between groups were determined using an intent-to-treat ANOVA.

Results: About 30% of the ankle sprains were first events and no differences in clinical assessments with those presenting but not volunteering for the study (N=341) was observed. Time to intervention was 39 ± 4 hours with no difference between groups. A significant reduction in VAS pain on both weight bearing and walking was observed at Day 8 for HA compared to PL (p<0.05). There was a significant difference in VAS pain on weight bearing at 18 months favoring the HA group (p<0.05). No serious adverse events were recorded during the 8-day treatment period to 90 days followup. At 18 months, in the PL versus HA group, there were 2 versus 0 lower limb fractures, 16 versus 8 second ankle sprains (p<0.05), 3 versus 1 third ankle sprains, and a significantly greater number of days missing primary sport activity (43 versus 21, p<0.002). An increased number of concomitant treatment was observed in the PL vs the HA group at 18 months. This included greater external ankle bracing (61 versus 28, p<0.02) and orthotics (21 versus 11, p<0.05). Significantly greater patient satisfaction was observed for HA vs PL at Days 4 (p<0.05), 8 (<0.001), 30 (<0.001), 90 (p<0.05) and 18 months (p<0.05). Time to pain-free and disability-free return to sport was 11 ±8 vs 17 ±8 days for HA and PL respectively (p<0.05).

Conclusion: Peri-articular HA treatment for acute ankle sprain was highly satisfactory in the short and long term versus PL. This was associated with reduced pain, more rapid return to sport, fewer recurrent ankle sprains, fewer missed days from sport with fewer associated adverse events.

EVALUATION OF A REHABILITATION PROTOCOL BY REPEATED MOTION CAPTURE ANALYSIS AFTER ACL RECONSTRUCTION: A SINGLE SUBJECT STUDY IN RUGBY

Nardello, F., Marcolin, G., Petrone, N., Baldo, M.
University of Verona and University of Padova, Italy

Rugby players are often prone to several types of injuries occurring at different body locations, in particular at head, neck, knee and ankle [1-2]. ACL injury is very common and usually leads to a reconstruction surgery; a quick rehabilitation program is crucial for the full recovery of elite players as they are fundamental to their teams. So it is very important to define an individual rehabilitative program and to monitor periodically its effects in order to apply possible adjustments during its development and to speed up the full recovery process. Moreover, individualized protocols allow to maintain and often increase the strength of the injured body segments. Aim of the present work was to evaluate how repeated motion capture analysis applied to a combination of gait tests (kinematics and kinetics) and specific training exercises could objectively identify and quantify the recovery progresses of an elite rugby player after ACL reconstruction.

A professional rugby player volunteered for 5 test sessions: the first was with the left knee injured, the following 4 sessions started 4 weeks after the surgery with intervals of 1 week. A motion capture system (BTS®-Italy) with six infrared cameras was employed to record kinematics data at 60Hz on each session. Reflective markers were placed on trunk (4), arms (4), hands (2), pelvis (2 at PSIS), great trochanters (2), knees (4), ankles (2) and feet (4). Ground reaction forces (GRFs) were recorded by means of two Kistler® force platforms working at 960Hz. Each test session consisted in 3 different tests: a static test (to measure the GRFs distribution between the two legs), a gait test (to study kinematics and kinetics of the stride cycle during the rehabilitation steps) and squat tests with/without overload (to quantify differences between eccentric and concentric phase). Kinematics data allowed to objectively quantify parameters such as vertical excursion of great trochanters and ankles during gait and squat. Kinetics data allowed to quantitatively describe GRFs with specific attention to vertical force. In this way it was possible to control the player’s condition during the rehabilitation program in order to refine the rehabilitation activities and to reduce the time of recovery. Results showed an increase of the injured leg ankle vertical excursion of 30% after 3 weeks and a progressive recovery of symmetry between the two legs in squat exercise.

EFFECT OF INTERMITTENT SPRINT CYCLE EXERCISE ON OXIDATIVE DNA DAMAGE AND SERUM ANTIOXIDANT CAPACITY

Kambayashi, I., Fujii, H., Kusakabe, M., Takeda, H.
Hokkaido University of Education, Sapporo, Japan

Purpose: It is reported that aerobic energy supply plays an important role in exerting higher power output during intermittent sprint cycle exercise (4). Little has been known about biomarkers of oxidative stress and antioxidant status following intermittent sprint cycle exercise although such type of exercise induces significant elevation of antioxidant enzyme activities (3). The purpose of this study was to examine effect of high-intensity intermittent sprint cycle exercise on oxidative DNA damage and serum antioxidant capacity. Methods: Prior to participation in this study, all subjects provided both verbal and written consent. Twenty-four male students belonging to the physical education course in the University (age 20.1±0.4 yr, height 173.4±1.0 cm, weight 65.8±2.1 kg) performed intermittent sprint cycle exercise for 20 sets. Each set consisted of 7-second maximal pedaling resistance was set at 8% of body weight and 53-second recovery (unloaded pedaling by 60 rpm) (4). The decline rate of power output as the following equation, [P(1-3)-P(17-19)]/P(1-3)*100, where P(1-3) and P(17-19) were averaged power output from 1st to 3rd and from 17th to 19th, was used as performance index in each subject. Urine samples were collected at Pre (Pre) and after 1 hour exercise (Post-1h) for the detection of 8-hydroxydeoxyguanosine (8-OHdG) in urine. Enzyme-linked Immunosorbent Assay (ELISA) was used for analyzing urinary 8-OHdG concentration (1). Blood samples were also collected at Pre, immediately after exercise (Post) and Post-1h for serum antioxidant capacity. Serum antioxidant capacity was measured by ESR spin-trapping method. Superoxide radical (O2-) was produced by in hypoxanthine/xanthine oxidase system, and its scavenging activity by the serum was measured by ESR spin-trapping method with 5,5-dimethyl-1,3-propanediyl-5-methyl-1-pyrroline N-oxide (CYP-MPO) as spin-trapping reagents (2). Results: Mean heart rate during exercise (20-min) was 160±4.2 bpm. Urinary 8-OHdG content significantly increased after exercise (6.62±1.16 ng/kg/h Pre vs. 27.92±2.40 ng/kg/h Post-1h). O2- scavenging activity significantly decreased at Post (61.3±0.9%) compared to Pre (71.0±1.1%) and Post-1h (71.9±0.8%). Performance index was significantly related to urinary 8-OHdG content at Post-1h (r=0.707, p<0.001) and O2- scavenging activity at Post (r=0.540, p=0.031), respectively. Conclusion: It is clear that high-intensity intermittent sprint cycle exercise induces oxidative DNA damage and transient change of serum antioxidant capacity. Results also suggest that urinary 8-OHdG content may be useful for fatigue indices after high-intensity exercise. References.

RISK FOR THE FEMALE ATHLETE TRIAD IN ADOLESCENT SYNCHRONIZED SWIMMERS

Clijsten, R., Kersing, M., Duquet, W.
Thim van der Laan Physiotherapieausbildung, Landquart, Switzerland

Objectives: The aim of the study was to examine adolescent synchronized swimmers for risk factors of the Female Athlete Triad and to investigate correlations between menstrual disorders (MD) and energy balance (EB) on the one hand, and anthropometric parameters on the other hand.

Relevance: Until now only two surveys in connection with the risk for the Female Athlete Triad in synchronized swimmers have been carried out, although prevalence has increased in aesthetic sports (1, 2, 3). Early recognition is of high importance.

Methods: 20 juniors of the Swiss Synchronized Swimming National Team (SY) (Mean age±SD = 16.4±1.2 years) were tested. Examination included anamnesis of menstrual cycles by questionnaires, determination of EB during a practice camp, measurements of 8 skin folds (SKF) and calculations of body fat percentage (%BF) and somatotype (S). MD were defined as polyMenorrhea (cycle length ≤15 days), oligomenorrhea (CL >35 <90 days) and amenorrhea (no menstruation >3-6 months). Subjects were divided into athletes with eumenorrhea (ATHLEu; n=9) and athletes with MD (ATHLMD; n=11). For statistics p<0.05 was fixed.

Results. Athletes were 164.3±5.3 (M±SD) cm tall, weighed 51.8±6.3 (M±SD) kg and had 22.1±3.7 (M±SD) % body fat. Altogether 55% of SY showed MD, distribution of 10% polyMenorrhea, 30% oligomenorrhea and 15% amenorrhea. Mean EB was -1132±607.9 (M±SD) kcal/day, mean EB of ATHLMD -1259.5±663.5 (M±SD) kcal/day was lower than mean EB of ATHLEU -976.1±527 (M±SD) kcal/day. There was no correlation between MD and EB (rPbis=0.230). Significant correlations were found between MD and SKF(biceps rPbis=0.524, MD and SKFpectoral (rPbis=0.452), and MD and S (rPbis=0.454), but not between MD and %BF (rPbis=0.415). Conclusion: The prevalence of MD found in SY is higher than that found in the literature (3). The conclusion may be drawn that adolescent synchronized swimmers show an elevated risk for MD and the Female Athlete Triad.

Keywords: synchronized swimming, Female Athlete Triad, energy balance, menstrual disorders, amenorrhea

PHYSICAL ACTIVITY PRESCRIPTION IN THE COMMUNITY; CORONARY RISK ESTIMATION IN SPAIN USING A CALIBRATED FRAMINGHAM FUNCTION

Bellver, M., Banquells, M., Guerrero, A., Dinares, M., Rueda, J., Galilea, P.
Consorti Hospitalari de Terrassa-Centre d’At Rendiment, Sant Cugat del Valles, Barcelona, Spain

Introduction: Physical activity has a role in disease prevention and is recommended to achieve good health. Coordination between family physicians, sports physicians, physical educators is also essential to promote physical activity in the population. Objective: We start a physical activity program in a family physician department in Terrassa (Barcelona) 6 years ago. We studied a sedentary group middle aged with chronic pathologies (coronary heart disease (CHD) risk factors, musculoskeletal and neuromuscular disorders. In this study we compare physical parameters and health autoperception in the CHD risk factors group, after the practise of supervised exercise during one year. Methods: We studied a group 45-65 years old with medical history in the familiar health department with CHD risk factors of hypertension, dyslipidaemia, obesity, diabetes. Calibrated Framingham function charts of CHD risk for the spanish population
are used. We did a medical evaluation before participation and after the completion of the exercise program, that includes a blood profile (blood glucose, total cholesterol, HDL-c, LDL-c, triglycerides), rest electrocardiogram, monitored quantized exercise test, kineanthropometry, and Nottingham test. For ethical and legal reasons, all programs required an informed consent. This group practise supervised physical exercise twice per week, 1h/session. They play a weight training circuit, moderate intensity aerobic activity, muscle strengthening activity and balance exercises as recommended by the ACSM and the AHA (2007). Results: The group was composed by 109 patients, BMI>30, that represents a moderate risk of morbidity. Only 70 patients finished the study (adherence to the protocol was 64%). The probability of CHD in 10 years before the program was 8.9% (the drop out group probability was 5.1%). After finishing the program the probability was 7.4%. Significant reductions in 10 years risk of CHD were observed (a=0.005). None of the subjects changed his/their habitual habits, so that the probability change was because of the effect of the controlled variables (total cholesterol, HDL-c, diabetes, repos systolic and diastolic blood pressure). Nottingham test increased significantly in emotional reactions. Conclusions: The study provides evidence for the benefit to CHD risk factors and mental health after one year of supervised physical exercise, in a sedentary group middle-aged.

THE EFFECT OF ENDURANCE TRAINING PROGRAM AND L-ARGININE SUPPLEMENTATION ON PLASMA NITRIC OXIDE CONTENT IN RATS

Khosravi, N., Gharakhanlou, R., Gaieni, A.

University, Iran

Khosravi, N. Exercise Physiology PhD (University of Alzahra), niku46@yahoo.com, Address: Department of physical education and sport science, Alzahra University, Tehran. Iran. tel: 09123871843

Abstract

The purpose of this study was to investigate the effect of endurance training program and L-Arginine supplementation on plasma Nitric Oxide content in rats.

Method: Eight-week-old male wistar rats (n=40) were divided into four groups. 1) The Exercise group, 2) The Exercise + the L-arginine group, 3) The L-arginine intake group, which was given L-Arginine supplementation (5g/kg body weight per day, in drinking water); 4) The control, sedentary group. The train groups (1,2) exercised for 9 week 5 day/week on a treadmill. The running time and speed of the treadmill were increased gradually. The mean of endurance training program was (50 min, 30 min, 0% grade). After the animals were anesthetized with Diethyl ether, blood samples for analysis of NO metabolites and Arginase enzyme and Total CK were collected after 24 hours from exercise and for NO metabolites after a recovery period of 48 hours and 72 hours. Results: Plasma NO level was higher in the trained rats than in the exercise + L-arginine and control groups (1.59 μmol/L vs 1.46 μmol/L and 0.39 μmol/L, p<0.05) and there was a significant decrease in plasma NO after exercise and after a recovery period of 48 hours and 72 hours (1.59 μmol/L, 1.08 μmol/L, 0.54 μmol/L vs 0.39 μmol/L). Plasma Arginase enzyme was higher in the L-arginine supplementation group than in three groups. Conclusion: The results indicated that oral supplementation of L-arginine, the precursor of NO, during an endurance training (9week, 5 day/week) caused an increase plasma NO concentration, but this increase is less than exercise alone. NO is an important mediator of homeostatic processes and changes in its generation contribute to pathologic states, some of which have been described in this research. Thus this study proposes a role for L-arginine as a dietary supplementation for endurance athlete.

Key Words: Endurance Training, Nitric Oxide, L-arginine, Sedentary, Exercise, Intervention.

TRAINING TIME AND ADAPTATION TO LACK OF DAY LIGHT - A PILOT STUDY

Cologniari, G., Beldo, S., Roveda, E., Montaruli, A., Carandente, F., Weydahl, A.

(1) University of Milan, Italy; (2) Finnmark University College, Alta, Norway, Italy

It is found that training done at different times synchronizes the HR circadian rhythm (1). Athletes in Northern Norway claim it is hard to achieve an optimal training effect during the darkness period. Knowledge about the effect of light conditions upon training response seems to be missing. As a start we did a pilot study to describe the reaction to lack of daylight and different training-time on circadian rhythms and nocturnal sleep in a 26 year old healthy, trained female arriving Northern Norway from Italy in the darkness period.

Monitoring Sessions (MS) were carried out in four experimental conditions: MS1 - no training in light-darkness periodicity (Italy), MS2 - no training in lack of daylight (Norway), MS3 - evening training (18.00-19.30) in daylight-dark, MS4 - morning training (9.00-10.30) in daylight-lack. Each monitoring session (that started in the last training-day) was composed by: questionnaire (analogue scale) to fill in every morning during the sessions, three-days continuous monitoring by heart rate (HR) monitor (IS810, Polar) and actigraph (Actiwatch, Cambridge Neurotechnology). Each training period was four consecutive sessions of outdoor fast-walking (63%HRmax, 43%VO2max) with backpacking during the sessions, three-days continuous monitoring by heart rate (HR) monitor (S810, Polar) and actigraph (Actiwatch, Cambridge Neurotechnology). Each training period was four consecutive sessions of outdoor fast-walking (63%HRmax, 43%VO2max) with backpacking during the sessions. The Circadian Rhythms (Single Cosinor Method) of HR and Rest Activity (RA) were compared with sleep analysis results and subjective perception expressed in the questionnaire. The HR and RA circadian rhythms were statistically significant (p<0.0001). MESOR values were lower in MS2 than in MS1, 3 and 4 for the Activity, while it was progressively lower for the HR. Acrophase was advanced in MS2 and 4 compared to MS1 and 3 for both Activity and HR. Sleep Analyses show higher values of Sleep Efficiency in MS 2, 3 and, especially, 4 than in MS 1, that correspond to low values in Mean Activity Score and Movement and Fragmentation Index. The questionnaires showed that the subjective perception of sleep and concentration ability were pretty close to the normality. It was also observed that the rest-HR decreased through the 3 monitoring weeks, even if the subject was already well trained. It seems as if the light-lack condition induced a bradycardial stimulus in addition to the training. This pilot study suggests that lack of daylight and no training condition induce an activity decrease, advance Acrophase (2,5h for the activity and 3h for HR), and enhance sleep. The training increased the activity MESOR, but influenced the circadian structure in different way according to the time in which it was carried out. The training time influenced the circadian parameters for both HR and RA. The evening session the Acrophase was postponed, whilst it was advanced after the morning session. The sleep quality seems to benefit the best from the morning training.

Injury Pattern in Portuguese Female Handball Players

Estriga, L., Carvalho, J., Bernardes, J., Massada, L.

University of Porto, Portugal

Background: Handball is the sport with more federated females in Portugal. Its injury incidence pattern is, however, poorly characterised. To know the magnitude of the problem and its causes is essential to adopt efforts to reduce the risk of injury.

Objective: To describe the injury profile of Portuguese players of different competitive levels and ages.

Design: Descriptive epidemiologic study performed between 2003 and 2007 using a custom made questionnaire. A sub-sample of players (8%) was also examined by an orthopaedic surgeon for consistency check.

Setting: Four year long retrospective and prospective cohort study.

Participants: 804 subjects, from infants (10-12 years old) to adults, sampled from the major national competitions, regional handball associations and the national and regional selection teams.

Results: In the first two full seasons (2003-04 and 2004-05) we computed an overall incidence of 3.0 injuries per 1000 player-hour of handball practice. From these, almost 72% were acute injuries. A Kruskall-Wallis analysis and corresponding post-hoc analysis revealed that the injury incidence followed exactly the increasing age categories (p<0.1%). Considering all the reported injuries (N=1227), the lower extremity was the most commonly injured body region, with 680 injuries (55.4% of all injuries), followed by the upper extremity, 403 injuries (32.8% of all injuries). The most injured sites were the ankle (28%, of which 94% were acute), knee (20%, of which 68% were acute, shoulder (10%, of which 66% were from overuse), finger (9%, of which 99% were acute), back (6%, of which 79% are from overuse) and elbow (8%, of which 78% were from overuse). About 27.5% of the injuries demanded an absence from practice of more than 4 weeks (82% of these were acute). Of these severe injuries, 50% were in the knee and 25% were in the ankle. A total of more than 28% of all the knee injuries demanded a surgical intervention. In the ankle the surgical intervention rate was only 6%. Of the severe injuries, the majority (57%) were sprains with ligament rupture and/or meniscal tears. The main structures affected in these severe injuries were the anterior cruciate ligament (28%), the meniscus (22%) and the collateral ligaments (11%). The majority of these severe, acute, injuries on the knee and ankle joints occurred during a match (75%), in the offensive phase (64%) and in the back players (73%).

Conclusions: In female handball players, the knee is the structure with most risk of severe injury and is strongly associated with the game structure and function.

Family Social Dynamics. A Parents’ Vision of Their Children’s Free Time

Pereira, A., Moreira, M.

Polytechnic Institute of Viseu - Higher Education School, University of Trás-os-Montes and Alto Douro, Portugal

Young people’s free time is important in determining their identity, education and development. (Munson & Savickas, 1998, Piko & Vazsonyi, 2004). The family, namely parents exerts a great influence on young people, providing them with many values and norms which are character forming (Caldwell & Darling, 1999, Fletcher, Nickerson & Wright, 2003).

The present study aimed to identify parents’ representations of their children’s free time and to know their aspirations at this level. The study was carried out on 90 parents of young people attending 9th year in state schools in Coimbra and Leiria using semi-structured interviews. The technique used for data analysis was content analysis (Miles & Huberman, 1994). The elaboration of the categories had been defined a priori and a posteriori (Bardin, 1977). The computer programme of qualitative data analysis QSR NVivo 7 was used in coding the transcripts of the interviews.

The categories found were «opportunities for development», «role models» and «sport». Children’s free time represents an opportunity for development, giving them a wide variety of experiences directed by guiding and vocational principles for their development as a whole.

Parents understand they should be role models and therefore develop qualities, ways of conduct, attitudes and initiatives capable of influencing their children’s choices and behaviour.

Most parents would like their children to do sport in their free time, which promotes health and is supervised by adults.

AN EMPIRICAL STUDY ON THE ROLES OF PHYSICAL ACTIVITIES IN IMPROVING THE DAILY LIVING FROM THE EXPERIENCES OF JAPANESE FEMALE ELDERLIES WHO LIVE ON THEIR OWN

Ishizawa, N.
Hokusho University, Japan

Introduction
The size of the national population aged 65 or over in Japan has been on a rapid increase (Ishizawa, 2000). Among this ageing population has been witnessed a growing number of eldery who live on their own. It accounts for as many as 3,860,000 (The National Census, 2000). This figure indicates an approximately 30% increase from the previous (2000) census record. This paper aims at examining the effects of physical activities on the daily life of the elderly population through an empirical survey in Japan.

Methodology
The author of this paper conducted a questionnaire (self-administered questionnaire) survey on a group of elderly females who live on their own at home in Kobe, in April 2004. Of the 60 copies distributed, 52 completed questionnaires were returned (Response rate: 86.7%). The respondents are divided into two groups, (1) 26 ‘actives’ who enjoy physical activities on a regular basis, and (2) 26 ‘inactives’ who have not been involved with any physical activities for the past six months. The former is defined as an individual who ‘performs physical activities for at least twenty minutes, three times or more a week’ (ACSM, 1998). For the purpose of the data analysis, T-tests are employed in order to measure the gap in the following attributes among the ‘actives’ and the ‘inactives’ in the sample population: (1) past medical records, (2) current medical status, (3) average monthly medical expenses, (4) existence of close friends, (5) degree of life satisfaction, (6) degree of well-being, and (7) ADL performance ability. Findings:
The average score in ‘life satisfaction’ is 30.0 in the ‘actives’ and 27.1 points in the ‘inactives’ group (Full score=35 points). This indicates a statistically significant differential (p<.01). The average ‘well-being’ is 28.9 points for the ‘actives’ and 24.7 points for ‘inactives’ (Full score=34 points), and the difference was statistically significant (p<.01). The average ‘ADL score’ accounts for 26.5 points among the ‘actives’ and 21.3 points among the ‘inactives’ (Full score=36 points), which shows another statistically significant gap between the two groups (p<.001). The result of this study has an implication that an active participation in leisure activities such as sports would have a positive impact upon the degree of their life satisfaction, well-being and ADL performance ability.

RETHINKING THE RELATIONSHIP BETWEEN SPORT AND ETHNICITY

Chiu, WC., Chiou, JS.
National College of Physical Education and Sport, Taiwan

Baseball has not only shared the important position as national sport in Taiwan, it also created many sports stars who enjoy fame and fortune, thus considered to be one of the stepping-stones that help the aborigine peoples of Taiwan to get away from the injustice of social stratification. Nonetheless, the belief that sports is beneficial for racial minority has clouded the fact of enshrined inequality of resources and power distribution in sports. On one hand, Sport is given with positive significance and chance of survival; on the other hand, it has also further reproduced the current status of inequality as well as racial ideology. Since aboriginal athletes are members living in wider social structure and will continuously exposed to the shaping power of kinds of social force. As such, this article will base on the position of social structure would, through the intervention of social factor and kinds of capital/resources, remain to affect the sports career development of aboriginal baseball player so that they can, as exposed to the rather unfavorable ethnicity and social stratification and inequality in wider social structure, still be reproduced in sports field.

YOUNG NATIONAL TEAM FOOTBALL PLAYERS- COMMON CHARACTERISTICS OR NOT?

Segberg, U.
University of Agder, Norway

In order to develop football players’ skills, possessing more knowledge about elite players’ backgrounds, lifestyles, activities and motivation may be important. The aim of this study is to describe some characteristics regarding to family backgrounds and motivation. 45 male football players in three National teams of Norway, U17, U19 and U21, participated in the study. Among these players, two thirds reported they were part of big families. Two thirds were three or more siblings and more than 20% reported they were four or more siblings. More than two thirds reported that they have older siblings. Furthermore, they reported about athletically active families; all of their siblings, more than fifty percent of their mothers and seventy five percent of their fathers had been athletically active. 35% of their siblings, 20% of their fathers and about 10% of their mothers had played sport at a high level. All of the players reported about a very high activity level in their childhoods, at age six, 65% and at age eight, more than 90% had been members of an athletics club. Moreover, most of the players also reported about a diversified involvement in a number of sport activities. From the ages of six until fourteen, more than 70% participated in one or more athletic activities in addition to football. The players’ ambitions were high; more than 75% wanted to be National team players or players on the international level.
FEMALE RIDERS’ PERCEPTIONS OF GENDER RELATIONS IN SNOWBOARDING

Sisjord, M.
Norwegian School of Sport Sciences, Norway

This paper will focus upon gender relations in snowboarding based on the meanings and experiences articulated by participants of the sport. Snowboarding has been characterized by male domination in quantitative terms as well as masculine connotations which both reflects sport as traditionally being a male domain, and snowboarding's relatedness to alternative youth cultures, which in general excel masculinity in style and behavior. Snowboarding along with surfing and skateboarding developed in a different social context relative to modern organized sports. The informal structure has an impact on the participants' position and status in the culture. Previous research on alternative sports has examined subculture characteristics and the insider outsider dimension has been given particular attention in descriptions of the core members' prestige versus more peripheral participants. In terms of gender relations most studies have explored females' position in a male-dominated context. The present study will examine gender relations in snowboarding by focusing upon relations between female and male snowboarders as well as between different groups of females.

The paper is based on a study of female snowboarders in the Norwegian Snowboard Federation (NSBF). Education about gender issues is a central part of the NSBF’s working programme and one sub-group, PowderPuff Girls (PPGirls), works on the recruitment of girls and women to snowboarding, and promoting females’ participation at various levels in the organisation. The study was made in connection with a workshop organized by the PPGirls in October 2004. Methods of the study were participant observation and qualitative interviews with six participants, aged 18 to 28 years.

The results show that the female riders' experiences of gender relation reflect inferiority versus male riders on a group level. Some of them expressed that they felt inclusion from the males’ side, but the males are the rulers of the pipe and parks. In terms of gender relations among female riders three different typologies or femininities were identified; babes, fast-girls, or invisible girls. The babes were described as passive, wanna-be’s and primarily attracted to snowboarding by male riders, whereas the fast-girls were active, striving for performance enhancement and challenging the male domination. They are the closest to the core snowboarders among the females. The invisible girls compose a variety of performance levels, aspirations, as well as snowboarding styles. The results are discussed in relation to Bourdieu’s concepts of capital, field and masculine domination.

BRAZILIAN ELDERLY: PERCEPTION THE BENEFITS OF THE PRACTICE OF PHYSICAL EXERCISE

Santiago, L., Pereira, A., Dantas, M., Silva, S.
Universidade Federal de Alagoas, Brazil

An active life can minimize the deleterious effects of ageing. Shephard (2003). The purpose of this study was to verify the benefits, perceived by elderly women from the practice of gymnastics. The sample was composed of 68 elderly women, aged above 60 years, participants of gymnastics three times a week in Maceio / Brazil. The instrument used a semi-structured interview. Composed of questions seeking to verify perceived benefits from the exercises practice. The data was interpreted through the Content Analysis, Bardin (1994). The elderly women reported that from the physical exercise realized: an increase the network of friends; increased autonomy, feel more secure, decreased anxiety, increased self-esteem. The answers confirm that physical activity may influence changes and provide improvement in the quality of life. It is concluded that the participation of the elderly in a regular physical activity influences them to develop a positive attitude in relations to life, which can contribute to the development of a new identity.

BODY IMAGE AMONGST ADOLESCENTS A SOCIOLOGICAL ANALYSIS

Pinheiro, C., Santiago, L., Magalhães, F., Maia, H.
Instituto Superior da Maia, Portugal

The adolescence is a period marked by important physical, physiological, psychological and social transformations being the body aspect one of the most relevant transformations (Jacob, 1994). Such body changes may bring about problems altering the body image of boys and girls. Because individuals, as members of large networks of interdependencies, are continually judged by their appearance, adolescent boys and girls become highly concerned with their physical appearance. However, girls seem to be more concerned with their physical appearance than boys mainly because they learn, from a very early age, that a slim body and a beautiful appearance is more likely to be valued by others than a body that does not fit in such ideal (Barbosa, 2001). Girls are bombarded with idealized images of a certain type of a female body that it is almost impossible to ignore. The effects, as Hargreaves (1994) points out, are dangerous. Adolescent girls rarely feel at ease with or proud of their bodies unless they conform to some notional ideal (Hargreaves, 1994; 156).

This study had as its main goal, to analyze and to interpret the concept of body in the adolescent boy and girl. The question Are male and female adolescents satisfied with their body image? was the starting point for this research. In this process we attempted to analyze and to interpret the way adolescents see their bodies. Our research was carried out in the school EB 2/3 D. Pedro IV - Mindelo, with students of the 9th year of schooling. Of the 123 students studied, 67 were males and 56 were females. To collect the data we used the Body Image Satisfaction Questionnaire, developed by Luther et al. (1990). This questionnaire is composed by twenty two items. For each item, concerning each part of the body, the person is asked to rate the way he/she feels about each part of his/her body. There are five possibilities of answer: 1 Have strong negative feelings and wish change could somehow be made; 2 Do not like but can put up with; 3 Have no particular feelings one way or the other; 4 Am satisfied; 5 Consider myself fortunate. The information that was gathered was then submitted to a statistical analysis. In the analysis we compared both genders.

This study revealed that girls are more critical of their body image than boys. Girls are more likely to value their bodies and an ideal type of body than boys. This shows that a human being is, without a doubt, carrier of an identity and self-esteem entailed to the corporal conscience.

References.
The participation in institutionalized sporting activity by children is point in the literature as a way that contributes for the increase of the energy expenditure, equally favoring the motor, social and cognitive development. It is also associated with the adoption of an active lifestyle. The objective of this study was to analyze practical of institutionalized sporting by children from Florianópolis, S.C., Brazil, in the working days. 180 children selected from schools (16) had participated of the study. The participants within schools informed consent from parents/guardians. This research is part of an extensive study concerning the identification of the life’s routines, independent mobility and perception of the physical space, using some suitable instruments of reference studies (questionnaire, interview, drawing, diary and production of texts). The data referring to this study were extracted from diary and the interviews and they had considered the age (10 and 12 years), the gender (masculine and femininel) and the social-economic status (high and low). The results were present in simple frequency, percentage and mean. The differences had been computed through test ‘U’ of Mann-Whitney and test ‘T’ of Student, both with level of significance of p < 0.05, in accordance with the nature of the variable. The general results had indicated that 40.0% of the children practice some sporting modality in the working days and that this practical is not related to the age, the gender or the social-economic status. Between the 12 mentioned modalities, the most practiced had been the soccer (25.0%), swimming (25.0%), dance (23.6%) and fights (15.3%). The soccer (p=0.000) and the fights (p=0.039) are more practiced by boys and the dance (p=0.037) is more practiced by girls. Volleyball (p=0.024) and swimming (p=0.013) are more practiced by the children with 10 years old and the athletics (p=0.050) is practiced for children with 12 years. Athletics (p=0.036) is also a most common practical between children of social-economic status. The great majority (82.6%) practices only one modality, 15.3% practice two modalities and the remains practice three or more modalities. The frequency with that they realize these activities in the working days varies from one until more than three times, with predominance of two times (41.7%) and only one time (33.3%). The variable that more influence the choice of the children are thus the gender and the age. The average time dedicated to these activities is of 00:33.32 hours, without significant difference between the groups. Our results are in intermediate position in relation to the studies realized with other national and international samples. As far to the practiced modalities, the small differences found, mainly in relation the international samples can be attributed to the cultural questions, that define among others, the offer of adequate spaces.

THE VOLTA A PORTUGAL CYCLING RACE: ITINERARIES, NARRATIVES, AND IDENTITIES

Santos, A.

Faculty of Human Kinetics, Portugal

The Volta a Portugal is a cycling race with a eighty year-long historical narrative. The first full-scale cycling circuit of Portugal was run in April 1927. In the beginning of the 20th Century, machines that started out as rich folks’ playthings were being reassessed as poor men’s horses. Indoor and outdoor races had popularized their possibilities for decades. The time had come to link technology and trade, speed and entertainment, to spur broadsheet circulation and cycle sales. The Volta a Portugal’s popularity, comparing with other cycling races, was its compromised boundary itinerary that embraces all territory as a big bow. The success of that boundary formula itinerary, beloved by all folks, will be the reason to disapprove and criticize all other itineraries that go far from the initial model. How have the Volta’s itineraries served as a means for constructing, and contesting, local, regional and national identities?

The territorial boundary is more than an imaginary line, it is also a relational process, it divides people in groups, in communities, promotes processes of internal and external definition and a sense of shared belonging within their group, or community. The Volta’s itinerary maps turned the sport event into an annual lesson in Portuguese geography, featuring topographical profiles, and detailed schedules of racers’ expected times of arrival in communities along the itinerary. During the first two decades these maps emphasized a traditional Portugal, following the ideas of Antônio Ferro (the ideologist spirit politic of Salazar’s regime) published in Panorama magazine. By the end of the fifth decade, the maps show a modern leisure tourist country, which combines beach, mountain and bullfighting. After the Revolution (1974) the maps lost these folk motives and explores new design’s formats, some of them tied to sponsors symbols. Based on folklore symbols they reinforce models of politic control about what must be defined as national identity. Based on commercial symbols they offer a counter narrative beyond territorial identities, and they went to global consumer space. What they have repeatedly taken for granted, however, is the tensions that existed, and exist, between competing narratives about what’s the meaning of us (Portuguese people).

In spite of the extension of the Volta’s itinerary, and its commercials motivations, eighty years on, I could notice the enduring power of the event to carry meanings that transcend the sport competition.

PRINCIPAL PROFESSIONAL DEVELOPMENT METHODS FOR EXPERTS BASKETBALL COACHES

Ibáñez, S., Jiménez, S., Lorenzo, A.

Faculty of Sport Sciences: University of Extremadura. Cáceres, Spain

The aim of this study is to analyze the process followed in the development of the coaching knowledge by expert basketball coaches in Spain. The researchers (Irwin, Hanton & Kervin, 2004; Jones, Armour, & Potrac, 2004) have been able to identify a number of specific events or situations use to develop coaching knowledge as mentoring, interactions with other coaches, reflection and playing experience. Therefore, we used a qualitative methodology (Patton, 2002) from a biographical point of view. In - depth interviews were carried out in order to analyze the vital itinerary of 16 expert basketball coaches, who develop their activity in ACB league or the Spanish national selection, using for their selection the criteria used in specific literature as: a) have been coaching at the national or international level for at least ten years; b) have been coaching at international player level; and c) have won a professional basketball competition. The results shows that the coaches do not follow a specific pattern for training in conjunction with various studies of the literature (Irwin et al 2004, Jones et al. 2004), and the importance that some coaches give to formal versus informal education received. The informal learning have been more important for our coaches education.
The principal methods have been the situated learning or learning every day (Lave & Wenger, 1991), mentoring (Irwin et al., 2004), and informal knowledge network (Culver & Trudel, 2006) with other coaches. Finally, all coaches stress the continuing practice reflective everything they saw and learned related to basketball (Irwin et al., 2004).

This indicates that the education of the coach does not have to be a rigid schedule of courses and systematic official. But a deliberate preparation can be developed from a large number of ways that highlights the coaches interviewed and make us raise the present formication to us that is being made with the future coaches.

BODY COMPOSITION ASSESSMENT IN YOUNG MEN; COMPARISON BETWEEN SEGMENTAL MULTIFREQUENCY BIOIMPEDANCE METHOD AND DEUTERIUM DILUTION METHOD

Salmi, J., Tanskanen, M., Westerterp, K., Kyröläinen, H., Linnamo, V.
University of Jyväskylä, Finland

Introduction

Stable hydration is important in reliable body composition assessment. Hence, body water content plays an important role in assessing total body composition. Deuterium dilution method (DDM) has been demonstrated to be a gold standard for total body water (TBW) assessment (Watson et al. 1980). Also, the often used bioimpedance method primarily assesses the body water amount. Other body compartments are then further calculated from these TBW values. The accuracy of body composition estimation depends on the equation used and constant measurement conditions. The objective for this study was to validate segmental multifrequency bioimpedance (SMFBIA) method against DDM for body composition assessment in young male subjects.

Methods

Body composition from twenty-four 19.0 years old young men, participating in military service, was assessed by DDM and SMFBIA methods. The DDM method was conducted as described earlier by Westerterp et al. (1995) and SMFBIA by InBody 720 device (Biospace Co. Ltd, Seoul, South-Korea) according to Bedogni et al. (2002). SMFBIA measurement was also conducted for twenty-two subjects on a two consecutive days to assess the repeatability of the method.

Results

Mean (+/-SD) height and weight for the study subjects were 178.5 cm (+/-7.5) and 77.6 kg (+/-14.9), respectively. The mean (+/-SD) TBW, FFM, and FM by DDM and SMFBIA were 43.6 l (+/-5.89) vs. 46.2 l (+/-6.85) (p <.001), 59.5 kg (+/-8.05) vs. 63.0 kg (+/-9.42) (p <.001), and 18.1 kg (+/-9.68) vs. 14.6 kg (+/-8.31) (p <.001), respectively. The correlations between the methods for TBW, FFM, and FM were r=0.977, r=0.995, r=-0.23 kg, r=0.995 and, r=0.15 kg, r=0.994, respectively. The mean day-by-day differences and correlations from SMFBIA for TBW, FFM, and FM were -0.23 l, -0.04 kg, r=0.995, -0.23 kg, r=0.995 and, 0.15 kg, r=0.994, respectively.

Conclusion

There was a good association between methods of DDM and SMFBIA to assess TBW, FFM, and FM. On the other hand, there was a significant systematic bias between the methods with SMFBIA overestimating the total body water and fat free mass. This bias was, however, relatively constant over the range of measurement scale and, therefore, can be corrected by improving the assessment equation in SMFBIA method. Due to the military environment, the measurement conditions were constant and SMFBIA method showed high repeatability in the day-by-day measurement.

UNEXPECTED SEASONAL VARIATION OF VO2MAX IN ELITE ALPINE SKIERS

Vogt, M., Lehmann, A., Breil, F., Hoppeler, H.
University of Bern, Switzerland

Introduction

Elite athletes in competitive alpine skiing are characterized by high leg strength and endurance capacities (Neumayr et al. 2003). Only before the introduction of carving skis, a few studies evaluated the development of endurance and strength performance during the competitive season (Bosco et al. 1994, Koutedakis et al. 1992). We measured anthropometric, endurance and leg strength variables during a competitive season in elite alpine skiers to evaluate the impact on physiological demand of modern alpine skiing.

Methods

On 16 elite alpine skiers (age: 20.3 +/- 2.9 years, body weight: 80.6 +/- 8.7, body fat content: 8.1 +/- 2.7%) competing at international level (IF races and European Cup), performance testing was executed immediately pre- and post-season. Muscle leg strength was evaluated by performing counter movement and squat jumps on a force plate. Endurance performance (VO2max, maximal power output and ventilatory thresholds) was measured by an incremental ramp test protocol to voluntary exhaustion. Training was recorded throughout the entire season and training load was quantified.

Results

The principal methods have been the situated learning or learning every day (Lave & Wenger, 1991), mentoring (Irwin et al., 2004), and informal knowledge network (Culver & Trudel, 2006) with other coaches. Finally, all coaches stress the continuing practice reflective everything they saw and learned related to basketball (Irwin et al., 2004). This indicates that the education of the coach does not have to be a rigid schedule of courses and systematic official. But a deliberate preparation can be developed from a large number of ways that highlights the coaches interviewed and make us raise the present formation to us that is being made with the future coaches.

References

Body weight and percent body fat were not different between pre- and post season measurement. VO2max (+5.1%, pre season: 52.8 +/- 3.6 ml/min/kg, post season: 55.6 +/- 5.3 ml/min/kg; p = 0.001) but not maximal power output (+1.7%, pre season: 5.4 +/- 0.3 watts/kg, post season: 5.5 +/- 0.4 watts/kg; p = 0.17) increased during the competitive season. Power output at ventilatory thresholds were not different between pre- and post season but heart rate was significantly lower post season at both thresholds. The slope of the submaximal VO2-curve was steeper at post season measurements. Jump performance testing showed a tendency for increased maximal power output in counter movement jump (+2.8%, p = 0.09) but in squat jump (+0.8%, p = 0.35). During the season, athletes performed 83 minutes/week endurance training and 132 minutes/week strength training.

Discussion:

It is shown that VO2max was increased within a competitive season with very low amounts of endurance type training. Differences in threshold heart rate and slope of submaximal VO2-curve point to some unexpected physiological disturbance. High training impact and overload during pre-season might have been led to a fatigue related lowering of physical performance which became restored during a less demanding competitive season.

INFLUENCE OF EVENT DISTANCE SPECIALISATION ON PERFORMANCE WITHIN A SEQUENTIAL RUNNING-CYCLING-RUNNING TEST IN AGE-GROUP TRIATHLETES

Alves, M., Alves, F., Veick, V.
Technical University of Lisbon - Faculty of Human Kinetics, Portugal

The Millet sports specific run-bike-run (RBR) test (Millet, Dreano and Bentley, 2003; Millet and Bentley 2004) was first used to predict performance and examine ability to run after cycling (Millet and Veick 2000) in ‘elite’ triathletes. This study compared performance on a modified version of the original RBR test (Bentley et al., 2005) between ‘age-groupers’ specialising in ‘Olympic distance’ (OD) or ‘long distance’ (LD) competition.

Eight OD- and eight LD specialists [mean ± SD age 30 ± 6 vs. yrs; run maximum oxygen uptake [VO2max] 64 ± 5 vs. 64 ± 9ml/kg·min−1; mass 74 ± 4 vs. 69 ± 9 kg, all NS] provided informed voluntary consent to participate in 3 tests over 10 days. Test 1 was an incremental running VO2max test (starting at 8 km/h, with increments of 1 km/h·min−1). Test 2 -the RBR- consisted of 4 stages. The first and fourth stages were a 7 min run at 15 kph. The second was an incremental cycling test (starting at 2 W/kg−1, with 30 W/min−1 increments) for peak power output (PO) and VO2max. The third was 10 min cycling at 3 W/kg−1. Test 3 was a laboratory distance (30 min cycle, 20-min treadmill) time-trial (TT).

Ventilatory and (fingertip) blood lactate ([BLa], and speed/power output (PO)/distance data for TT. One way ANOVAs and Pearsons product moment coefficients were used to assess inter- and intra-test relationships between groups.

The OD and LD athletes differed as regards RBR bike ventilatory threshold (VT) as a percentage of bike peak PO (78.7±5.0 vs. 62.1±8.5, p<0.05) or bike VO2max (77.1±8.7 vs. 91.1±5.6, p<0.01), RBR bike VO2max (56 ± 5.1 vs. 53.9±5.3, p<0.05), RBR bike PO (332.4±33.6 vs. 313.2±12.3, respectively, all NS). RBR R2 VO2 as a percent of RBR R1 VO2 (100.6±4.9 vs. 98.7±16.1), RBR power to weight ratio at VTbike (r= -0.86, p<0.05 vs. 0.17, NS). The extent to which differences between OD and LD age groupers on the modified Millet RBR test reflect training differences deserves investigation.

THE INFLUENCE OF WATER EXERCISE TRAINING ON BLOOD PRESSURE AND CENTRAL ARTERIAL STIFFNESS IN THE ELDERLY

Matsui, T.
Faculty of Healthcare Management, Japan

It is well known that water exercise (swimming, aquabics, walking) is useful for keeping or improving health and fitness level of people, especially of elderly people. This is because of the physical characteristics of water which have buoyancy, viscous drag. Therefore, elderly people can do exercise or movement with varied posture (e.g. stretching), and can continue those with proper duration and without injury. These advantages bring in improvements of balance ability, flexibility, and muscle strength. But it is more important to keep appropriate level of resting blood pressure (BP) or to normalize BP by exercise training in the elderly. It has been reported that endurance training on land reduces central arterial stiffness and BP. On the other hand, muscular strength training on land increases the stiffness and BP. However, there have been few studies of the effects of water exercise training on blood pressure or central arterial stiffness. Water exercise seems to have both endurance and muscular strength training effects.

We investigated the effects of water exercise training on resting blood pressure and central arterial stiffness. One hundred fifty three elderly registered for the water exercise training class. The training class was held on a weekly basis, and totally 32 times from April to December in 2006. In the 76 elderly out of 153, resting BP and central arterial stiffness were measured both in the middle of April (before the middle of November) and the middle of November (after the middle of November) period using a method of brachial-ankle pulse wave velocity (baPWV) by BP-203RE/OMRON COLIN Co.). Mean systolic BP was significantly decreased (p < 0.05) at P2(134 +/- 16 mmHg) compared to P1(139 +/- 21 mmHg). Mean diastolic BP was also significantly decreased (p < 0.05) at P2(77 +/- 9 mmHg) compared to P1(80 +/- 12 mmHg). Mean baPWV did not show significant difference between P1(1174 +/- 329 cm/sec) and P2(1172 +/- 343 cm/sec). But, in the elderly who participated in the exercise class more than 20 times, 66% of them showed decreased baPWV at P2 compared to P1, in contrast, 47% as for under 20 times elderly. Based on these results, it was suggested that water exercise training held on a weekly basis is useful in improving resting BP.
Further, proper volume of water exercise training seemed to be needed to improve baPWV which gives an indication of central arterial stiffness.

HEART RATE AND RPE RESPONSE TO VARIATIONS IN BALL SIZE AND COACH INTERVENTION IN 3-A-SIDE SPECIFIC HANDBALL DRILLS

Duarte, R., Carvalho, N., Roque, P., Batalha, N.
University of Evora, Portugal

Introduction: Sport specific drills are constantly used in Handball training sessions, with intuitive coach variations. However, the knowledge about the real impact of these variations on drill intensity is very insufficient. Therefore, this study aimed to measure the effects of ball size and coach intervention variations in 3-a-side specific handball drill by the elicited percentage of maximal Heart Rate (HRmax%) and Ratings of Perceived Exertion (RPE).

Methods: The studied sample was constituted by six players from a Portuguese Second Division team (meanSD age: 24.3±1.1 years; weight: 83.0±15.5 kg; height: 1.80±1.11 m; bone mass index: 26.3±3.1). The exercise testing consists in a 3-a-side, played in 20x20 meters with dimension areas of 4 meters and with the official rules. The protocol consist in repeat and collect data of each exercise in different practice conditions, in the same day of two consecutive weeks, in the competition period (Week 1: ball size 3, without intervention, with specific feedbacks and with encouragement; Week 2: ball size 2, without intervention, with specific feedbacks and with encouragement). Every exercise was preceded by the teams’ usual warm-up. Every condition of the exercise lasted for 8 minutes, followed with an active break of 4 minutes during which the players carried out continuous running with low intensity and filled the original Borg scale.

Results: In ball size variation statistical differences were found in HRmax% without coach intervention (size three 86.3±8.0) to size two 83.6±6.2, p=0.021), with coach feedbacks (size three 87.9±5.6) to size two 83.5±5.0, p=0.001) and with coach encouragement (size three 87.7±5.3) to size two 84.0±4.8, p=0.001). In coach intervention statistically significant differences were found only in RPE with ball size three (without coach intervention 10.3±2.4) to coach encouragement 13.7±1.6, p=0.017).

Conclusions: In every coach intervention conditions, the decrease in the ball size resulted in a significant similar intensity decrease, probably due to the most regular practice with the third ball size. These findings suggest that the traditional use of a small ball associated to coach intervention however only coach encouragement was demonstrate significant increase. The use of verbal motivation and encouragement can be useful to coaches increase training intensity during small-sided games. On the other hand, there is no evidence that using coach specific feedback during the exercise decrease players’ intensity.

ENERGY COST OF WINGATE ANAEROBIC TEST IN PARALYMPIC SUMMER ATHLETES WITH LOCOMOTOR DISABILITY

Bernardi, M., Alviti, F., Baratta, A., Egidi, F., Fiola, F., Fattorini, L., Marini, C., De Angelis, M., Castellano, V.
1 Sapienza University of Rome - 1 Faculty of Medicine and Surgery; 2 Italian Paralympic Committee; 3 Italian Olympic Committee; 4 Motor Sciences of University of L’aquila; 5 Fondazione Santa Lucia, Italy

All out exercise tests, performed following methods of Wingate Anaerobic test (WAnT), have been used since the ‘70s for evaluating anaerobic fitness (1,2). Recently, repeated bouts of lower limb WAnTs have been used as an effective modality of exercise training in able-bodied individuals (3). Series of arm cranking WAnTs (AC-WAnT) can be hypothesized as effective modality of training also in athletes with locomotor disability (LDA). To investigate this topic, we studied, in Paralympic Athletes with different levels of both physical fitness and disability, energy cost of AC-WAnT evaluating its energetic sources (aerobic -Eaer-, anaerobialactic -EalAn- and anaerobic lactic acid -ElAn- energies).

Forty-seven male LDA (6 amputees, 6 with tetraplegia, 24 with paraplegia, 4 with poliomyelitis, 1 with spina bifida, 2 with orthopedic disorders; 4 with cerebral palsy, campeling in 11 summer sports disciplines (Athens 2004 Paralympic Games) and with a functional class (International Paralympic Committee swimming) ranging between 2 and 10 (6.3±2.2), participated in the present study after a comprehensive health and fitness evaluation. Under metabolic monitoring, they underwent an AC-WAnT carried out through an electronically braked constant torque cycle-ergometer (Ecalibur, Lode, NL) equipped for upper limb evaluation. Oxygen uptake was measured through a breath by breath metabolimeter (Quark b2, Cosmed, Il). Earlobe blood samples were collected before and at the end of the AC-WAnT to evaluate blood lactate peak and to estimate ElAn (4). Eaer and EalAn were estimated respectively from oxygen uptake during the WAnT and fast component of post-exercise oxygen uptake during recovery (4,5).

MP of AC-WAnT was equal to 289±110 watt with a range from 77 (in a tetraplegic track athlete) to 525 watt (in a wheelchair basketball leg amputee), being significantly related to the functional class (r²=0.62). AC-WAnT total energy expenditure (Etot) was equal to 64.4±19.7 kJ with contributions of Eaer, EalAn and ElAn equal respectively to 9±4.2%, 44±10.3% and 47±9.2%. Etot correlated significantly with MP (r²=0.651). Efficiency was equal to 13±3.1%.

In conclusion, total mechanical work (8.63±3.383kJ) carried out by Paralympic LDA during AC-WAnT is mainly determined (r²=0.518) by lactic acid anaerobic metabolism (ElAn= 31±10.9 kJ). Aerobic contribution to Etot during repeated bouts of AC-WAnT should significantly increase, due to both the exhaustion of the anaerobic sources and the high metabolic level during the first minutes of the slow component of post-exercise oxygen uptake of each bout of AC-WAnT.

NATURE OF SELF-TALK IN ISOMETRIC MUSCULAR EXERCISE UNTIL FAILURE
Company, G., Hristovski, R., Balagué, N.
INEFC Barcelona, Spain

The role of self-talk during exercise may be a crucial component of conscious perception and self-awareness alerting the mind about changes in emotional and physical state. Meanwhile self talk during exercise of low intensity is dissociative, when the level of fatigue increases it becomes more associative with voices urging the individual to cancel and voices urging to continue (St. Clair Gibson & Foster, 2007). Recent studies agreed that positive-negative related cue words serve two main functions, cognitive (instructional) and motivational (Hardy, 2006).

Following the dynamical systems approach, we hypothesize that self-talk reflects the complex interactions between personal, task and environmental constraints during exercise. The aim of this study is to show the effects of self talk awareness on the dynamics of the self talk during an isometric muscular exercise until failure. Five physical active subjects (20 y.o) performed during 3 alternative days an isometric arm curl exercise with 90° elbow flexion until failure holding an Olympic bar weighting 25kg for men and 17kg for women. The subjects sat backwards on an inclined bench to minimise the participation of other muscles than biceps brachialis in the exercise. A reference rob was used to help them to keep the elbow angle constant in both extremities during the trials. The verbalisation of their inner self-talk; simplifying its content (positive-UP, negative-DOWN), was recorded during the exercise using a video camera.

The results show that with the trials the awareness of the self talk increases. In the state of self talk awareness the dynamics changes and the system passes from a relatively stable UP state to an intermediate metastable UP-DOWN state until a stable DOWN state coinciding with the failure point.

In conclusion, self awareness of self talk can be trained showing all the effects expected from a complex dynamical system. This can be taken as a support of the hypothesis that the self talk is a dynamical product of complex interactions between personal, task and environmental constraints.

THE EFFECT OF SWIMMING POOL WATER TEMPERATURE ON CARDIOVASCULAR RESPONSES AND TOLERANCE TO EXERCISE DURING IN-WATER CYCLING
Yázigi, F., Silva, P., Alves, F.
Faculty of Human Kinetics, Technical University of Lisbon, Deiras, Portugal

Introduction: The exercise intensity related to water cycling has been the topic of recent studies that show that this activity may reach high intensity depending on cycling cadence. This knowledge is essential for exercise prescription and to adjust the effort associated to water cycling to the individuals needs. Water is a better heat conductor than air and therefore exercise in an aquatic environment might increase the body heat load even for slight differences in water temperature. Heat load per se might diminish the tolerance to exercise or be detrimental to cardiovascular responses. The goal of this study was to compare the cardiorespiratory responses and tolerance to fatigue during in-water cycling at two different water temperatures. Methods: On separate days, 10 young active males (22.4±1.4 yrs) performed a maximal test in a stationary bike (Manorak, 829E) (Max) and twice an incremental cycling exercise on a hydrobike (Hydrodyne) in an indoor swimming pool at 27 degrees (Hydro27) and 31 degrees (Hydro31) Hydrobiking consisted on 3-min stages with cadences of 50, 60, and 70 RPM and then increasing by 5 RPM steps until reaching 100 RPM. Expired air was measured to obtain oxygen consumption and carbon dioxide elimination rates, and minute ventilation (K4D2, COSMED). Heart rate was measured by telemetry (Polar Electro Oy). Capillary Blood Lactate concentration (BL) was measured at 60, 80 RPM and at end of exercise. Thermal Comfort (TC) was obtained by an 11-point scale (0 cold, 5 neutral, 10 hot). Repeated measures ANOVA was used to compare between the three conditions or between different cadences stage. Results: Maximal values during Max, Hydro27 and Hydro31 were, respectively, 4.20 ± 0.43, 4.06 ± 0.52, and 4.25 ± 0.54 L/min (p=0.05). Maximal heat rate was also similar between the three cycling exercises. In Hydro27, the lowest maximal cadence was 90 RPM (one subject) whilst in Hydro31 it was 85 RPM. In Hydro27, 6 of the subjects reached 100 RPM but in Hydro31 this number reduced to 3 subjects. TC scored 7.4±1.1 and 9.2±0.8 units in Hydro27 and Hydro31, respectively (p=0.001). BL concentration during exercise was similar in Hydro27 and Hydro31. Final BL concentration was 11.4±2.2 and 11.9±2.1 mmol.L-1 in Hydro27 and Hydro31, respectively (p=0.05). Discussion: This study shows that hydrobiking might attain maximal intensity. With cadences between 85 and 100 RPM young active subjects reach maximal oxygen uptake and exhaustion even when in cool water. Elevating the water temperature from 27 degrees to 31 degrees, exhaustion occurred at lower cadences and subjects reported high levels of heat discomfort, despite similar BL levels. It is concluded that hydrobiking might be a strenuous exercise and that cadence should be adjusted according to water temperature.

This study was supported by Instituto do Desporto de Portugal (8/DSFDRH/DF/2005).

THE EFFECTS OF 6 DAYS INTENSIVE TRAINING ON SALIVA IMMUNOGLOBULIN - A RESPONSES
Laing, S., Dijedovic, N., Jackson, A., Cardinale, M.
British Olympic Association, United Kingdom

Salivary Immunoglobulin-A (s-IgA) concentration has been shown to decrease during prolonged periods of intensified training at rest and following exercise (Tharp and Barnes, 1990). The aim of this investigation was to determine the effects of high intensity training over a short period (8 day period) upon s-IgA concentration and secretion rate, and salivary cortisol and testosterone concentrations. Four highly trained short track speed skaters (Mean ± SD: height: 181 ± 2 cm; weight: 72 ± 2 kg) were monitored during the 8 day training period which was 3 days training, 2 days rest and 3 days training. Short track speed training consisted of 11 on-ice sessions and 2 off-ice sessions. Total training volume varied daily (range: 20 to 143 laps; Mean ± SD: 84 ± 34 laps). Mean session blood lactate concentrations were significantly lower during aerobic training sessions compared with anaerobic speed training sessions (Mean ± SD: aerobic session average 5.8 ± 2.2 mmol.L-1, anaerobic session average 10.1 ± 0.6 mmol.L-1). Unstimulated whole saliva samples were collected using
passive drool between 0700 and 0730 h. The s-IgA, cortisol and testosterone concentrations were determined using sandwich-type ELISAs. Saliva IgA secretion rate was determined by multiplying the s-IgA concentration by saliva flow rate. Blood lactate concentration was determined during training sessions using a lactate pro analyser. There were no significant alterations in saliva flow rate and salivary testosterone concentration during the 8 day monitoring period. Saliva IgA concentration decreased by 54% following 3 days intensive training (P < 0.01), increased following 2 days rest (albeit 23 % lower than pre-training) and reduced by 35 % following a further 2 days training compared with pre-training (P < 0.05). Saliva IgA secretion rate followed a similar trend to s-IgA concentration decreasing by 50% following 3 days intensive training (P < 0.01), increasing following 2 days rest (albeit 26 % lower than pre-training) and decreasing by 46 % following a further 2 days training compared with pre-training (P < 0.05). Salivary cortisol concentration increased by 45% following 3 days intensive training (P < 0.05) and was significantly reduced during the 2 day rest periods (P < 0.05). These results show that athletes undertaking intensive training have a reduction in s-IgA concentration and secretion rate. Additionally, these data demonstrate that 2 days rest was adequate to allow s-IgA concentration and secretion rate and cortisol concentration to recover. Therefore, athletes undertaking intensive training periods should ensure they have adequate rest to allow the immune system to recover and prevent long periods of immune suppression.

COMPARISON OF FOREHAND RECEIVING ABILITY OF MALE TABLE TENNIS PLAYERS AT THREE DIFFERENT LEVELS
Yite, L., Tseng, W.
National Changhua University of Education, Taiwan

Serving and receiving abilities are crucial to determine if one can take the initiative and win in a table tennis match. The strength and quality of receiving is directly related to bringing skills and tactics into a play.

Purpose: In the present study, a new procedure to assess forehand receiving performance of three level male table tennis players in simulated conditions was adopted. Method: 42 male table tennis players were recruited in this study. Ten are at national-level in 2007, 20 belong to senior high school champion team in 2007 National High School Games, and 12 are in junior high school champion team in 2007 National High School Games. The protocol consists of 5 tests including basic control, reflection, agility, judgment and match-like condition. Every test is composed of 6 spin types of serving repeated 6 times, which are topspin, backspin, left-side spin, right-side spin, left-side downspin and right-side downspin. Each player performed 180 receives in total. Every serve was driven by the same table tennis player at national-level to reproduce a neutral and offensive situation as in a real game. Receiving quality was determined by simultaneous record of success rate and accuracy of target area on the table. Results: In terms of success rate, national-level players scored significantly higher than junior high school and senior high school players on agility, judgment (P<0.05), and match-like condition (P<0.001). But, there are no significant differences on basic control and reflection. National-level group outperformed the other two groups from the viewpoint of accuracy, especially on basic control, agility, and match-like condition (P<0.001). It is not significantly different when compared national-level group to the other two groups on downspin and right-side downspin in the aspect of accuracy. Overall, national-level players performed better than the other two groups on 6 spins in accuracy. Conclusion: In the present study, we found junior high school players performed worst on the accuracy of different complex spins under match-like situation. This test is reliable and valid for evaluating forehand receiving quality. Based upon these test results, coaches can employ different training programs to improve the receiving ability of individual player.

EVALUATION OF FOREHAND RECEIVING QUALITY AT WORLD-LEVEL MALE TABLE TENNIS PLAYERS
Yite, L., Tseng, W.
National Changhua University of Education, Taiwan

In a table tennis match, serving and receiving abilities are crucial to determine if one can take the initiative and win. The strength and quality of receiving is directly related to bringing skills and tactics into a play.

Purpose: In the present study, a new procedure to assess forehand receiving performance of national level male table tennis players in simulated conditions was adopted. Method: Five male table tennis players participated in 2007 Table Tennis World Cup and 5 at national-level in 2007 were recruited in this study. The testing protocol consists of 5 tests including basic control, reflection, agility, judgment and match-like condition. Every test is composed of 6 spin types of serving repeated 6 times, which are topspin, backspin, left-side spin, right-side spin, left-side downspin and right-side downspin. Each player performed 180 receives in total. Every serve was driven by the same table tennis player at national-level to reproduce a neutral and offensive situation as in a real game. Receiving quality was determined by simultaneous record of success rate and accuracy of target area on the table. Results: World-level players scored significantly higher than national-level players in the tests of success rate and accuracy on reflection, agility, and judgment (P<0.05). In term of success rate, world-level players performed better than national-level players on right-side spin, right-side downspin (P<0.05), left-side spin, and top spin (P<0.01); nevertheless, it does not reach significant differences by 6 spin types from the viewpoint of accuracy between two levels. Conclusion: Both groups of participants do not make significant difference on success rate and accuracy under match-like situation. That means all the participants are even when it comes to agility. Coaches can adopt this reliable and valid instrument to evaluate and employ different training programs to improve the receiving ability of individual player.

INFLUENCE OF PERFORMANCE LEVEL ON OXYGEN UPTAKE KINETICS IN SWIMMING
Reis, J., Millet, G., Vleck, V., Bruno, P., Alves, F.
Faculty of Human Kinetics - Lisbon, Portugal

Although a faster VO2 kinetics have been associated to a lower O2 deficit and a greater fatigue tolerance, it is unclear if it is a determinant of endurance performance. In swimming, to our knowledge, the VO2 kinetics parameters have never been compared in subjects of different performance levels. Therefore, the purpose of this study was to compare the parameters of VO2 kinetics in heavy intensity swimming between elite (E) and club-level (C) swimmers. We hypothesized that E have faster kinetics than C. Seventeen Portuguese swimmers divided into two groups: E (n = 5, 23 ± 1.7 yr.; 85.0 ± 13.7 Kg; 1.86 ± 0.08 m, personal best over 400m freestyle PB400 < 245 s) and C (n=12; 19.2 ± 2.8 yr., 68.9 ± 7.0 kg, 176.7 ± 0.03 m, average PB400 = 267 s) performed on two separate days: 11.5 x 200 m with 30 s rest and 5-10% velocity increment in between for determination of maximal oxygen uptake VO2max and
ventilatory threshold (VT). The last repetition was performed at maximal velocity (vVO2max). VO2max was recorded as the highest 30 s average and VT was established by the V-slope method. 2) Two 6-min constant velocity exercise bouts at 62% VT = 20.1 ± 5.3 s, p = 0.04) were used instead of the others, while the other parameters were not statistically different, i.e. ID: 10.7 ± 2.6 vs. 10.7 ± 4.3 s; A1: 38.6 ± 3.2 vs. 35.1 ± 5.1 mmol/L/kg.1; ID: 20.1 ± 68 vs. 166 ± 15 s; 12: 51.9 ± ± 63 s vs. 35.5 ± 43.4 s; A2: 3.7 ± 0.9 vs. 4.9 ± 2.9 mmol/L/kg.1. The E group presented significantly higher mean values of VO2max (4992 ± 507 vs. 3735 ± 465 mmol/L/kg, p = 0.002) and VO2max (5.2 ± 0.05 vs. 4.0 ± 0.04 mmol/L/kg, p = 0.001). 3) Shorter time constant for the primary phase of the VO2 response seems to be related to higher aerobic fitness and performance level in aerobic swimming exercises, whereas when measured at the same relative intensity, the slow component amplitude appears to be similar between elite and sub-elite swimmers.

EFFECTS OF STRENGTH TRAINING DURING SIDE-ALTERNATING VIBRATION ON KNEE AND ANKLE STRENGTH AND STATIC BALANCE CONTROL
Spiliopoulos, S., Amiridis, I.
Laboratory of Neuromuscular Control and therapeutic exercise, Greece

The purpose of this study was to determine the effect of strength training using a Side-Alternating Vibration (SAV) plate on knee and ankle muscles strength and static balance control. Twenty four women (age: 28.35 ± 2.12yr, mass: 66.33 ± 11.90kg, height: 169 ± 6.60cm) were randomly assigned into the Training (TG, n=14, static and dynamic exercises on a vibration plate for 9 weeks) and the Control (n=10) groups. Moment/angular velocity relationship for knee extenders, knee flexors (-120, -60, -30, 30, 60, and 120 deg/sec), plantarflexors, dorsiflexors, and eversion/extensor exercises were established using an isokinetic dynamometer (Kin-Com, Chattanooga, USA). Isometric moment/angular position relationship was also determined for all muscular groups. Three static balance tasks of increasing difficulty were performed with and in the absence of vision, while standing on a force platform (Cormex SA, Loran Engineering Ltd, Bologna, Italy, 50Hz). Normal Quiet Stance (NQS), Sharpened Romberg (SR), and One-Legged Stance (OLS). Anterior/Posterior (A/P) and Medio-Lateral (M/L) postural sway in direction was quantified using maximum range (CoPmax) and standard deviation (CoPsD of Centre of Pressure displacement. Bipolar surface electrodes were used to record the Electromyographic activity (EMG) of Rectus Femoris (RF), Semi-Tendineous (ST), Tibialis Anterior (TA), Medial Gastrocnemius (MGAS), Peroneus Longus (PL) and Peroneus Brevis (PB). The results showed that after training, concentric knee extensors and flexors strength remained unaltered, whereas eccentric (p<0.05) and isometric (p<0.01) strength was significantly improved. Regardless of type of action and contraction velocity, ankle muscles strength was significantly improved after training. However, the improvement in ankle extension was greater (p<0.001) compared to the other movements. SAV training resulted in decreased postural sway, especially in M/L direction and greater PL and PB muscles EMG activity (p<0.001) during the SR and OLS tests. Improvements were greater in the absence of vision. It is concluded that SAV training, could enhance lower limb strength and reduce postural sway. Specific, reductions in M/L direction following training could be associated to the greater use of ankle evertors as a result of their strength improvements.

PRECISION OF HAND-HELD LACTATE-ANALYZERS AND THEIR PRACTICABILITY FOR EXERCISE PRACTICE
Nitsch, S., Sperlich, B., Achtzehn, S., Strouta, S., Hägele, M., Mester, J.
German Sport University Cologne, Germany

INTRODUCTION: Lactate (lac) controlled endurance training often is based on mathematical-physiological reference points such as individual lac thresholds or the 4mmol threshold. In exercise practice portable lac-analyzers are frequently used in lots of disciplines due to low costs, easy han-dling and fast analysis. However scientists and coaches need to be aware of the fact that these ana-lyzers are subject to device dependent measurement variability. Knowing these variances is essential for giving precise exercise recommendations. Additionally to this device variance an individual biologi-cal variance of the athlete must be kept in mind. Based on these facts, aim of the study was to point out the influence of the precision of 3 hand-held analyzers on training control recommendations. METHOD& MATERIAL: 14 lac dilutions with unknown concentrations (c[ lac]) where prepared by using a control solution for lac-analyzers (EKF Diagnostics, Barle ben). Each dilution was measured tenfold using either two LACTATE SCOUTs (LS1 & LS2, Senslab, Leipzig) or ACCUTREND LACTATE (AL, Roche Diagnostics, Mannheim). For each dilution variance (V'), standard deviation (s), variation (spread from minimum to maximum score) (V) as well as coefficient of variation (CV) was calculated. RESULTS: For device LS1 a minimum V' of 0.2 mmol/L was detected by testing lac dilutions with a mean c[ lac] of 10.8 mmol/L. Subdivided in ranges LS1 & LS2 show a mean V' of 0.2 mmol/L in the range from 0.7 to 3.6 mmol/L, a mean V' (LS2) of 0.7 mmol/L in the range from 3.8 to 8.0 mmol/L and a mean V' of 1.5 mmol/L (LS1&LS2) in the range from 8.5 to 11.9 mmol/L. For AL a minimum V' of 0.4 mmol/L was identified in dilutions with a mean c[ lac] of 1.6 resp. 4.0 mmol/L whereas a maximal V' of 4.0 mmol/L was found in dilution with a mean c[ lac] of 13.9 mmol/L. Subdivided in ranges AL shows a mean V' of 0.8 mmol/L in the range from 0.5 to 2.1 mmol/L, a mean V' of 1.3 mmol/L in the range from 4.0 to 6.5 mmol/L and a mean V' of 3.4 mmol/L in the range from 10.0 to 13.9 mmol/L. CONCLUSION: Lac controlled endurance training based on lac threshold may lead to a measurement error of ±0.1 mmol/L for LS and ±0.4 mmol/L for AL in intensity corresponding to 0.5 to approx. 4.0 mmol/L Lac due to device depending variance. Higher workloads lead to greater variance. No differences were found when using two iden-tical devices. From our point of view by accepting these little variances modern hand-held lac analyzers seem to be a useful and mostly accurate way to get viable scores. Nevertheless every researcher and coach should first determine the device dependent variance before interpreting lac values. There-fore are reliability test is recommen
ded.
REPEATABILITY AND SYMMETRY OF SOME TECHNICAL ACTIONS IN ITALIAN KARATEKAS: A COMPARISON BETWEEN KATA AND KUMITE ATHLETES

Michielon, G., Scurati, R., Longo, S., Invernizzi, P.
Faculty of Exercise Sciences - University of Milan, Italy

INTRODUCTION AND AIMS

Studies were carried to integrate the evaluation of some specific karate elements (arms, legs, hip actions and coxofemoral joint flexibility) with physical fitness. Another important ability is to lead effective technical actions with either dominant or non-dominant limbs. The aim of this study was: a) to verify the repeatability of some specific evaluation tests in Italian mid-high level athletes of karate; b) to evaluate the differences between the dominant and non-dominant limbs; c) to analyze the differences between kata and kumite competitors.

MATERIALS AND METHODS

Twelve mid-high level karate athletes (1st Dan to 3rd Dan, six kata and six kumite specialists) volunteered for the study (Mean±SD, age 22.0±2.0 years, weight 71.0±7.1 kg, height 175.0±0.05 cm, BMI 22.9±1.3). Sterkowicz's protocol (1) was applied to collect data regarding both dominant and non-dominant limbs, such as: i) Hip Turning Speed (HTS), ii) Speed Punches (SP), iii) Hip Flexibility Index in the kicks (HFI), iv) Rapide Kicks (IKR). Each test was executed five times (test) and repeated one week later (re-test). All the time needed to complete 30 hip turnings starting from the guard position was recorded. In SP, the time needed to complete 30 Kizami-Gyaku Zuki combinations (in order to alternate punches directed to the face and the body) was recorded. For the HFI, athletes performed five Mawashi-geri kicks. The the kick's height reached by the back leg against a suspended training bag was measured, then the index was calculated as hT / hA, where hT is the average height of the five kicks and hA is the athlete's stature. The HR test, subjects were asked to execute 30 consecutive Mawashi-geri kicks with the front leg against a hand kicking target placed at a face level. The elapsed time from the beginning of the action (guard position) to the foot's contact on the ground after the last kick was recorded.

RESULTS

No differences were found between test and re-test (ICC > 90).

No differences were found between dominant and non-dominant limbs (p>0.05).

No differences were found between kata and kumite athletes (p>0.05).

CONCLUSIONS

All tests executed appear to be repeatable, then suitable to evaluate the training effects in mid-high level karate's athletes. The practice of karate leads to a well balanced development and control of both the dominant and the non dominant limbs, then athletes are able to perform similar effective actions regardless to the guard position.

TECHNICAL AND TACTICAL DIFFERENCES IN REGIONAL AND NATIONAL LEVEL THAI BOXERS

Michielon, G., Scurati, R., Longo, S., Invernizzi, P.
Faculty of Exercise Sciences - University of Milan, Italy

INTRODUCTION AND AIMS

Analytic observation of athlete's behaviors and actions during combats may supply important elements about their abilities or skill levels (1,2), thus it is essential for planning proper training programs designed to improve the performance.

The aim of this study was to analyze and to compare the tactical and technical behaviors employed by regional and national level Thai boxers during their matches.

MATERIALS AND METHODS

Six national level (NLA) (Mean±SD, age 24.0±2.2 years, weight 70.1±0.4 kg, height 178.6±2.0 cm, BMI 22.0±0.5) and six regional level (RLA) Thai boxers (Mean±SD, age 25.3±2.8 years, weight 74.5±0.5 kg, height 178.3±2.7 cm, BMI 23.4±0.8), weight category 70 to 75 kg, were followed through some competitions. Video-recorded matches of the Italian Championships and the Lombardia Championships were used to compare the technical actions, grouped in four classes: arms (AC), legs (LC), elbow (EC) and knee (KC). Further analysis with respect to their outcome (to target (T), failure (F), parry (P), diverted (D)) and to the round were carried out.

RESULTS

Compared to RLA, NLA led more actions to target (59.1% vs. 42.6%, p<0.01) and failed less (16.0% vs. 31.6%, p<0.01). They used more KC (82.1% vs. 64.9%, p<0.01) and LC techniques (69.5% vs. 48.3%, p<0.01). Significant differences were found mainly in the 3rd round: NLA showed less failures than RLA (15.6% vs. 33.0%, p<0.01), less diverted (13.3% vs. 27.1%, p<0.05) and more targets (69.7% vs. 39.8%, p<0.01).

Compared to RLA, NLA used more KC actions in the 2nd round (90.0% vs. 60.6%, p<0.01) and more LC actions in the 1st and 3rd round (69.4% vs. 46.2%, p<0.01; 78.6% vs. 42.2%, p<0.01). Right blow with the knees is the specific action preferred by NLA (27.1% vs. 8.44%, p<0.01) whereas Jab is the preferred one by RLA (17.5% vs. 11.4%, p<0.05 compared to NLA).

Right front kicks, right middle kicks and left low kicks are the most used actions to target.

CONCLUSIONS

Considering the actions to target and failed, there is evidence of the higher precision of NLA with respect to RLA. Thanks to the better athletic state, even if fatigue arises, NLA are still able to execute knee actions during the second round and the most exhausting leg actions during the first and the third round in particular. Besides, NLA show a better tactical management compared to RLA: the specific action used by RLA is Jab (arm action), whereas NLA prefer knee actions, which score is higher.

TRAINING CONCEPTIONS OF GOALKEEPER COACHES OF FIRST AND SECOND PORTUGUESE SOCCER LEAGUES

Silva, N., Batalha, N., Falgado, H., Duarte, R.
University of Évora, Portugal

In modern soccer, the goalkeeper is a crucial element in the dynamical team organization, due to your own privileged position and your differentiated role, unlike other players. The evolution of the goalkeeper position is described in the training conceptions. However, the knowledge about the training conceptions associated with the goalkeeper coach is very insufficient. The aim of this study was to compare the training conceptions associated with the goalkeeper coach of Portuguese First (1stLg) and Second (2ndLg) top soccer leagues.

The sample was composed by sixteen goalkeeper coaches’ of the 1stLg (n=8) and the 2ndLg (n=8) [mean±SD: age 43±0.7 (7); coach level 2.6±0.8; years as goalkeeper coach 7.5±5.5]. It was elaborated, construct validated and applied a direct questionnaire at the conceptions related to the planning and sport periodization, to the training contents and to the evaluation and control of goalkeepers’ performance. The Mann-Whitney and the independent T test were applied according to the normality distribution of the variables.

Statistically significant differences were found between the 1stLg and the 2ndLg, with more elevated mean values to the 1stLg to the following aspects: larger duration of the team training sessions per week in the preparatory period (113±32) to the 1stLg and 78±12 minutes to the 2ndLg, p=0.02, larger duration of the goalkeeper coach training sessions per week in the preparatory period [503±200] minutes to the 1stLg and 259±127 minutes to the 2ndLg, p=0.01, more goalkeeper training sessions made separately to the team in the competitive period (3.3±0.7) to the 1stLg and 2.3±0.7 to the 2ndLg, p=0.01, complementary resources like a video analysis are more used (3.4±0.7) to the 1stLg and 2.4±0.7 to the 2ndLg, p=0.04 and the evaluation of the goalkeepers is more frequently made through the performance into the different training exercises (4.6±0.5) to the 1stLg and 3.8±0.9 to the 2ndLg, p=0.04. In the 2ndLg they use often the programs of Indoor Cycling in small-sided games to implement the team game model (3.9±0.5) to the 1stLg and 4.4±0.7 to the 2ndLg, p=0.03. The time spent in the general training sessions, in the goalkeeper training sessions and in goalkeeper training sessions made separately to the team in the competitive period is more elevated in the 1stLg. In future researches, it’s very interesting to understand the influence of these variables in the goalkeepers’ access to the 1stLg. Relatively to the evaluation and control of goalkeepers’ performance, it’s more frequently made through the performance into the different training exercises and it’s more used complementary resources like a video analysis by the goalkeeper coaches’ of the 1stLg than the 2ndLg. The superior importance given to these facts can be as consider specific precise details in maximizing the performance of Portuguese top goalkeepers.

INDOOR CYCLING - LACTATE KINETICS CONCERNING THE ANAEROBIC THRESHOLD

Van der Laan, T., Clijisen, R., Pfister, R., Wüthrich, M., Cabri, J., Taeymans, J., Duquet, W.
Thim van der Laan Physiotherapieausbildung, Landquart, Switzerland

Objectives

Indoor Cycling (IC) providers promise an attractive, interesting, health-orientated aerobic endurance-training. Following motivating music a virtual track is simulated. The compound is emulated by changing the resistance. The resistance was set subjectively or according to the heart rate (hr). The aim of this study was to determine lactate kinetics during a IC session with resistance set subjectively (ICsubj) and set at a heart rate control (IC Chr).

Methods

31 subjects (M=15; F=16) between 32 and 46 yrs. (41.2±6.2 yrs.) were recruited. The tests took place on three consecutive weekends. To determine the individual exercise capacity a submaximal bike-ergometer test was conducted. Afterwards each subject participated in both subjectively controlled and heart rate controlled IC session. These sessions were identically composed of seven intensities profiles: WarmUp, Hill, Recovery, Jumps, Slipstream, Sprint and CoolDown. Concerning the lactate concentration one baseline value and after each profile a further value was measured using LactatePro LT1710. The hr was constantly monitored using Polar RS800. The perceived exertion was assessed using the RPE-scale by Borg. The statistical analysis was conducted with SPSS 14.0. To determine the deviation of the individual results regarding the lactate threshold (4 mmolL-1) a one-sample t-test to test-value 4 was accomplished. Significance was set at p<0.01.

Results

During IC Chr the lactate baseline was 1.8±1.2 mmolL-1. Already after the WarmUp lactate increased above the anaerobic threshold (4 mmolL-1) and resulted during the sprint in the highest value of 8.0±3.3 mmolL-1. The lactate values of the profiles Hill (p=0.000), Sprint (p=0.000) and CoolDown (p=0.000) were significantly above the lactate threshold. During IC subj the lactate baseline was 2.2±1.6 mmolL-1 and the peak-value after the Hill was 9.6±3.3 mmolL-1. The profiles Hill (p=0.000), Recovery (p=0.001), Jumps (p=0.001), Slipstream (p=0.003), Sprint (p=0.000) and CoolDown (p=0.000) were significant above the lactate threshold.

Conclusions

In total, the anaerobic component during the IC subj was 70%, during the IC Chr 47%. Therefore IC cannot be promoted as aerobic endurance training. Already after the WarmUp lactate concentration increased above the anaerobic threshold and reached in particular cases peak values above 14 mmolL-1.

IC does not represent aerobic endurance training. For healthy ath-letes Indoor Cycling can act as an alternative workout, though regarding overtraining it should not be attended as daily exercise unit. Against the background of risks with high hr values it is not suitable for patients with coronary or cardiac heart disease, overweight or for seniors and sports-newcomers.

INDOOR CYCLING - LACTATE KINETICS CONCERNING THE ANAEROBIC THRESHOLD AND DIFFERENCES IN PHYSIOLOGICAL PARAMETERS BETWEEN SUBJECTIVELY AND HEART RATE CONTROLLED LESSONS

Van der Laan, T., Clijisen, R., Pfister, R., Wüthrich, M., Cabri, J., Taeymans, J., Duquet, W.
1 Thim van der Laan Physiotherapieausbildung, Landquart, Switzerland

Objectives

Indoor Cycling (IC) providers promise an attractive, health-orientated aerobic endurance-training. Following motivating music a virtual track is simulated. The compound is emulated by changing the resistance. The resistance is set subjectively or according to the heart rate. The aim of this study was to determine lactate kinetics during a IC session with resistance set subjectively (IC subj) and set at a percentage of maximal heart rate (IC Chr) estimated by the Kar-vonen-formula (hrmax=220-age). Furthermore the significant deviation

Saturday, July 12th, 2008 14:15 - 15:15
from the anaerobic 4 mmol threshold was traced. In addition the differences in heart rate (hr), lactate (lact) and RPE-value were determined between these two lessons.

Methods: 31 subjects (M=15; F=16) between 32 and 46 yrs. were recruited. Each subject participated in both ICSsubj and IChr. These sessions were identically composed of seven intensity profiles. Concerning the lact one baseline value and after each profile a further value was measured. The hr was constantly monitored. The perceived exertion was assessed using the RPE-scale by Borg.

Results: During IChr the lact baseline was 1.7 ± 1.2 mmol.L-1. Already after the WarmUp lact increased above the anaerobic threshold and resulted during the sprint in the highest value of 8.0 ± 3.3 mmol.L-1. The lact values of three profiles were significantly above the lact threshold. During ICSsubj the lact baseline was 2.2 ± 1.6 mmol.L-1. The peak-value after the Hill was 9.6 ± 3.3 mmol.L-1. Six profiles were significantly (p<0.01) above the lact threshold.

The composition of the lessons concerning lact shows, that five out of seven profiles resulted in higher values during the ICSsubj compared to the IChr, two profiles were significantly higher for the ICSsubj in terms of hr, six out of seven profiles were higher during the ICSsubj compared to the IChr. Five profiles were significantly higher for the ICSsubj. Regarding the RPE six out of seven profiles were higher during the ICSsubj compared to the IChr. Five profiles were significantly higher for the ICSsubj.

Conclusions: The anaerobic component during the ICSsubj was 85%, during the IChr 47%. Therefore IC cannot be promoted as aerobic training. Already after the WarmUp lact increased above the anaerobic threshold and reached in particular cases peak values above 14 mmol.L-1. The comparison of both lessons shows, that a majority of the IC-lesson participants had a less distincted body and performance feeling. That is the reason why in most cases they had difficulties to judge and convert the subjectively induced intensities. Therefore we could find significantly higher lact, hr and RPE during the ICSsubj compared to the IChr.

Against the background of risks with high hr values it is not suitable for patients with coronary or cardiac heart disease, overweight or for seniors and sports-newcomers.

DIFFERENCES IN HEART RATE, LACTATE AND RPE-VALUE BETWEEN HEART RATE AND SUBJECTIVELY CONTROLLED INDOOR-CYCLING LESSONS

Hebbelinck, M., Taeymans, J., Pflister, R., Wüthrich, M., Cabri, J., Clijsen, R., Duquet, W.

Vrije Universiteit Brussel, Belgium

Objectives

Indoor Cycling (IC) is said to be an health-orientated aerobic endurance training. Following motivating music a virtual track is simulated. The compound is emulated by changing the resistance. The resistance is set subjectively or according to the heart rate (hr) which was indicated by a percentage of the maximal heart rate estimated by the Karvonen formula. The aim of this study was to determine if there are significant differences in heart rate, lactate and RPE-value between heart rate (IChr) and subjectively (ICsubj) controlled Indoor-Cycling lessons.

Another purpose was to answer the question if people who are less well trained in endurance, IC beginners or sports-newcomers should rather practice the IC-lesson heart rate or subjectively controlled.

Methods

There were 31 subjects (M=15; F=16) between 32 and 46 yrs. recruited. The tests took place on three consecutive weekends. To determine the individual exercise capacity a submaximal bike-ergometer test was conducted. Followed by a subjectively controlled and a heart rate controlled IC lesson. Concerning the lactate concentration one baseline value and seven further values were measured using Lactate-ProTM LT1710. The hr was constantly monitored using Polar RS800. The perceived exertion was assessed also seven times by using the RPE-scale by Borg. The statistical analysis was conducted with SPSS 14.0 (Ancova for heart rate and lactate and Wilcoxon for RPE-values). Significance was set at p<0.01.

Results

Concerning lactate, two out of seven profiles were during the ICSsubj significantly (p<0.01) higher compared to the IChr. In terms of heart rate, five out of seven profiles were significantly (p<0.01) higher during the ICSsubj compared to the IChr. Regarding the RPE-values we found similar results. Five out of seven profiles were significantly (p<0.01) higher during the ICSsubj compared to the IChr.

Discussion

A majority of the IC-lesson participants had a less distincted body and performance feeling. That is the reason why in most cases they had difficulties to judge and convert the subjectively induced intensities. Therefore we could find significantly higher lactate, heart rate and RPE-values during the ICSsubj compared to the IChr.

Conclusions

According to the results it is advised for people who are less well trained in endurance, IC beginners or sports-newcomers that they should rather practice the IC-lesson heart rate controlled than subjectively controlled. In this manner it is less stressful for the entire heart circulation system. In addition to this, Indoor-Cycling is not an aerobic endurance sport, which confirms the above mentioned recommendation.

SOMATOTYPIING OF SWISS TEAM SKIALPINISM ATHLETES

Taeymans, J., Clijsen, R., Rinderer, S., Hebbelinck, M., Cabri, J.

Ausbildung Physiotherapie „Thim van der Laan“, Landquart, Switzerland

Introduction: Skialpinism was an Olympic sport at the OlympicWinter Games from 1924 (Chamonix) to 1948 (St.Moritz). The popularity of this sport has again increased over the last decade. Different institutions (e.g. Union Internationale des Associations d’Alpinisme) try to establish its Olympic status again. Race distances may vary between 10 and 20 km (the longest reaches 50 km). During such an event athletes have to climb 3000 to 7500 meters. Individual and team competitions are organized. Skialpinism athletes generally participate at 23 races per winter season.

Aim: To assess the somatotype (S) of Swiss Team Skialpinism (STS) athletes.

Methods: Ten male and three female STS athletes participated in this study. Anthropometry was assessed following the ISAK guidelines. S was calculated using the Carter&Heath method (1990). References of other ski disciplines were used for comparison. A simple t-test procedure was used for analysis. Significance was set at the 5% level.

Results: Age ranged from 17 to 37 years. Male stature and body weight were 179.5 ± 2.6 cm and 73.4 ± 4.0 kg respectively. BMI ranged from 20.5 to 24.9 kg.m-2. Male mean S was 2.0-5.1-2.8 ± 0.6-0.7-1.4. Female stature and body weight were 162.3 ± 3.8 cm and 61.5 ± 7.2 kg respectively. BMI ranged from 19.9 to 24.1 kg.m-2. Female mean S was 3.4-5.1-1.7 ± 0.8-1.6-1.4.
Discussion: Male STS athletes are ectomorphic-mesomorphs, borderline to balanced mesomorphs. Individual World Cup ranking of the athletes increases with mesomorphy levels. Compared with the 5 of 46 Tjech elite cross-country ski athletes (1.7-6.3-2.0), the male STS athletes show significant lower mesomorphy and higher ectomorphy (Orvanova, 1987). European elite Alpine ski athletes show significant higher mesomorphy levels compared to male STS athletes (Carter&Heath, 1990). These findings may suggest that an increase of the degree of mesomorphy should be a major training objective in male STS athletes to ensure further athletic success. Strength training together with nutritional advice of the athletes may therefore be appropriate.

Female STS athletes are endomorphic-mesomorphs. No significant differences with the reference data of other ski disciplines were observed.

Conclusion. Male and female Swiss Team Skialpinism athletes show ectomorphic-mesomorph and endomorphic-mesomorph somatypes respectively. Male STS athletes show significant lower mesomorphy levels than athletes of other ski disciplines. In the male group, mesomorphy is positively associated with World Cup ranking. Hence, our data suggest that training should be aimed at a further increase of mesomorphy in male STS athletes.

HIGH INTENSITY SHOCK MICROCYCLES: AN EFFICIENT METHOD TO IMPROVE VO2MAX
Institute of Anatomy, University of Bern, Switzerland

Introduction: Maximal oxygen consumption (VO2max) as a determinant of cardiorespiratory fitness is an often used predictor of aerobic endurance capacity. In already trained soccer players, VO2max can further be improved by performing high-intensity interval training (HIIT) sessions over two month twice a week (Helgerud et al., 2001). Alternatively it seems, that VO2max can effectively be increased when HIIT sessions are performed daily once or twice within a 10-day shock microcycle (Stolen et al., 2005). The aim of our study was to investigate the effect of a 15-day high intensity shock microcycle on endurance performance and muscle fatigue in moderately endurance trained subjects.

Methods: Two female and five male subjects, age 29.7 ± 5.0 yr, performed during 15 days an average of 17 ± 3 HIIT-sessions. One session consisted of 4 times 4 min cycling on a cycle ergometer at 90-95% of the individual maximal heart rate with a 3-min recovery period in between. Continuous heart rate measurement, rating of perceived exertion and lactate measurement were used to supervise the training sessions. Before (T1), as well as 2 days (T2) and 7 days (T3) after the last training session a incremental exercise tests to exhaustion on a bicycle ergometer was performed to determine maximal heart rate, maximal oxygen consumption and maximal aerobic power output. At T1, T2 and T3 as well as at day 3, 6, 9 and 11 during the training additional counter movement jumps on a force plate were performed.

Results and discussion: VO2max increased by 5.8% (from 58.5 ± 4.9 mLkgmin-1 to 61.7 ± 5.4 mLkgmin-1 (P < 0.01)) and maximal aerobic power output by 5.4% (from 396 ± 59 watts to 418 ± 62 watts (P < 0.01)). Maximal counter movement jump performance decreased during the microcycle by 16.3% from 48.7 ± 4.5 watts/kg to 41.8 ± 1.7 watts/kg (P < 0.01) and recovered by 12.0% at T3 (46.7 ± 5.0 watts/kg).

We conclude that 17 sessions of high-intensity interval training during a 15-day shock microcycle effectively improves VO2max and maximal aerobic power output. Decreased jump performance indicates for substantial muscular fatigue immediately at the end of the microcycle, which was not fully recovered one week after cessation of the training.

ACCURACY AND RELIABILITY OF MINIMAXX GPS TECHNOLOGY IN ROWING
Vogler, A., Lindh, A., Rice, A.
Australian Institute of Sport, Australia

Background
Improvements in GPS technology have provided a platform for the monitoring and tracking of athletes on a much wider scale than ever before. The size and low cost of GPS hardware now allows for a complete unit to be worn by the athlete or alternatively placed unobtrusively on their equipment. Rowing is a perfect sport for the implementation of GPS technology due to the uninterrupted view of the sky and that movements of the boat are recorded predominantly in the horizontal plane. Despite the near perfect environment of rowing there are still uncertainties with respect to the accuracy and reliability of GPS determinations of position and time.

Methods
The Australian Institute of Sport has been involved in the designed and manufacture of inertial data loggers with built-in GPS and RF capabilities that weigh under 70g. The GPS devices (MinimaxX, Catapult Innovations, Australia) have been used by the Australian Rowing Team for the last 3 years. Inertial data are recorded at 100Hz and GPS data at 5Hz. The devices were placed on 244 boats during major competitions at international standard rowing courses. Race time from the GPS device (MinimaxX 2000m race time) was compared with official race time from each boat monitored. In addition, 45 boats were fitted with two devices to calculate a reliability of the MinimaxX 2000m race time measure.

Data Analysis
MinimaxX 2000m race time was calculated as the time taken from the first boat movement (measured by the inertial sensors) to the time when the boat had travelled a straight line distance of 2000m. Standard error of the estimate (SEE) was calculated using official race times and corresponding 2000m race times from the MinimaxX unit. Reliability typical error measure (TEM), s and % and 95% confidence limits (CI) of MinimaxX 2000m race times were determined (1).

Results
Mean difference +/-SD between official race time and MinimaxX 2000m race time was 0.02+/-0.42s. Correlation between the measures was near perfect (R2=0.99999). SEE between MinimaxX 2000m race time and official race time was 0.45s. This translates to a boat displacement error of 2-3m depending on the boat class. MinimaxX 2000m race time from boats which had 2 units fitted during the race had a TEM of 0.30s with a lower CI of 0.25s and an upper CI of 0.37s. When expressed as % reliability data was 0.12% with a lower CI of 0.10% and an upper CI of 0.15%.
CONTRIBUTIONS AT THE CONCEPTUAL AND PRACTICAL OPTIMIZATION OF THE METHODOLOGY FOR THE REALIZATION OF THE PHYSICAL PREPARATION IN THE HANDBALL GAME

Aurel, I., Mihaila, I.  
VALAHIA UNIVERSITY OF TARGOVISTE, Romania

Introduction. The performances in handball are determined by a multitude of factors that condition each other. The interdependence between these factors is correlated with the athletic mastery of the players and the team. The unification of the technical-tactic value in the performance sport as well as the use of methods, means and equipment used for training gives back to the physical value its real contribution, this being the fact which could determine the result in the competitions. Organization of the research. The research for the present experiment was realized during a competition year, the experimental sample being constituted of two groups, each of 14 players and participants in the performance echelons of the handball in Romania. During the experiment on the experimental group there was acted with a series of means for the perfection of the previous 400-m. Obtained results. The new aspects in the conceptual and practical optimization of the methodology of the physical preparation in handball are offered by the instructional project in which the instructional operations insure a tight connection between the objectives of the training methodology. I visualize that the entire preparation and especially the physical training should be developed according to a clean-cut, in the main time in tight connection.

DECREASE IN OXYGEN UPTAKE AT THE END OF A SUPRA-MAXIMAL 400M  
Hanon, C., Leprêtre, PM., Thomas, C.  
1) INSEP 2) Université d’Evry, France

A decrease has been observed in all subjects during an 800-m running test (Thomas et al 2005). This study was realized according to the pacing strategy of competition (fast start and velocity decrease in the final part). During a 1500m this phenomenon has been observed only in 8/12 subjects (Hanon et al 2008). The purpose of the present study was 1) to verify that a decrease occurs during a 400-m running test performed according to the usual event pacing regulation and 2) to determine the relationship between the magnitude of the decrease and the metabolic state at the intermediate 300m of a 400-m running trial. Nine well-trained runners (8 male 400-m and one woman) (age 21.6 ± 6.3 [18] years, height 177.7 ± 6.3 [165] cm, and body mass 70.0 ± 4.7 kg [56], average performance 50.7 ± 1.3 [1,586] for the men [wman] volunteered for the study. The first track running test was a supra-maximal 400-m exercise reproducing the conditions of competition and the second test was a 300-m exercise realized two days later with help of audio-signal aiming to duplicate the exact pacing strategy of the previous 400-m. For both tests, ventilatory variables were recorded by means of a breath by breath gas exchange system (Cosmed K4b2, Roma, Italy). Heart rate (HR) was measured and recorded continuously with a heart rate monitor (Sport Tester PE 3000, Polar, Kempele, Finland). Blood samples were collected from the ear lobe and measured with the i-stat portable clinical analyser (Abbott, East Windsor, USA) before and 1, 4, 7, 10 min after the end of the running test. The difference between the time at 300-m on the 400-m running test and the time at the 300-m running test was not significant. The mean velocity decrease in the last 100m was 8.9% and ranged from 2.20 to 15.9% according to the subjects. During the 400-m running test, the maximum average value was detected 200m after the onset of the race. From this moment, a decrease was observed until the end of the race. This phenomenon was significant in the last 100m of the race and equal to 11.7 + 4.2 mlO2·min^-1·kg^-1 that was 20.4 + 7.0 % of peak.

The peak and nadir metabolic results after the 400-m were 7.01 + 0.04, 21.6 + 2.6 mmol·l^-1, 5.5 + 1.0 and 96 + 1.8 % and were 7.18 + 0.03, 16.5 + 1.5 mmol·l^-1, 10.9 + 1.6 and 96.3 + 1.5 % after the 300m for pH, blood lactate, HCO3-, SaO2, respectively. A significant relationship was observed between decrease and pH (r= -0.76), HCO3- (r= -0.67) and SaO2 (r= -0.73) p< 0.05. These track running data highlighted the fact that the decrease is the consequence of metabolic perturbations linked to acidosis status and that the buffering capacity of the athletes is of importance to success in this distance.

COMPARISON OF PHYSIOLOGICAL PROFILES BETWEEN ELITE CADET AND YOUNG SENIOR JUDOKS

Radovanovic, D., Bratic, M., Nurkic, M.
Faculty of Sport and Physical Education, University of Nis, Serbia and Montenegro

Previous investigations showed that functional abilities represent one of the determinants of success in judo competition. A significant correlation between functional abilities and technical elements in judo means that an improvement in some of the physiological variables can have a positive effect on the execution of techniques during fights. The aim of the conducted study was to determine and compare the functional characteristics between elite cadet (n=11, age 15 yrs. +/-0.5) and young senior judokists (n=8, age 20yrs. +/-1.2). All subjects underwent an identical study protocol (measurement of anthropometric characteristics, estimation of parameters of anaerobic capacity by 30-s all-out Wingate test on arm cycle ergometer, estimation of VO2max on leg cycle ergometer, estimation of VO2peak on arm cycle ergometer and measurements of parameters of dynamic lung function) in the concluding part of preparation periods before European Championship in respective age groups. Results: Cadets vs. young senior judokists (mean+/-SD): Peak power (W/kg) 9.66+/-1.02 vs. 9.34+/-3.32 (p>0.05); Mean power (W/kg) 6.86+/-0.91 vs. 6.72+/-0.89 (p>0.05); VO2max (ml/kg/min) 58.82+/-4.78 vs. 57.32+/-5.24 (p>0.05); VO2peak (ml/kg/min) 40.72+/-4.47 vs. 47.12+/-4.47 (p<0.05); FVC (l) 5.56+/-0.31 vs. 6.99+/-1.36 (p<0.05); FEV1 (l) 4.69+/-0.5 vs. 5.44+/-0.45 (p<0.05); body fat (%),10.38+/-5.6 vs. 8.22+/-3.06 (p<0.05). The results obtained showed that young senior judo players were characterized by a lower percentage of fat tissue, better aerobic capacity of upper body and better dynamic lung function in relation to cadet judo athletes. Contrary to the supposed, relative values of maximum power were higher in cadet judo athletes, but without statistical significance. Results of the conducted investigation provide information for quantitative presentations of physiological adaptation of elite cadets and young senior judokists to the physical demands over many years lasting specific training process. The proposed test battery may be used in the estimation of functional status in competitors and more precise determination of competition profile in top judo.

RELATIVE AGE EFFECT IN ELITE YOUTH SOCCER PLAYERS - BIRTHDATES DISTRIBUTION AND BODY MEASUREMENTS ANALYSIS

Folgado, H., Garcia, G., Duarte, R., Sampaio, J.
Universidade de Évora, Portugal

Relative age effect studies have systematically showed a skewed birthdates distribution among participants, in several sports and different age-groups, reporting a higher number of participants born in the early part of the year. Although many researchers pointed physical development and maturation as one of the possible causes for this effect, few works have related physical measurements with birthdates distribution. Therefore, the aim of this study was to analyse the distribution of birthdates from elite youth soccer players, and relate them to players' height and weight. All studied players (n=1007) were participants in the UI7 and U20 FIFA 2007 World Cup and were divided according to their specific field position (Goalkeepers, Defenders, Midfielders and Forwards) and according to their teams Confederation (Asian Football Confederation AFC, Confederation Africaine de Football CAF, Confederation of North, Central American and Caribbean Association Football CONCACAF, Confederacion Sudamericana de Futbol CONMEBOL, Union des Associations Europeennes de Football UEFA, and Oceania Football Confederation OFC). Each player's birthdate was analysed and classified by trimester. The distribution of all players and groups (Position and Confederation) was compared through Chi-Square test and body measurements comparison between trimesters of birth was made using one-way ANOVA. Significant differences were found in the distribution of the total group (p<0.01), in all of the field positions (p<0.01) and in AFC, CAF, CONCACAF, CONMEBOL and UEFA (p<0.01), revealing that the players from these groups tend to be born near the beginning of the selection year. On the contrary,CAF players tend to be born in the late part of the year. Significant differences were also found in players' height comparison between trimesters of birth, revealing taller players in the beginning of the selection year (F=2.716, p<0.05). These results suggest that the time of year when a player is born may have influence on the selection of young elite soccer players, and that body measurements are also related to this selection.

EVALUATION OF BODY COMPOSITION USING THREE DIFFERENT METHODS COMPARED TO DEXA IN TURKISH UNIVERSITY STUDENTS

Duz, S., Kocak, S., Korkusuz, F.
Middle East Technical University, Turkey

Purpose: This study evaluates the simple methods of Skinfold (SKF), Ultrasound (US) and Bioelectrical Impedance Analysis (BIA), using dual-energy X-ray absorptiometry (DEXA) as a reference method for the assessment of body fat (BF) in normoactive Turkish male and female university students. Moreover, we aimed to develop new regression equations to predict %BF from SKF and US measurements. Methods: Two hundred and eight students (104 males, 104 females) aged between 18 to 26 years participated in this study. Differences among DEXA, SKF, US and BIA were examined by ANOVA test. Intra-class correlation coefficient and Bland and Altman plot analysis were used for comparative analysis among the methods. Moreover, multiple regression analyses were conducted to developed regression equations to predict %BF from SKF and US measurements. Results: Results demonstrated the mean %BF derived from DEXA was significantly (p<0.01) greater than those of SKF, US and BIA in both genders. Regression analysis for predicting %BF using three sites simultaneously for male and female university students was r= 0.92, SEE=2.40 and r= 0.91, SEE=2.82 for SKF and r= 0.93, SEE=2.31 and r= 0.90, SEE=3.00 for US, respectively. Conclusion: With these new regression equations, US appears to be a reliable, portable, and non-invasive tool which can be used by any field investigation.

KINEMATIC STUDY OF THE CHOKU-ZUKI PUNCHING MOVEMENT PERFORMED BY THE PORTUGUESE KARATE TEAM AND PEOPLE WITHOUT KARATE EXPERIENCE

VencesBrito, A., Pezarat-Correia, P., Pascoal, A., Fernandes, O.
Sports Sciences School of Rio Maior – Polytechnic Institute of Santarém – Portugal; Faculty of Human Kinetics – Technical University of Lisbon – Portugal, Portugal

Introduction

This study compares the upper limb kinematics in a karate punching movement (choku-zuki) on a makiwara (training instrument) performed by a group of karate athletes (KGI) and by a group of subjects without any karate experience (NKG).
PHYSIOLOGICAL RESPONSES TO SHORT-TERM, HIGH-INTENSITY INTERMITTENT ROWING EXERCISE ON ERGOMETER

Higuchi, M., Takada, H., Yamada, K., Horibata, A.
Waseda University, Japan

Purpose: This study was designed to observe physiological response during one bout of high-intensity intermittent short time rowing exercise and to evaluate the effect of repeated bouts of the exercise on rowing performance by using the indoor rowing ergometer for college rowers.

Methods: In the first experiment, nine male collegiate rowers were participated in the high-intensity, intermittent short time exercise on rowing ergometer. Vo2max was measured by incremental rowing exercise on the ergometer. The high-intensity, intermittent exercise consisted of either five or eight bouts of 20-sec rowing with the maximal effort of the subjects, and each bout was separated by 10-sec rest. Oxygen consumption and heart rate were monitored during the test. Blood lactate concentrations were analyzed before, immediately after the high-intensity exercises. In the second experiment, 13 male collegiate rowers performed 6-week training regimens which consisted of high-intensity rowing exercise (8 sets with 10-sec interval, either 20-sec rowing with 10-sec interval, or 2 times/week). Performance tests and maximal incremental exercise on rowing ergometer were carried out before and after the 6-week training.

Results and Discussion: In the first experiment, subjects reached to the maximal level of Vo2 and heart rate at the fourth set during both 5- and 8- sets of high-intensity, intermittent exercises. However, blood lactate concentration immediately after high-intensity, intermittent exercise was significantly lower in the 5-set protocol than in the 8-set protocol (9.1±1.2 vs. 11.3±1.6 mM, p<0.05). This result suggests that the 8-set protocol is much more vigorous and better than the 5-set protocol as high-intensity, intermittent rowing exercise for rowers. In the 6- week high-intensity, intermittent exercise training, low frequency group (LF; 2 times/week) significantly improved their rowing performance (3.2±1.9 sec/1000m and 8.4±5.5 sec/2000m time trials), whereas high frequency group (HF; 5 times/week) significantly improved their performance in 1000m trial (4.5±2.3 sec), but not in 2000m trial (3.1±6.7 sec). Maximal power during incremental rowing test was not changed in both LF and HF groups in response to the repeated bouts of high-intensity intermittent exercise for 6 weeks. When compared with HF group, LF group seemed to be less burdened with the 6-week high-intensity, intermittent exercise regimen. These results suggest that high-intensity, intermittent rowing exercise on ergometer, which consists of 20-sec maximal exertion with 10-sec interval, 8 sets/bout, 2 times/week, more than 6 weeks, could be recommended to the young rowers in order to improve their rowing performance.

RUNNING- VS. STRENGTH-BASED WARM-UP: ACUTE EFFECTS ON THE NEUROMUSCULAR FUNCTION

Girard, O., Micallef, J-P., Carbonnel, Y., Candau, R., Millet, G.
University of Montpellier I, UFR STAPS, France

Introduction: Although active warm-up (WW) is often prescribed before physical activity, little is known on its effects on the neuromuscular function. The aim of this study was to investigate the influence of two running- vs. strength-based warm-up protocols on neural and contractile properties of knee extensor (KE) muscles.

Methods: 10 trained subjects performed randomly two different WW protocols, one of which (running warm-up, RWU) included a slow running of 8-10 km.h-1, 10 min, athletic drills of 10 min and sprints of 3 x 60 m accelerations and 5 x 15 m; ~15 min, while the other (strength warm-up, SWU) consisted of strength exercises (e.g. bilateral 90° back squats (2 x [3 reps at 90% RM followed by a set of 6 reps at 30% recovery) and 2 min), Olympic lifting movements (clean and snatch, 3 x [6 reps at 30 kg followed by a set of 6 reps at 20 kg], recovery = 2 min) and reactively running (4 x 10 m exercises). Of importance is that all work performed was similar between RWU and SWU (318±7 vs. 318±6 J.kg⁻¹). Before and immediately after WW, maximal percutaneous electrical stimulations were applied to the femoral nerve. Changes in EMG activity of vastus lateralis (VL) and vastus medialis (VM) muscles normalized to M-wave amplitude (RMS/M) as well as muscle activation (VA) were quantified during KE maximal voluntary contraction (MVC). M-wave characteristics and twitch contractile properties were assessed after each stimulus. The torque and EMG data were recorded (2000 Hz).

Results: Subjects performed I+51.6%, P<0.01 and +10.9%, P<0.05 and VA I+10.9 and +12.9%, P<0.05 increased to the same extent after RWU and SWU, respectively. The changes in MVC and VA were highly correlated (r = 0.83 and 0.85; P<0.01) and the raw EMG activity during MVC increased in VL I+18.6 and +22.2%, P<0.01 and VM I+18.3 and +20.1%, P<0.05 for RWU and SWU, respectively, RMS/M increased in the two vasti (32.4% and 28.9% in VL and VM, both P<0.05) for SWU, whereas did not change significantly for RWU I+14.8 and +20.4% in VL and VM, P=0.32 and P=0.07, respectively. Both protocols caused a significant and similar shortening of time to contraction (-12.8 and -11.8% after RWU and SWU), both P<0.05, while the other twitch parameters and the M-wave amplitude of both vasti did not change significantly.
Simultaneous strength and endurance training can result in interference effects on neuromuscular adaptations compared with both type of training performed alone. Few studies investigated concurrently swimming endurance training and strength training. The purpose of present study was compare the neuromuscular adaptations of 17 untrained women to 10 weeks of concurrent strength and swimming training or strength training only, 3 times per week. The subjects were assigned to strength training group only (STO, n=7), or strength and swimming training group (SST, n=5). A third group, control (C, n=5), did not train during the period of training. The following measurements were made before and after 10 wk of training: isokinetic peak torque concentric and eccentric of the knee extension, elbow extension and elbow flexion at speed of 90°·s⁻¹. One-repetition maximum (1RM) leg extension, 1RM bench press, 1RM elbow extension and 1RM elbow flexion. Swimming training (freestyle) was performed 3 times per week for 40 minutes between 90% and 95% of critical speed. Strength training program consisted of 2-4 sets with 50-60% of 1RM on 8 exercises designed to train all the major muscle groups of the body. All sets were performed until the failure of the muscle involved. Both swimming and strength training was performed in sequence always beginning for strength training. Results indicated that 1RM leg extension increased 30 and 32% (p < 0.05) for the STO and SST groups, respectively. 1RM bench press increased 23 and 19% (p < 0.05) for the STO and SST groups, respectively. 1RM elbow extension increased 26 and 21% (p < 0.05) for the STO and SST groups, respectively. 1RM elbow flexion increased 26 and 21% (p < 0.05) for the STO and SST groups, respectively. No significant changes were found for any of the 1RM exercises in the C group. No differences on 1RM were detectable among groups at the conclusion of training in all exercises (p > 0.05). Peak torque concentric and eccentric during knee extension increased for the STO and SST groups (p < 0.05). Peak torque concentric and eccentric during elbow extension increased only for the STO group (p < 0.05). Peak torque concentric and eccentric during elbow extension increased for the STO and SST groups, except peak torque concentric for the STO (p < 0.05). No significant changes on peak torque were found for any exercises in the C group. There were no differences on peak torque among groups at the conclusion of training in any exercises (p > 0.05). The present results indicate similar strength gains on 1RM in both training groups, and do not demonstrate any negative effects on 1RM strength development for women concurrently training for strength and swimming. Peak torque may be compromised when the same muscle groups is exercised by both methods of training.

PREDICTING 1 RM VALUES BY BODY MASS AND LEAN BODY MASS IN STRENGTH TRAINED AND UNTRAINED MEN
Silva, R., Cadore, E., Brentano, M., Silva, E., Spinelli, R., Pinto, R., Kruel, L.

One repetition maximum test (1 RM) is usually used to measured muscle strength and to prescription of strength training. However, the determination of test load and the time to perform this test make difficult its execution in non-individualized ambient. Thus, the purpose of present study was determinate coefficients of prediction of 1 RM load, based in the relationship between muscle strength with body mass (BM) and lean body mass (LBM). Twenty-eight (40 ± 4 years old) middle-aged men strength-trained (ST, n=13) and untrained (UT, n=15) participated of this study. Maximal strength was determined by 1RM test in four free-weight exercises: bench press, supported row, squats and leg press. Body composition was measured by skinfolds thickness method. The coefficients were calculated by ratio of maximal strength [kg] and body mass [kg] (1 RM/BM) and maximal strength and lean body mass [kg] (1 RM/LBM). Pearson's product moment correlation test was used to verify the associations between the variables measured and Student independent t-tests were used to compare muscle strength. Due to significant differences on strength values between groups (ST > UT), different coefficients were calculated to ST and UT groups. After that, independent t-tests were used to compare of coefficients between groups. Significant correlations were observed between BM and LBM with 1RM values in all exercises (r = 0.47 - 0.76, p < 0.05). The higher correlations were observed between maximal load in bench press and LBM (r = 0.76, P = 0.0001), supported row and LBM (r = 0.64, P = 0.001), squat and LBM (r = 0.65, P = 0.0001) and leg press and LBM (r = 0.56, P = 0.001). The coefficients calculated were significant different between groups in all exercise tested (p<0.05). In ST, the coefficients by the ratio 1RM/BM were 1.1, 1.1, 1.7 and 4.9 for bench press, supported row, squat and leg press and by the ratio 1RM/LBM were 1.4, 2.1, 1.3 and 6.0 for bench press, supported row, squat and leg press. In UT, the coefficients by the ratio 1 RM/BM were 0.7, 0.8, 1.3 and 3.0 for bench press, supported row, squats and leg press and by the ratio 1 RM/LBM were 1.0, 1.6, 1.1 and 4.0 for bench press, supported row, squat and leg press. There were no differences between 1 RM values tested and predicted by coefficients. The present results have demonstrated that the coefficients of prediction of test-load of 1RM must to considerate body composition and training status of subjects. The coefficients could be used to make easier the strength testing and in the prescription of strength training in non-individualized situations.

AN INVESTIGATION OF THE RELATIONSHIP BETWEEN ANAEROBIC POWER-CAPACITY, BODY COMPOSITION AND HEART RATE IN TURKISH NATIONAL SENIOR HANDBALL PLAYERS
Bilge, M., Sevim, Y., Ersöz, G.

KIRIKKALE UNIVERSITY, Turkey

The purpose of this study was to analyze the relationship between Peak Anaerobic Power (AnP)-Capacity (AnC), body composition and heart rate on male handball players, who played in Turkish National Senior Handball Players, and also to compare their data with non regular trained Physical Education and Sport (PES) students. At this study 22 national male handball players (trained group) were measured who involved in training 5-29 years (Mage= 15.50, SD= 6.16 years) and aged between 18 to 38 years (Mage=27.22, SD=5.45 years). The control group consisted of 22 non regular trained PES students aged between 18 to 26 years (Mage= 21.54, SD=2.06 years). Wingate Anaerobic Test (WAnT) was used to measure AnP and AnC for both groups. During the test, heart rates of the subjects were recorded using heart rate telemeter. In addition, body compositions of all subjects were measured by bioelectric impedance analyzer.
It was found that the mean of AnP and AnC of national players were 11.51 ± 1.32 W/kg, and 6.54 ± 0.48 W/kg, while those of PES students were 12.31 ± 1.84 W/kg, and 6.36 ± 0.42 W/kg, respectively. The mean heart rate (HRmean) and the mean of maximal heart rate (HRmax) during the WAnT were found 146.17 ± 7.30 bpm and 163.54 ± 5.85 bpm for national players, and 168.93 ± 8.76 bpm and 180.50 ± 8.52 bpm for PES students, respectively. In terms of body composition of subjects, percent of body fat was measured as 12.47 ± 2.19 for national players, and 11.50 ± 3.06 for PES students.

The results of the study revealed that there was a significant relationship between AnC and HRmean in national players (r=.52, p<.05). Besides, significant difference was found between HRmean, HRmax, and AnC values of national players and those of PES students (p<.05). National players had higher AnC values than that of PES students.

2x6 (Group x Time) split plot design of analysis on variance was conducted on changes in AnC and HR values in time (6 measures with 5 seconds interval in 30 seconds) separately. Results of analysis yielded significant main effects for time in AnC and HR values (F15, 210=189.52, p<.01; F15, 210=301.17, p<.01, respectively). Significant group x time interaction was found in both values (F15, 210=3.36, p<.01; F15, 210=10.44, p<.001, respectively).

DECISIONAL ANALYSIS OF THE PICK & ROLL IN NCAA

Refoyo, I., Domínguez, J., Sampedro, J., Sillero, M., Calleja, J.

Universidad Politécnica de Madrid, Spain

INTRODUCTION.
The target of this work is to carry out an analysis of the decisional analysis in pick&roll situations in order to establish a proper framework for our study. The decisional analysis in pick&roll situations will include different approaches: the decision making and the offence/defence systems in basketball.

MATERIAL AND METHOD.
The data for this work were collected from videos of the five final matches of the NCAA, using registry sheet elaborated for this work, in which we took as reference the following variables: total positional offences, total pick & rolls, defensive action, offensive action, zone, time and success.

RESULTS.
346 positional offensive actions were put under study from which the following results were obtained: 58.38% of those actions were pick&roll, obtaining success in a 40.10% of the cases. In addition, we must emphasize that the most used options by the defenders were pass over pick (27.23%), aid and recovery (28.71%) and change of player (23.27%). In offensive actions, we found that the possibility of passing to a free player (52.97%) was the most frequent option.

DISCUSSION.
The direct blockade in positional offensive actions is quite often in NCAA, however its use is not so relevant in order to achieve success in the attack. Within the defensive possibilities we found as most frequent the over screen, help and recover and the switch, in addition, they are the most significant in terms of success in defence. With regard to the offensive options, we appreciated that most outstanding is pass to the unmarked player, being the most effective stop and shot and pass to rolling. The area where most of the pick&roll are made are the central zone, in which player can find a wider space to develop the different offensive options, being the lateral zone left the one that accumulates the higher percentage of success. As far as the temporary distribution of the picks, we found that they regularly occur during the whole match, although we observe that the effectiveness of them increases as it comes closer the end of each quarter.

THROWING ACCURACY OF WATERPOLO PLAYERS OF DIFFERENT AGE AND SWIMMING PERFORMANCE, IN STATIC POSITION AND AFTER PREVIOUS SWIMMING

Platanou, T., Kottis, K., Varamenti, E.

University of Athens, Greece

There are two possibilities for shooting in water polo. Shots that become while the players are static and shots that players have previous swim with the ball. The effectiveness of shooting mainly depends from accuracy. In water polo, a few researches exist referring on the study of kinematic and on velocity of throwing, while exists absence of studies that would examine the effect of chronological age and swimming performance with the effectiveness of shooting (static or with previous swimming). Aim of this study was to compare the accuracy of shooting, static or with previous swimming, in relation to a) chronological age and b) swimming performance. Totally 50 players were tested. 21 of the sample belonged to the age group 10-12 years, 15 to the age group 13-14 years and 14 were older than 15 years. Each individual executed, from a constant place and 5 m away from the goalpost. 5 shots to a standard goal and then 5 more shots after swimming 10m away from the goalpost and stopping in 5m for shooting. Goals had been placed at 2 corners of goalpost with dimensions double size of ball’s diameter. Two 1WAY ANOVA compared the accuracy on throwing, with swimming and static, in relation to age and performance. Static shots that were achieved with accuracy were significantly (p<0.001) more than those achieved by shooting with previous swimming. In addition, more successful shots were achieved by older players. More specifically, players who belonged in the age group of 10 to 12 years old achieved in average from static position 1.7 times the goal (54.3%); players 13 to 15 years old 3.3 times (63.5%), whilst players over 15 years old, 3.9 times (77.3%). In motion the number of successful shots for each age group was 0.8 (16.2%), 2.1 (41.3%) and 2.6 (51.4%), respectively. No significant differences were found between the successful shots in static position and with previous swimming across the three age groups. Similar results were observed concerning the swimming performance of the players as those with the best swimming record were considerably more accurate in shooting. Accordingly, players with swimming time 60-40 sec in 50m crawl achieved on average 1.6 times the goal (32%); players from 39.90 to 32.0 sec, 2.7 times (54.1%) and players who swim in less than 31.9 sec, 3.8 (76.7%). The corresponding values while in motion were: 0.5 (10.7%), 1.6 (32.9%) and 2.7 (53.30%), respectively.

High coefficient correlation was found between chronological age and accuracy in static position and after previous swimming (r=0.75, 13TH ANNUAL CONGRESS OF THE EUROPEAN COLLEGE OF SPORT SCIENCE
RELATIONS BETWEEN MUSCLE FUNCTION AND GAIT PARAMETER ASYMMETRY IN TOTAL HIP ARTHROPLASTY PATIENTS

Impellizzeri, F., Widler, K., Bizzini, M., Leunig, M., Munzinger, U., Maffiuletti, N. 
Schulthess Clinic, Switzerland

INTRODUCTION: Total hip arthroplasty is considered one of the most successful orthopedic interventions and is recommended for severe hip osteoarthritis. Its effectiveness in relieving pain and improving function has been well documented. However, while relief in pain and self-perceived improvement in physical function occur soon after the discharge from the hospital (<2 months), restoration of muscular strength necessitates more time. Indeed, muscle strength asymmetries (>10%) can be found after 1 year from surgery (Shin et al., Clin Orthop Relat Res, 1994). The ability to perform daily-life activities such as walking, rising from a chair or climbing stairs has been suggested to be related to hip muscle strength (Bean et al., J Gerontol A Biol Sci Med Sci, 2003). In addition, muscle strength bilateral asymmetry has been shown to be related to risk of falls in older people (Skelton et al., Age and Aging, 2002). However, very few studies have examined whether asymmetries in the strength of the muscles surrounding the hip are related to asymmetries in walking (spatio-temporal gait parameters). Therefore, the first aim of this study was to examine this relation in total hip arthroplasty (THA) patients 6 months after surgery. Secondary aim was to examine the associations between subjective measures of pain and function ability with objective measures of muscle strength and walking ability. METHODS: Nine male (age, 71±6 years; BMI, 29±4) and 11 female (age, 72±5 years; BMI, 26±4) THA patients were involved in the study. Maximal isometric strength of hip abductor, flexor and extensor muscles and gait parameters during normal and fast walking were measured 5-7 months after surgery. Patients also filled the Western Ontario and McMaster Universities Index and the Harris Hip Score questionnaires. The alpha level was set a 0.01 (pseudo-Bonferroni adjustment). RESULTS: After 6 months patients showed strength asymmetries in flexor and abductor muscles (operated leg 89 and 91% of nonoperated leg, respectively). No correlations were found between asymmetries in strength measurements and asymmetries in gait parameters during normal walking (mean r after Fisher transformation, 0.15<r<0.29). During fast walking significant moderate correlations were found between flexor strength asymmetries and swing (r=0.66) and stance (r=0.64). No correlation were found between subjective and objective measures of functional ability. DISCUSSION: The results of this study showed that, according to the literature, significant impairments in muscle strength are still evident 6 months after surgery. However, only hip flexor bilateral asymmetries were significantly related to asymmetries in gait parameters during normal or fast walking. The lack of correlations between objective and subjective measures of physical function further underlines the importance of performance measures to obtain a complete picture of osteoarthritis patients (Stratford et al., J Clin Epidemiol, 2006).

ELABORATION OF A CIRCUIT FOR THE TRAINING AND THE EVALUATION OF SPECIAL ENDURANCE IN KICK BOXING K1 STYLE

Villani, R., Di Vincenzo, M., Gesuale, D., Distaso, M. 
Cassino University, IUSM Rome, Italy

Introduction
Some studies show that the anaerobic metabolism has a key role in the performance of combat sports. In such sports, the athletes may reach concentrations of blood lactate of about 15 mmol/l. So, to excel in Kick Boxing K1 Style are necessary a good training and evaluation of speed endurance. We experimented a standard protocol of a specific test/training: the specific circuit K1 (SCK1).

Methods
SCK1 consists in 3 series, each one of 2’, with a pause of 1’ (amateur fight duration) and in 4 places where the athlete perform the typical techniques (with PAO1: 1) ob-cross-hook 2) Low kick and Middle kick right; 3) knee left and right 4) Low kick and Middle kick left. The experiment was conducted over 20 k1 agonists (age:22±4; w:73±6kg; h:178±7cm; years of practice: 5±2). We divided them into 2 groups (EG and CG, each one of 10 athletes), with the same physical and technical characteristics. The groups had to do a series of tests (SCK1 and Fight), surveying the performance and measuring the lactate in three moments (basal, after 3’ and after 6’ from the end of the circuit/combat) with Lactate Pro. The tests reliability was proved by the correlation test-retest. Then all the athletes had to do a 4-weeks standard training, the athletes of the Experimental Group made also the SCK1. At the end of the training period, all the tests were repeated.

Results
The values of the correlation test-retest are high for the rounds number (SCK1), the kicks number and the lactate, with r always bigger than 0.79. (p<0.01). The study on SCK1 showed a big improvement of the EG results in the 1st series (+35%; p<0.0001), in the 2nd (+48%; p<0.0001) and in the 3rd (+50%; p<0.0001), against non significant lactate variations (-5/-8%). In the 3 series, the EG improved only for (+2/+5%). Lactate formation during the combat is lower than that of the circuit because during the fight pauses and tactical rests are more frequent. The lactate produced by the GS in the circuit is about 12mmol/l (min 9.6, max 15.3), while during the fight it is about 10mmol/l (min8.7, max 13.6).

Conclusions
The experimentation prove the usefulness of SCK1 as specific training exercise in K1. This circuit in the training program of the athletes examined, had very positive effects on the increase of the attack rate during the training, with no increase of the lactate levels. In conclusion, the circuit may be considered an effective training and specific evaluation method.

Interval Training Group (ITG n=30). The TR has been carried through during a period of 8 weeks (W) with frequency of 5 days/W and based in corresponding intensities to the LAn. The speed of LAn (SLAn) and the lactate concentration in the LAn ([Lac]-LAn) have been evaluated.

**METHODS:** 60 Wistar rats (190-210g), separated randomly have been used in two groups: Continuous Training Group (CTG n=30) and Interval Training Group (ITG n=30). The TR has been carried through during a period of 8 weeks (W) with frequency of 5 days/W and based in corresponding intensities to the LAn. The speed of LAn (SLAn) and the lactate concentration in the LAn ([Lac]-LAn) have been evaluated before the TR, after 4W and after 8W. The lactate concentration was evaluated in blood analysis in Yellow Spring® 1500 Sport. The CT was executed to 95% of the LAn and duration of 30'/session. The IT was carried through in 7 series (1ª-5ª with 4' and 6ª-7ª with 5' of duration) before the TR, after 4W and after 8W. The lactate concentration was evaluated in blood analysis in Yellow Spring® 1500 Sport. The CTG and ITG were of 1200 min, but, the realized were 1303 and 1141 respectively. CONCLUSION: CT as well as the IT of 8W monitored by the LAn didn’t cause positive adaptations in the aerobic performance (AP) of Wistar rats in running exercise, showing that variations in the intensity alone are not enough to promote positive adaptations in the LAn. The CT seems to have positive effect on the LAn only in the initial W, therefore, with the maintenance of the protocol for longer periods, the negative effect of the monotony become evident, reducing the AP. Such notes corroborate to the concept of the relation duration/intensity and the effect of the monotony in the TC.

**TIME AND MOTION ANALYSIS OF ELITE MALE SOCCER PLAYERS - A COMPARATIVE ANALYSIS OF THE AUSTRALIAN A-LEAGUE**

Janse de Jonge, X., Clark, A., Dwyer, D.
University of Newcastle, Australia

In recent decades there has been growing interest in time and motion analysis of soccer players, which has been used to describe the physiological demands of the game. The application of GPS technology and computerised video analysis has undoubtedly improved the accuracy and variety of measurements available to sport scientists. The present work describes the findings of a time and motion analysis of soccer players from the professional Australian A-League and compares the results with similar previous reports from Europe (Di Salvo et al. 2007) and Brazil (Barros et al. 2007). Defending and midfield players were tracked during games for one season using GPS devices (Minimaxx, Catapult Innovations). The devices measured and recorded displacement, velocity and acceleration during 53 games. Total and relative distances, and relative time, were calculated for five velocity ranges (Di Salvo et al. 2007), as well as the number of bursts of high intensity activity per game for each player. The average total distance covered by all players during a game was 11361±1580 m. Most of the total distance covered during a game occurred whilst walking and jogging (66%), while smaller distances were covered during low speed running (13%), moderate speed running (13%), high speed running (5%) and sprinting (3%). Even though the distance covered in the second half of a game was typically less than the first half (51% vs. 49%), they were not significantly different (p=0.08). Midfield players covered a greater distance than defending players during each game (p<0.001), with the difference occurring in all velocity ranges. Midfield players also performed more bursts of high intensity activity (3.3±0.2 km/h) per game than defending players (2.4±0.2 km/h, p=0.001).

The total distance covered by an Australian player for each game is very similar to what has been reported in European players (Di Salvo et al. 2007) and slightly more than in Brazilian players (Barros et al. 2007). The profile of relative distance covered in each velocity range is also very similar between the three leagues. However, the decrease in distance covered in the second half is lower in the A-League (2%), compared with the European (9%) and Brazilian (7%) leagues. There are also differences in the distribution of high intensity activity performed by different playing positions. Overall, this time and motion analysis of the Australian A-League reveals similar results to previous studies from Europe and Brazil.

**CHANGE IN PHYSICAL FITNESS IN MALE MILITARY CADETS DURING FIRST YEAR ATTENDANCE AT THE ROYAL NORWEGIAN AIR FORCE ACADEMY**

Aandstad, A., Hageberg, R., Nilsen, R., Sæther, Ø., Sævénborn, R.
(1) Norwegian School of Sport Sciences, (2) The Royal Norwegian Air Force Academy, Norway

**Introduction**

Good physical fitness is considered one of the basic features of military personnel due to possible high physical occupational demands. Compared to 20-30 years ago, physical fitness is reduced in young Norwegian civilian (1) and military (2) adults. Despite the fact that all Norwegian cadets must pass physical fitness screening tests before admittance to Military Academies, physical fitness levels of cadets is assumed to vary. Hence, the aim of this study was to identify initial physical fitness in Norwegian cadets and examine changes in fitness during the first year at the Air Force Academy.

**Methods**

All first year cadets enrolled at the Royal Norwegian Air Force Academy in August 2006 were invited to participate in the study (n=31). Among them was only one female, who therefore was excluded from analysis. Anthropometric data were collected from 30 male cadets (age 23.2 ± 4.0 yrs), while 26 cadets twice undertook treadmill testing. All fitness tests were conducted within two weeks after entrance
and at the end of the first year (May 2007). Direct maximal oxygen uptake (VO2max) and exercise tolerance time (ETT) were measured from treadmill running until exhaustion. Percent body fat was estimated from biopendence measurements (Quantum II, RJL Systems, USA), using the Weight Manager equation.

Results
VO2max was unchanged during the first year at the Academy, 57.1 ± 4.2 vs. 57.9 ± 4.3 ml/(kg∙min) (p = 0.23), and 4.49 ± 0.57 vs. 4.52 ± 0.60 l/min (p = 0.43). ETT was also unaltered, 323 ± 30 vs. 323 ± 47 sec. (p = 0.93). Peak heart rate in the two treadmill tests was similar, 199 ± 8 vs. 200 ± 6 beats/min (p = 0.17). Height was measured only at entrance (179.5 ± 5.1 cm), while bodyweight was unchanged from entrance to end of first year, 78.4 ± 8.5 vs. 78.6 ± 9.1 kg (p = 0.75). Percent body fat decreased during the first year from 17.8 ± 4.1 to 16.7 ± 4.1% (p = 0.02).

Discussion/conclusion
VO2max, ETT and bodyweight did not change in male cadets during the first year at the Royal Norwegian Air Force Academy. However, estimated percent body fat decreased slightly (6%) in the same period. VO2max was higher than previously reported for Norwegian conscripts during basic training [3] and also favourable compared to values reported in other international studies of military cadets [4,5]. In conclusion, Norwegian male cadets at the Air Force Academy had relatively high initial levels of fitness that were maintained during the first year at the Academy.

SPEED AND AGILITY IN YOUTH SOCCER AND YOUTH HANDBALL PLAYERS
Philippaerts, R., Matthyss, S., Vaeyens, R.
Ghent University, Belgium

Activities in soccer and handball are characterised by short intense efforts, such as sprinting and changes in direction. Straight speed and agility have been identified as independent qualities that are specific and produce limited transfer to each other. In this perspective, it is useful to evaluate differences in speed and agility between two similar team sports: soccer and handball. Anthropometrical measurements were performed in 241 youth soccer and 312 youth handball players. Both soccer and handball players performed a 10x5m shuttle sprint and a 30m sprint. The timing of the shuttle run and the 30m sprint (split times at 5m and 30m) were recorded, using Raceliner2 Stopwatch (Microgate, Italy). Independent t-tests were used to compare soccer with handball players. On 30m U12 and U14 soccer groups ran significantly faster than handball players but no significant difference was found after 5m. Also the shuttle sprint did not show a significant distinction between soccer and handball players. Also, there was no significant difference on the 30m sprint and shuttle sprint between soccer and handball players from the U16 and the U18 age groups. The shuttle sprint does not significantly differ between soccer and handball players. Changing in direction for catching the ball or to follow an opponent is in both team sports very important. On the 5m point no significant difference is found for all the age groups between soccer and handball. A possibly explanation is that the first meters in both sports are of major importance. Only in the younger groups (U12 and U14) soccer players run faster than handball players on 30m. The differences in speed and agility between soccer and handball are very small, due to the similar activities in both sports.

INVENTORY OF SURF TECHNIQUES
Moreira, M., Peixoto, C.
Technical University of Lisbon – Faculty of Human Kinetisc, Portugal

Introduction
Even so some studies in surf approach the techniques, these are not characterized in depth, being therefore necessary to find a way to describe the act of riding waves, so to identify all the manoeuvres. This study intended to create a surf techniques taxonomy through an inventory of techniques having this a steady and perceivable nomenclature.

Methods
The inventory of surf manoeuvres was applied to 9 participants (surfers, coaches and judges) and the results were analysed through a qualitative and descriptive statistical analysis (frequencies and model). The inventory of techniques construction had a first version based on bibliographical retraction and after being evaluated it resulted in a 2nd version with 168 manoeuvres. After a pilot application it was verified that it was very extended being reduced to 110 manoeuvres. It is organized in sets of two slides for each manoeuvre including a video of the same one. The first slide is to know what term is used for the shown manoeuvre and the second one is to choose a term from a list presented from the 10 classes of manoeuvres for the chosen terms and when analyzing the sample in its totality, 373 answers were verified that it was very extended being reduced to 110 manoeuvres. It is organized in sets of two slides for each manoeuvre including a video of the same one. The first slide is to know what term is used for the shown manoeuvre and the second one is to choose a term from a list presented from the 10 classes of manoeuvres for the chosen terms and when analyzing the sample in its totality, 373 answers were verified that it was very extended being reduced to 110 manoeuvres. Moreover, the inventory of surf manoeuvres was applied to 9 participants (surfers, coaches and judges) and the results were analysed through a qualitative and descriptive statistical analysis (frequencies and model). The inventory of techniques construction had a first version based on bibliographical retraction and after being evaluated it resulted in a 2nd version with 168 manoeuvres. After a pilot application it was verified that it was very extended being reduced to 110 manoeuvres. It is organized in sets of two slides for each manoeuvre including a video of the same one. The first slide is to know what term is used for the shown manoeuvre and the second one is to choose a term from a list presented from the 10 classes of manoeuvres for the chosen terms and when analyzing the sample in its totality, 373 answers were verified that it was very extended being reduced to 110 manoeuvres. It is organized in sets of two slides for each manoeuvre including a video of the same one. Results
Having in consideration the 110 presented manoeuvres, when analyzing the sample in its totality, it was verified that for the used terms there were 767 different terms being the average of approximately 7 terms for each manoeuvre. It was perceived that the answers tend to be different for all participants, being this confirmed by the value of the mode which had maximum possible terms for each manoeuvre. Through the used terms were identified by unanimity the following manoeuvres: bottom turn, roundhouse, floater and tube. Having in consideration the 110 presented manoeuvres for the chosen terms and when analyzing the sample in its totality, 373 answers were identified with an approach average of 3 terms for each manoeuvre being this also the value for the medium and the mode. The chosen terms were identified by unanimity the following manoeuvres: frontside drop, frontside bottom turn, frontside air, frontside cover up and frontside tube. Surfers changed riding stance in the backside reverse 180° bottom turn and had some difficulty differentiating details in tubes. Coaches presented some difficulties with the rotation axis in aerials and also differentiating details in tubes. Judges changed riding stance in the backside 180° bottom turn, had some difficulty with the rotation axis in aerials but they identified the grabs better.

Conclusions

Saturday, July 12th, 2008

14:15 - 15:15
The choices made were not influenced by the participants’ functions. Coaches presented the biggest number of choices concordant with the respective terms of manoeuvres. There is a difficulty in identifying the terms for the respective manoeuvres, proving that the participants have trend in not differentiating the manoeuvres and do not have a steady trend.

**TYPES OF JUMPS VS SPORTS RESULTS IN ATHLETIC JUMPS**

Sadowski, J., Makaruk, H.
Faculty of Physical Education in Biala Podlaska, Poland

Introduction: Jumping exercises are undoubtedly a leading training element in athletics jumps. The aim of this study was to make an attempt at highlighting these types of jumping exercises whose volume was the most closely connected with sports results of elite jumpers with long training experience.

Methods: Annual training programmes of 19 long jumpers (LJ) and 23 triple jumpers (TJ) were analysed. The parameters of the subjects in LJ and TJ were as follows: age: 24.74±/−2.12 and 25.82±/−2.75 years, training experience: 7.16+/-1.63 and 7.95+/-2.21 years, and sports level (season's best)=7.66+/-0.32 and 15.94+/-0.59 m respectively. The relations between examined parameters were evaluated using Pearson's correlation coefficient. The exercises were divided into single-leg jumps (SLJ) and double-leg jumps (DLJ), horizontal jumps (HJ) and vertical jumps (VJ), external load jumps including depth jumps (ELJ) and without external load jumps (WELJ). The volume of exercises was expressed with the number of jumps (contacts).

Results: Long jumpers and triple jumpers performed the following number of contacts (respectively): 55±39+/-8 26 and 7204±/−877 SLJ, was expressed with the number of jumps (contacts). Heart rate was verified and recorded all long race. Blood was taken before the start (bf), immediately after swimming (as), after cycling training. Basing on our research we recommend depth jumps from the height of 60 and 80 cm to elite athletes.

**SELECTING LOADS IN PLIMETRIC TRAINING BY MEANS OF BIOCHEMICAL MEASUREMENTS**

Makaruk, H., Sadowski, J., Sacewicz, T.
The Faculty of Physical Education in Biala Podlaska, Poland, Academy of Physical Education, Warsaw, The Faculty of Physical Education, Biala Podlaska, Poland

Introduction: The main criterion for selecting the height of a depth jump is the displacement of the centre of mass (CM) after a depth jump or Reactive Strength Index (RSI) which additionally includes the time of a contact. The technique correctness of performing an exercise, e.g. on the basis of stability of biomechanical parameters in a particular exercise, is taken into consideration less often. The aim of this study was to select the height of depth jumps on the basis of the stability of biomechanical parameters.

Methods: This study was performed on 8 athletics jumpers (age: 21.3+/-2.4 years, mass: 77.5+/-5.2 kg, height: 182.3+/-7.3 cm). Five depth jumps per each height were performed with landing on the ball of a foot from 20, 40, 60, 80, 100, 120 cm with the trial height order randomized for each subject. The task was to jump as high as possible immediately after the landing. Repeatability (within-subject) of two parameters was evaluated: vertical Ground Reaction Force (GRF) by means of the coefficient of variance (CV), and the ground contact time (CT) by means of standard deviation (SD). The measurements were made using a piezoelectric force platform (Kistler). To reveal significant differences between GRF and CT for various heights of depth jumps a 1-way between-group ANOVA was used. In order to highlight uniform groups the LSD test was applied (p<0.05).

Results: The highest repeatability of GRF was noticed from the height of 60 cm (6.87%) and 80 cm (10.18%), whereas the lowest was observed in depth jumps performed from 20 cm (12.76%), 40 cm (13.28%), 120 cm (14.29%) and 100 cm (16.44%). In turn, the highest repeatability of CT was seen from 80 cm (0.009 s), 40 cm (0.011 s), 60 cm (0.015 s), while a lower one was observed in depth jumps from 100 cm (0.022 s), 20 cm (0.023 s) and 120 cm (0.026 s).

Conclusion: Stability of biomechanical parameters while performing depth jumps may be a criterion for selecting loads in plyometric training. Basing on our research we recommend depth jumps from the height of 60 and 80 cm to elite athletes.

**EFFECTS OF AN OLYMPIC TRIATHLON ON BIOCHEMICAL AND PHYSIOLOGICAL MARKERS**

Universidade Federal do Paraíba, Brazil

The aim of the study is to investigate the effects of strenuous exercise on commonly used biochemical, hematological and physiological variables in male subjects participating in the Olympic triathlon competition. The sample consisted of 12 males volunteers triathletes (mean ± standard error) age, 27.9±1.7 yr; body mass, 73.9±2.1kg; height, 177.9±1.7 cm, body fat, 7.3±0.6%).

Methods: Annual training programmes of 19 long jumpers (LJ) and 23 triple jumpers (TJ) were analysed. The parameters of the subjects in LJ and TJ were as follows: age=24.74+/−2.12 and 25.82+/−2.75 years, training experience=7.16+/-1.63 and 7.95+/-2.21 years, and sports level (season's best)=7.66+/-0.32 and 15.94+/-0.59 m respectively. The relations between examined parameters were evaluated using Pearson’s correlation coefficient. The exercises were divided into single-leg jumps (SLJ) and double-leg jumps (DLJ), horizontal jumps (HJ) and vertical jumps (VJ), external load jumps including depth jumps (ELJ) and without external load jumps (WELJ). The volume of exercises was expressed with the number of jumps (contacts).

Results: Long jumpers and triple jumpers performed the following number of contacts (respectively): 55±39+/-8 26 and 7204±/−877 SLJ, was expressed with the number of jumps (contacts). Heart rate was verified and recorded all long race. Blood was taken before the start (bf), immediately after swimming (as), after cycling training. Basing on our research we recommend depth jumps from the height of 60 and 80 cm to elite athletes.

Conclusion: We assume that jumping training in athletes with extensive competition experience ought to be based on high intensity efforts. The view can be supported by strong correlations between sports results and the number of jumps performed with additional external loads and single-leg jumps. Moreover, it seems that exercises done in accordance with spatial movement structure of a performance exercise (e.g. horizontal jumps) play an important role in the jumping training.

The results confirm previous studies reported elsewhere in the literature for longer and strenuous events (REID et al, 2004; SMITH et al., 2004). There are many changes in biochemical, hematological and physiological parameters during a triathlon. If some coaches make...
Eighty basketball games were observed and reconstructed in their evolution of point's difference per ball possession. The Variation Coefficient of Point's Difference (VCPD) was game balance and success. Critical moments on basketball game using the referred method and to identify the critical moments according the independent effects of episodes. This was confirmed in the two analyzed game periods. However, the statistical means of the differences only was determined found for both periods in the game balance variable. The analysis of success demonstrates that winning teams provoked more of these episodes. In the first three periods unbalanced games presented more critical episodes than balanced games. Statistical differences were not determined for the first three periods of game. No differences were depicted for the last period. Ten points of the final game result was the mark to distinguish each category (Ferreira, 2006). The success variable was the qualitative use of these parameters acknowledgments to elaborate a different kind of training before and after competitive events, it may be possible to minimize effects of overtaining, skeletal muscular damages and injuries.

A COMPARISON OF VARIETY SOCCER PLAYERS PHYSICAL ACTIVITY EXPENDITURE DURING TRAINING SESSIONS AND MATCHES

Destounis, A., Comtois, A.
Université du Québec à Montréal (UQAM), Canada

Goal: The purpose of this study was to analyze and compare men’s variety soccer player’s physical activity expenditure (PAE) during training (T) and matches (M) days over a Canadian university season (end of August till end of October). Methods: A total of 17 players were recruited and participated in the study for a 10-week period. Heart rate (HR) during training sessions (T/week) and match days (T/week) were recorded with heart rate monitors (Polar Team System, Fi). Prior to heart rate monitoring, all subjects completed a maximal incremental treadmill test in order to obtain each player’s respective VO2max and HR max. The soccer players were instructed to run at a constant speed comfortable to them set between 8km/h and 12 km/h with a 2% increase inclination every 2 min until exhaustion. VO2max was measured directly using a breath-by-breath metabolic gas analyser. The PAE response was quantified for every individual by 5 different methods: %HR reserve (HRR), %VO2max, %VO2 reserve (VO2R), TRIMPS (HR-zone) and TRIMPS/min. %VO2max and %VO2R were calculated from the extrapolated VO2 of the player’s own VO2/HR relationship (established during the treadmill test) TRIMPS were calculated as proposed by Edwards (1993) and used by (Ferreira, 2000) Statistical analysis was performed by paired t-test for training vs match of the same week. ANOVA was used for comparing the same variables across time (week 3 vs week 6 vs week 10) Post-hoc analysis was performed by using Tukey HSD. Level of significance was set at p < 0.05. Results: Mean VO2max and HRmax for the group was 66.2±5.44 ml/kg/min and 187±7.11 b.p.m., respectively. All PAE variables were all significantly larger, unless noted otherwise, during match days when compared to training sessions: %HRR T vs %HRR M, respectively, was for week 3, 51±8.1 vs 80.3±10.8, week 6, 50.4±10.5 vs 82.8±5.9, and week 10, 53.1±7.8 vs 85.4±12.5; %VO2 max T vs %VO2 max M, respectively, was for week 3, 45.5±9.3 vs 75±9.71, week 6, 47.5±8.5 vs 75.1±5.7, and week 10, 50.2±6.3 vs 74±7.71; %VO2R T vs %VO2R M, respectively, was for week 3, 44.5±9.3 vs 74±4.7, week 6, 44.8±8.6 vs 73.6±5.8, and week 10, 47.3±6.3 vs 76.0±7.4, TRIMPS (HR-zone) T vs TRIMPS (HR-zone) M, respectively, was for week 3, 225±60.7 vs 306.0±115.7, week 6, 253.0±90.9 vs 359.2±151.3 (not significant), and week 10, 234±72.0 vs 502.7±114.4, TRIMPS/min T vs TRIMPS/min M, respectively, was for week 3, 2.6±0.31 vs 3.0±0.53, week 6, 2.6±0.48 vs 3.0±0.46, and week 10, 2.8±0.30 vs 3.4±0.34.

Summary: Comparing week 3 to week 10 there was a significant increase in intensity of some PAE variables (TRIMPS (HR-zone) T vs TRIMPS (HR-zone) M, week 3 vs 10) for both training sessions and matches. However, all PAE variables were higher during matches when compared to training sessions. Conclusion: PAE increased during the 10 week season and was higher during matches when compared to training sessions.

INDEPENDENT EFFECTS OF GAME BALANCE AND SUCCESS ON BASKETBALL CRITICAL MOMENTS

Ferreira, A., Sampaio, J., Ibañez, S., Volossovich, A.
1 Faculty of Human Kinetics – Technical University of Lisbon (Por); 2 Sport Department – Trás-os-Montes and Alto Douro University (Por); 3 Sport Sciences Faculty – Extremadura University (Spain), Portugal

The Variation Coefficient of Point's Difference (VCPD) represents a variation ratio of punctual difference obtained among consecutive intervals of game time (Ferreira, Volossovich & Gonçalves, 2003). However, understanding the basketball game as a sequence of ball possessions shared by both teams, their succession can describe VCPD during the game’s course as a timeline. Ferreira (2006) suggested it as a more appropriate functional perspective to observe basketball game dynamics. This study has the aim of determining the critical moments on basketball game using the referred method and to identify the critical moments according the independent effects of game balance and success.

Eighty basketball games were observed and reconstructed in their evolution of point’s difference per ball possession. The VCPD was determined for episodes of six consecutive ball possessions (three for each team) and described in an independently way for the three first periods and for the fourth period. Ferreira (2006) demonstrated that coaches divide the basketball game in two main parts: the 1st, 2nd and 3rd as a unitary block and the 4th period. A critical moment was considered when some critical point could interrupt the normal flow of the VCPD dynamics. To determine what it could be normal or abnormal flow of the VCPD dynamics, the 95 percentile was considered as a cut-off value. After the determination process each critical moment was subtracted from the whole game and studied as a physical episode of the game. Game balance was defined by a dichotomous division: balanced and unbalanced games. The reference of ten points of the final game result was the mark to distinguish each category (Ferreira, 2006). The success variable was the qualitative expression of the final game result: win and loss. In the first three periods unbalanced games presented more critical episodes than balanced games. Statistical differences were not found for both periods in the game balance variable. The analysis of success demonstrates that winning teams provoked more of these episodes. This was confirmed in the two analysed game periods. However, the statistical means of the differences only was determined for the first three periods of game. No differences were depicted for the last period.

The results suggests a negligible influence from game balance in the number of critical moments generated during a basketball game. On the other side, game success also appears as an important variable. To provoke some critical episodes in order to disturb the normal flow of game final score differences seems to be an important reason to lead a winning game. The reference is used of these parameters acknowledgments to elaborate a different kind of training before and after competitive events, it may be possible to minimize effects of overtaining, skeletal muscular damages and injuries.

STUDY OF THE OFFENSIVE ACTIONS THAT CULMINATE IN SHOT AT GOAL IN THE EURO 2004

Costa, J., Alves, N., Crispim-Santos, A.
Sport Science School of Rio Maior, Portugal

Introduction
This study proposes to characterize the offensive situations that culminate in shot at goal in football teams that had participated in Euro 2004. We did the characterization of the actions depending on its duration, number of passes, number of players involved and technical-tactics actions used. The characterization of the stages of the process offensive. The characterization of communication established in the team, in the resolute action of the game depending on the areas of the field and players. And, the analyse view of the last pass, in the resolute action of the game, depending on the areas of the field and players.

Method
In this study our sample is composed by 7 games of the final stage. Based on previous work, especially, Maças (1997) and Costa (2005), developed and validated a system of observation, classified by categories with 11 variables. Several measures of fidelity were also undertaken. 165 offensive situations that culminate in shot were observed (systematic observation, indirect and not participated). The methods used to collect data were the registration of occurrences for most of the variables of duration and registration for other, until the minimum unit of the second.

Results
There was higher percentage of offensive situations that culminate in shot at goal between 75 and 90 minutes. More goals were done between 45 and 75 minutes. On average, are needed, only 2 pass and 3 players by offensive action to reach situations of shot at goal. In 52.1% of the offensive situations exist free kick. Almost 39% of the offensive situations not had success.

Discussion/Conclusions
The number of offensive actions with shot at goal increase with the time of the game elapsed. There is also an increase in the number of offensive actions without success to the course of the game. In football there is a current trend towards a decrease in the number of players involved in offensive actions. Nowadays the free kicks have an increasingly crucial importance in football. We see an increasing of the intervention of the Defenders of offensive actions teams in the game. Increasingly the observation and analysis of the game is an indispensable tool for any coach, team or player wishing to improve their income. It is important realize that structural whether to intervene so that the process of training have the results indicated more for the teams.

AEROBIC GYMNASTICS (AER) IN FEDERAL UNIVERSITY OF MINAS GERAIS SEARCHING FOR THE MOST EFFICIENT TRAINING

Lemos, K., Diniz, R.
Federal University of Minas Gerais, Brazil

Aerobic Gymnastics (AER) has a recent history as a sport modality. Nowadays, Brazil is considered one of the major nations in AER. Since 1996, when AER’s project in the Federal University of Minas Gerais (UFMG) was initiated, it has been offered with free cost for internal and external communities of the university. Totally inserted in the three pillars of UFMG (graduation, research and extension), numerous nationals and internationals championships were conquered by the elite team of UFMG over the years. Currently, through voluntary work, we have a multidisciplinary technique team: biomechanics, physiotherapy, strength training, exercise physiology and sports psychology. In 2007, we looked for a training program that integrates these research areas to attend the Elite team. Based on the data from 2006 and aiming upgrades on technical trainings and physical preparation of the athletes (considering the national and international competitions of 2007), we programmed a periodization including differentiated and integrated strategies of training. Initially, we carried out an analysis of the elements using videos and biomechanical studies. Also, the progression of learning elements of high degree of difficulty was accomplished with the help of artistic gymnastics coaches. The strength training was realized initially aiming increases in strength through morphologic adaptations (muscular hypertrophy). The workload of training has been chosen based on the literature (1), using general and specific exercises related to the sport modality. After a specific technique analysis of each movement used by the gymnasts in their competition’s routines, the major goal was then focused on the neural adaptations, through specific exercises, considering the individual demands of strength of each athlete. On the other hand, in technical training, the micro-cycles were designed considering the major requirement of AER’s Competitions: a perfect performance, including endurance methods developed in partnership with the physical trainer. The training was conducted in six weekly sessions with 5 hours a day; each session included the technical and physical preparation. An assessment of technical performance was made in each micro-cycle. This interactive and multidiscipline dialogue become real with the active participation of the athletes who had understood, discussed and assisted the professionals involved in each sphere of the sports training. As a result, we reached a better performance that was confirmed by various national titles and 12 gold medals won at the Pan Championship and World Cup Series of AER.

VALIDATION OF WATER AND LAND ANAEROBIC TESTS USING WINGATE TEST AS A GOLD STANDARD

Soares, S., Aleixo, I., Santos, I., Machado, L., Vilas-Boas, JP., Maia, J.
University of Porto. Faculty of Sport. Porto, Portugal

Anaerobic performance assessment still being a not fully accomplish mission (Bangsbo, 1998). The several methods and tests applicable in sports field are indirect and surrounded by a number of limitations. The cycleergometer Wingate anaerobic test seams to be the most worldwide accepted method for measure anaerobic performance. Nevertheless, the Wingate test is very unspecific for a number of sports, like swimming, for instance. This is especially because it takes place out of the swimming pool and because in swimming legs don’t seem to be prominent as propulsive segments. The aim of the present study was to validate other 30s land and water tests taking
as a gold standard the Wingate test performed in cycloergometer. 90 swimmers, 30 pre-pubertal, 30 pubertal and 30 post-pubertal, being 15 males and 15 females in each group, participate in the study. Pubertal stages were defined using stages described by Tanner (1962). Experimental procedures consisted on live 30s tests: (I) free swimming with the swimmers connected to a cable velocimetric system; (II) fully tethered swimming (Globus strain-gage); (III) simulated swimming on a biokinetic swim bench; (IV) crank ergometer Wingate test and (V) cycloergometer Wingate test (the gold standard test). Post-exercise maximum blood lactate concentration ([La-]) was measured after each test with a LactatePro analyser. Validation was tried considering as variables: the maximum [La-], stroke or pedalling movement rate (WV) and fatigue index (FI). First validation procedure consisted on an exploratory study of the association (Pearson Correlation Product, p<0.05) observed between gold standard test and concurrent ones, for each variable. Concordance degree was then established by a repeated measures ANOVA test (Bonferroni adjustment; p<0.05). Finally, a factorial confirmatory analysis was made. Four factorial models have been tested. The metabolic indicator [La-] showed the strong possibility of any test to produce information similar to the one produced by the gold standard test (63% r² 75%). The variables MV and FI failed in establishing the same relation-ship for [La-] variable, swim bench and crank ergometer Wingate tests were the closest to the gold standard in representing anaerobic potential. Free and tethered swimming represent the same potential, but with a less strong relationship with gold standard. This is probably due to the fact of these last tests were performed in aquatic environment.

ANALYSE OF THE INFLUENCE OF OFFENSIVE SEQUENCES IN THE ATTACK SUCCESS IN BEACH VOLLEYBALL

Vicente, JP., Fernandes, N., Gomes, I., Leite, N., Motã, P., Vaz, L., Sampaio, J.
University of Trás-os-Montes e Alto Douro, Vila Real, Portugal

Introduction
The purpose of this study was to analyze the influence of offensive sequences in attack success in two groups of beach Volleyball teams, according to their position in the World Ranking.

Methods
Two groups of top-level beach volleyball competing in a Pool of the World Circuit of Beach Volleyball in Espinho in 2006 were considered in this study: G1, was composed by teams classified in the 'Top-five' of the World Ranking, and G2 included teams classified between the 13th and the 26th position of the World Ranking. For the effect, 854 offensive retreats of the games were analyzed considering the moment, space and task, in the ¼ final, ½ final and final, in a total amount of 8 games, that put in confrontation the 26 best teams of the World, according to the Ranking of the International Federation of Volleyball (FIVB). A descriptive analysis was done to obtain the frequency and occurrence percentages. An inferential analysis was done through contingency tables and a qui-square (2) test to find out the possible association between variables. The level of significance was established in 5%.

Results / Discussion
The results pointed out that: i) the highest success in the analyzed games have occurred in Side-out; iii) The middle zone near the net was the most often used zone to pass, iii) lateral zones had more success in the attack; iv) although the finger pass was the most used the pass was more succeeded; vi) in the beach volleyball the best teams had more passes of good quality and also get of higher success; vii) the use of strong attack was related with the final result of the match; vii) despite the players used more frequently the crossed attack, the higher success was obtained when the attack to the line was performed; viii) the situation of opposition with a blocker is the most frequent and well succeeded; ix) players usually chose the attack situations without touch in block, but the results revealed an increase in success in situations where touch in the block exists.

Conclusion
The G1 presented higher values of point and lower values of continuity and error, in almost the totality of the variables analyzed compared to G2. According to the results of this study effectiveness in attack is a technical tactical element that was significantly higher for the winning when compared to the defeated teams.

COMPARISONS BETWEEN TWO AEROBIC POWER TESTS IN SOCCER PLAYERS: VO2MAX TEST AT TREADMILL AND THE YO-YO INTERMITTENT ENDURANCE LEVEL 2

Osiecki, R., Fornaziero, A., Leite, R., Stanganélli, L., Dourado, A., Daros, L.
Federal University of Paraná, Brazil

The objective of this study was to compare the maximal cardiopulmonary responses and the performance of soccer players submitted to two different types of assessment for aerobic power: the Yo-yo intermittent endurance level 2 test performed on the soccer field (Bangsbo, 1996) and the VO2max test performed in the laboratory on a motorized treadmill. In both tests the subjects ran until maximal exertion. The sample was composed by 16 young soccer players and the tests were performed at least one week apart. In both tests the subjects had their expired air continuously monitored by the analysis of O2 and CO2 concentrations (Cosmed k4b2, Rome-Italy). The Student t test for dependent samples and Pearson moment correlations were determined for the selected variables. There was statistical significance for the values obtained on the treadmill and Yo-yo tests (p<0.05), respectively, in the following variables: Minute ventilation: 149.7±15.86 and 135.8±15.94 l/min; Respiratory exchange rate: 1.28±0.07 and 1.21±0.05; Heart rate: 193.9±7.86 and 190.00±6.71 bpm. The VO2MAX (56.00±6.33 and 57.20±4.67 ml/kg/min) was not statistically different when comparing both tests. Based on the Pearson Moment Correlations, two equations were proposed to predict the VO2MAX using the total time (min) [r=0.91 e r²=83,13%] or the distance covered (m) in the Yo-Yo (r=0.89 e r²=79,1%). VO2time=13,2537+5,762time and VO2(distance)=20,196+0,0334distance. Considering these results, it seems that the Yo-yo intermittent endurance level 2 test could be used to evaluate the aerobic power of soccer players since it showed similar responses to a gold-standard VO2max test and also it seems to have a much easier applicability, less costs and it is specific to soccer.
ANAEROBIC METABOLIC AND VELOCIMETRIC FATIGUE THRESHOLDS IN SWIMMING

Aleixo, I.; Morais, P.; Fernandes, R.; Vilas Boas, J.; Machado, L.; Soares, S.
University of Porto. Faculty of Sport, Porto, Portugal

Delivering fatigue onset is one of the training purposes. Moving fatigue thresholds in response to training, like the anaerobic threshold, it's an example of it. Although, fatigue thresholds use seems to be possible only for evaluations performed under aerobic metabolic domain. This could be due to difficulties associated to anaerobic potential evaluation (Bangsbo, 1998). The aim of the present study was to determine if metabolic and velocimetric anaerobic fatigue thresholds are coincident on time. Research protocol consisted on two tests performed by two different groups. First group (10 male and female pubertal swimmers) accomplished a maximal front crawl 30s swimming test attached to a cable velocimetric system. The second group (10 pubertal male swimmers) performed 6 maximal front crawl swim stages with 5s increasing time from 5 to 30s. Post exercise peak blood lactate was measured (LactatePro analyser) after each stage of the incremental exercise. A especially developed Matlab program allowed to determine fatigue thresholds on the continuous 30s effort v(t) function based on frequency analysis using wavelets (Soares et al., 2006). It was possible to observe velocimetric curves with one (13.83±1.33s) and two (9.67±2.27 and 17.42±2.35s) fatigue thresholds. Metabolic fatigue threshold determined trough blood lactate kinetics during the incremental 30s protocol showed differences in blood lactate accumulation near to 15s swimming effort. Results showed that metabolic thresholds are close to velocimetric thresholds of v(t) curves were one threshold was observed.

ANAEROBIC CRITICAL VELOCITY AS A POSSIBLE TOOL FOR SWIMMERS’ EVALUATION

Aleixo, I.; Soares, S.; Machado, L.; Morais, P.; Fernandes, R.; Vilas Boas, J.
University of Porto. Faculty of Sport, Porto, Portugal

Considering that most of swimming competition distances are equal or lower than 200m, and that events last around 2 min or lower, it's commonly recognized the importance of swimmers' anaerobic potential (Troup, 1999). Although, valid and easily applicable methods for anaerobic potential evaluation still missing. Wakayoshi et al. (1992) adapted the critical power concept of Scherrer e Monod (1960) to swimming. Authors proposed the regression of swimming distances over respective times of maximal intensity. This method allowed for critical velocity calculation, and has been well accepted as an aerobic capacity indicator. Some authors get the y-intercept value of that regression line and tested it in order to be used as an anaerobic potential indicator. Results were somewhat encouraging (Soares et al., 2003). In an attempt to implement an alternative, simple and non-evasive test that evaluate swimmers anaerobic performance based upon CV concept, the purpose of this study was to calculate and analyze CV, determined only with supposed anaerobic swimming distances - short distances - (CVanaer), in order to understand its meaning, namely on what means swimmer’s anaerobic performance evaluation.

10 pubertal male swimmers (12.8±0.7 years) were evaluated. Subjects have accomplished 6 maximal front crawl swim stages with increasing time-duration from 5 to 30s. The increments were of 5s. Recovery between bouts was 20 min active front crawl swimming and two distances swim test of 200 and 800m swam at maximal intensity. CVanaer was on average 6.5±2.3m.s-1 higher than CV (p<0.05). Mean average difference was 0.1±1.5s and that seems to confirm that VCanaer could be used as a possible indicator of the anaerobic swimming capacity performance.

INVESTIGATION OF THE INDIVIDUAL CONTRIBUTION TO CREW PERFORMANCE IN ROWING

Topslakal, N.; Cotuk, B.; Pelvan, O.
Marmara University. Turkey

The main aim of the study was to investigate the individual contribution of each rower to team performance in a quad scull boat. Two quad scull teams consisting of eight rowers with similar physical age 19.7±1.6 years, weight 84,0±3.2 kg and height 185,9±3.9 cm and no age profile participated in the study. On land, a 1000m ergometer test measured the performance of the rowers while a staged rowing ergometer test yielded the physiological capacity parameters. In the 2000m ergometer test, power per stroke was recorded continuously by RowPro® software. In the staged rowing ergometer test heart rate, oxygen uptake and carbon dioxide output were recorded by Zan® Ergospirometer, and max-VO2 and anaerobic threshold were determined by Zan® software and Wasserman® plots. On water, a staged test with increasing stroke rate and a 2000m race test were performed. In these tests, the force generated by left and right oars, stroke arc, boat velocity, boat acceleration (two axes), and heart rate were continuously recorded by the RowX-outdoor® system and analyzed by Webas Expert® and Dataplore® software.

Max-VO2 of the rower was 4.99±0.08 l/min and the anaerobic threshold was reached at 77.2±2.1% of max-VO2. On the ergometer, with exception of the first and final sprint period, the variation of the individual contribution to total team power output was confined to 1%. In the on water staged test mean boat velocity significantly correlated with power, drive time power, force, efficiency of stroke rate, stroke arc, effective arc, angle to force peak and angle at force peak (p<0.05). In the 2000m on water test, power and force production of both the teams and the individual rowers varied instantaneously. Individual force curves remained stable, but were different between rowers. For all parameters left-right differences were observed. The individual contribution of the rowers to total power output of the team showed a variation of 2.1% for team 1 (the more experienced one), and 2.7% for team 2. Contrary to the variation profile observed on the
EXAMINING HEARTH RATE DURING GOLF TRAINING
Odabas, I., Guler, L., Ozcan, G., Topar, I., Camliguney, F. 
Marmara University, Turkey

The aim of the study was to determine the hearth rate of a golfer, and how many steps the golfers walk during training and approach about the structure of golf.

Total 3 male golfers with handicaps of -2.6 / 2.1 (mean age 20.4±2.19) and 2 female golfers with handicaps 2 - -3 took part in this study.

The golfers have been involved in golf for 10 years. Measurements were taken on a golf course with 18 holes in Antalya.

The golfers did not do any intense physical activity the day before training. The resting hearth rate of the golfers was taken before training.

They went into the course after hearth rate monitors and a pedometer (Yamax Digiwalker CW-701 Pedometer) was worn on the belt. It started to record as the golfer walked on the golf course and stopped on the last hole. The distance was calculated by multiplying number of steps and step length (distance = number of steps x step length).

Heart rate monitor (Polar S610i) was used in order to determine the hearth rate of the golfers during training. Heart rate monitor was worn before warming up and the monitor was stopped after the game completed. Golfers played the game as pairs. In the beginning of every session and at the end of the session, time marker (lap time) was used in order to evaluate the heart rate of the golfers on every hole including warming up and warming up with the ball. Every exercise file of each golfer was transferred to a computer via infrared. Exercise files of the golfers were examined one by one in order to revise any mistake which could occur in hearth rate monitor during the game. After that all the data of the whole group was evaluated statistically.

The mean resting hearth rate of the golfers was 68±6.52, 91 minutes (minimum 71 minutes, maximum 120 minutes) and mean hearth rate was 123±5.07 per minute after warming up. Golfers completed 16 holes owing to weather condition. It has been seen that minimum heart rate was 116±6.6, while maximum heart rate was 163±11.48 after the game. Total duration the golfers spent on the golf course including warming up was 249 minutes (minimum 202, maximum 300 minutes). Average number of steps the golfers walked was 14931.

It has been seen that golfers do an intense physical activity when the distance they treaded was taken into consideration and their hearth rate decreased remarkably in aerobic level. It is conspicuous that golf is a sport which requires pretty much aerobic endurance.

KINETICS OF STROKE RATE, STROKE LENGTH, AND SWIMMING VELOCITY, DURING A SHORT-COURSE 100M FRONT CRAWL SWIMMING EVENT
Coelho, J., Fernandes, R., Colaço, P., Soares, S., Vilas-Boas, J.
University of Porto, Faculty of Sport, Portugal

The ratio between stroke rate (SR) and stroke length (SL), as well as the changes of swimming velocity (v), during competitive swimming, are widely regarded as macro characteristics of sport technique and its efficiency, specially when combined in the stroke index: SI = SL * v (Costill et al., 1985). Efficient movements allow lower energy expenditure, highlighting the importance of biomechanics as a factor of energy saving.

The purpose of this study was two-fold: (i) to analyze the kinetics of the stroking characteristics - SR, SL, stroke index (SI) -, and v throughout a 100m front crawl swimming and (ii) to analyze the relationships between these indexes and the specialty of the swimmers (sprinters, middle distance, and endurance swimmers).

Seven elite front crawl swimmers were divided into three groups: 2 sprint swimmers (50.3±0.9s personal best in 100m freestyle), 3 middle distance swimmers (242.2±4.5s personal best in 400m freestyle) and 2 endurance swimmers (956.7±3.4s personal best in 1500m freestyle). The subjects were tested in a 4 phases protocol: (i) a maximal 100m front crawl event, recording the four 25m time splits (and corresponding v); (ii) after 1h of active recovery, a 25m paced swim at the velocity assessed in the first 25m split and (iii and iv) 24 h after, corresponding v).

Throughout the 100m front crawl, the velocity decreased significantly during the three first laps (increasing in the last 25m split), and the SR rises and the SI decreases, being these parameters inversely correlated (r=-0.98, p<0.05), as found by Seifert et al. (2005). Additionally, it was observed a high correlation between SR and v (r=0.661; p<0.05). When comparing swimming specialists, the sprinters were significantly faster than middle and long distance swimmers, presenting higher SR. Furthermore, we found lower SL and SI in sprinters than in middle and long distance swimmers.

It was possible to conclude that the 100m event imposes specific fatigue effects and, complementarily, that the specific specialized aerobic training allows swimmers to keep with a apparently specific event strategy.

CHANGES OF KINETIC MEASURES IN YOUNG WOMEN ATHLETES
Rousanoglou, E., Plessa, E., Boudolos, K.
National & Kapodistrian University of Athens, Greece

Kinetic measures may provide information for differences due to training background [Ligrinoiwhi et al., 2007], as well as for changes in the progress of a training season [Häkkinen et al., 1993]. They may also be used for optimizing an athletic movement [Hochmuth, 1984]. This study evaluated changes in kinetic measures of jumping performance in young track & field jumpers [TFJ: n=13, 17.5±1.5yrs, 57.3±5.6 kg, 168±4.6.6cm] and volleyball players [n=19, 16±1.9yrs, 61.7±6.8 kg, 170.3±8.7cm]. Athletes were initially tested in the preparation...
EFFECT OF THE CRITERION TO DETERMINE MAXIMAL LACTATE STEADY STATE DURING AN INTERMITTENT PROTOCOL WITH ACTIVE RECOVERY

Greco, C., Barbosa, L., Souza, M., Pelarigo, J., Caritá, R., Caputo, F., Corvino, R.

Human Performance Laboratory, Brazil

Introduction: Most endurance athletes have utilized interval training, which involves repeated bouts at exercise intensities equals or near to maximal lactate steady state (MLSS), interspersed with recovery periods. MLSS corresponds to the highest workload exercise that can be maintained over time without continual blood lactate accumulation and it has often been determined trough 30-min continuous exercise sessions (Beneke et al., 2003). In general, an increase in blood lactate concentration by no more than 1.0 mM during the final 20 min of the test is used as a criterion to calculate MLSS. However, there is few knowledge referred to its determination at intermittent exercise conditions. Since test interruptions may interfere in the blood lactate response, the moment of blood collection may interfere in the blood lactate values (Beneke et al., 2003). Therefore, the objective of this study was to analyze the effect of the criterion utilized to determine the workload (MLSSw) and blood lactate concentration ([La]) corresponding to MLSS.

Methods: Eight trained male cyclists (25 ± 4 yr, 71.30 ± 11.60 kg, 178.00 ± 4.50 cm), performed the following tests on different days on a cycle ergometer: (1) incremental test in order to determine the workload (MLSSw) and blood lactate concentration ([La]); (2) two to five constant workload tests to determine MLSS and [La], consisting on eight 4-min bouts and 2-min of active recovery at 50%Pmax (i.e., 46 min of exercise protocol). The first trial was performed at 105%AT. If during the first constant load test a steady state or a decrease in lactate was observed, further subsequent constant load tests with 5% higher workload intensities were performed on separate days until no [La] steady state could be maintained over time without continual blood lactate accumulation.

Results: The [La] obtained trough constant load tests with 5% higher workload intensities were performed on separate days until no [La] steady state could be maintained. If during the first constant l oad test a steady state or a decrease in lactate was observed, further subsequent constant load tests with 5% higher workload intensities were performed on separate days until no [La] steady state could be maintained.

Discussion: Results revealed that MLSS was calculated using two criteria: a) Delta [La] between 10th (after the second bout) and 30th min (after the fifth recovery period) of the entire test protocol (i.e., considering recovery periods IC1 and IC2 between 14th and 44th min (in the middle of the eight bout) of the entire test protocol (i.e., without considering recovery periods IC1 and IC2). Results: The [La] obtained trough C1 (6.06 ± 1.76 mM) was significantly higher than C2 (5.41 ± 1.8 mM). There was no significant difference in MLSSw calculated from C1 (303.50 ± 24.22 W, 84.87 ± 4.23%Pmax) and C2 (310.75 ± 26.47 W, 84.40 ± 5.01%Pmax). Conclusions: Although metabolic response is higher when the recovery period is considered for the data analysis, the exercise workload corresponding to MLSS is not affected by the criterion used for its determination.

THE EFFECTIVENESS OF THE SIDE-OUT IN A HIGH LEVEL TEAM OF VOLLEYBALL IN 2007 SEASON

Vicente, JP., Dias, R., Vaz, L., Gomes, I., Mota, P., Sampaio, J.

University of Trás-os-Montes e Alto Douro, Vila Real, Portugal

Introduction

The aim of this study was to evaluate the efficacy in the side-out situations of a Portuguese team, the Leixões Sport Club (LSC), during the 2006/2007 championship.

Methods

The last five male seniors games of the LSC were observed using the observation system SOS-vgs (Moutinho, 1993) in a total amount of 18 sets and 296 technical actions concerning to the side-out phase. In order to appreciate the association between variables (reception, distribution, attack), descriptive and inferential statistics were used namely the Chi-Square and Monte Carlo test. The reliability was confirmed through the Kappa of Cohen statistic.

Results / Discussion

Our results revealed that LSC had a high percentage of success in the pass quality (reception) as well as a high quality of jumping pass increasing the number of pass possibilities in the attack, varying between 75.0% and 81.2%. The distribution action was also positive with increasing the number of pass possibilities in the attack, varying between 75.0% and 81.2%. The distribution action was also positive with increasing the number of pass possibilities in the attack, varying between 75.0% and 81.2%. The distribution action was also positive with increasing the number of pass possibilities in the attack, varying between 75.0% and 81.2%. The distribution action was also positive with increasing the number of pass possibilities in the attack, varying between 75.0% and 81.2%. The distribution action was also positive with increasing the number of pass possibilities in the attack, varying between 75.0% and 81.2%.

Conclusion

When a comparison between the games carried out 'at home' and of the games carried out 'outside home' was made, our results failed to find any difference in the effectiveness of reception, distribution and attack.
The most pertinent conclusion was the high team efficacy realization on the side-out phase. Despite this level of efficacy, this team was unable to qualify for the play-offs, reaching the sixth place on the final ranking.

**BAKEBALL GAME-RELATED STATISTICS THAT DISCRIMINATE BETWEEN TEAMS’ LONG-TERM SUCCESS**

Ibáñez, S., Sampaio, J., Feu, S., García, J., Parejo, I., Ortega, E.
Faculty of Sport Science, Spain

The study of basketball game-related statistics in game situation has been used to identify variables that can distinguish between successful teams and players, and consequently lead to better sport results. Several studies have been showing that basketball winning teams outperform losing teams in shooting field-goals and securing defensive rebounds Ibáñez, Sampaio, Sáenz-López, Giménez, & Janeiro, 2003). No study has been conducted in several basketball seasons in order to identify long-term success. Therefore, the aim of the present study was to identify the basketball game-related statistics that discriminate between teams’ long-term success, as measured by teams’ qualification for the playoffs. The sample was constituted by all 145 average records per season from the 3274 games played during the 2000-2001 and the 2005-2006 regular seasons in the basketball Spanish league (LEB1 league). The following game-related statistics were gathered from the official boxscores of the Spanish basketball federation: 2 and 3 point field-goals (both successful and unsuccessful), free-throws (both successful and unsuccessful), defensive and offensive rebounds, assists, steals, turnovers, blocks (both made and received), and fouls (both committed and received). In order to control season variability all results were normalized to minutes played each season and afterwards they were converted in z-scores. The first result was the absence of statistical significant differences between best and worst teams’ game ball possessions, which represent game rhythm (Oliver, 2004). This result allows to suggest that basketball overall team success is not associated with higher or lower game rhythms. On the other hand, the best teams did exhibit higher offensive efficacies than the worst teams (1.42±0.07 vs. 1.35±0.07, p<0.05). Results from discriminant analysis were statistically significant (Wilks’ Lambda[1,15]=0.46, p<0.01) and allowed to emphasize the structure coefficients (SC) from assists (SC=.42), steals (SC=.33) and blocks (SC=.30). The obtained function correctly classified 84.2% of the cases. In conclusion, high-level basketball team success was not dependent on how many opportunities the team has to score but on how to take profit from current opportunities. The best teams’ exhibited better passing skills and better outside and inside defensive pressure.

**DIFFERENCES BETWEEN GAME LEVEL AND GENDER BASKETBALL PLAYERS IN FORMATIVE YEARS**

Ibáñez, S., García, J., Feu, S., Cañadas, M., Lorenzo, A., Gómez, M.
Faculty of Sport Science, Spain

Various studies have analyzed the differences in the performance of basketball players with regard to gender and level from the study of game actions. Men’s teams differ from women’s teams by executing a higher number of blocks, a lower number of steals, and by having a higher number of successful two-point field goals. Junior teams differ from senior teams by executing fewer assists and more turnovers (Sampaio, Ibáñez & Feu, 2004). In the literature, no studies have been found that analyze these differences in periods of formation. The purpose of the present study was to identify the differences in the game through the study of the official game statistics between male and female basketball teams from the U16 and U14 categories. The sample was composed of 148 games from the 2007 Spanish championships (U16 males n=43, females n=36; U14 males n=40, females n=29). The variables studied were the following official game statistics: 1-, 2-, and 3-point shots (attempted and successful), defensive and offensive rebounds, assists, steals, turnovers, blocks (made and received), and fouls (committed and received). To avoid the game rhythm effect, all variables were normalized to 100 possessions (Oliver, 2004). The file was divided in order to analyze only the games ending with a close score (n=190, final point difference of 1-12 points). The discriminant analysis for the level of the teams showed a statistically significant relationship (p<0.01). The study of the structural coefficients demonstrated the importance of the attempted 2-point field goals (SC=-.30), attempted 3-point field goals (SC=.40), and turnovers (SC=-.32). The results of the discriminant analysis for gender were equally significant (p<0.01). It was found that the game action that most predicts a male team are attempted 3-point field goals (SC=.44). For the discriminant analysis for level and gender, the function obtained was statistically significant (p<0.05) and correctly classified 90.9% of the cases. Discriminant function 1 correctly classified 60.1% and discriminant function 2 correctly classified 26.8%. The structural coefficients of function 1 reflect the importance of both successful (SC=38) and attempted (SC=-32) 3-point field goals. There were no significant structural coefficients in function 2. The results show the importance of game actions that require greater effort and precision (3-point field goals) when discriminating teams, and these actions are associated with a greater evolutionary development.

**1 X 1 IN EURO 2004, THE BEHAVIOR OF FIRST DEFENDER IN THE GAME OF FOOTBALL**

Crispim-Santos, A., Lageira, R.
SPORT SCIENCES SCHOOL OF RIO MAIOR, Portugal

**Introduction**

The aim of this study is characterise the behaviour of the first defender, verifying if exists differences over the behaviour application in the different zones, sectors and field sides. Methods

That behaviour is composed by four stages that include: ii) approach to the offensive player with ball possession (stage 1); ii) adequate speed approach between offensive player with ball possession and defender (stage 2); iii) leading the offensive player with ball possession into the lateral field limits (stage 3); and iv) attempt to disarm or disarm (stage 4). There were defined twelve field zones. We analyse 5659 defensive behaviours (1x1) on the 17 recorded games played by the best four selections of the EURO 2004 Football Championship took place in Portugal: Greece, Portugal, Check Republic and The Netherlands. There was used the Contingency Coefficient, the Chi square test with an error probability 0.05.
Results
Was detected a characterization of several behaviour profiles on specific zones. The first defender, in greater proportion, applies stages 1 (approach) and 4 (disarm) of contention (first defender behaviour) in the central defensive zone (zone 2) since that's a good zone to shoot to goal. In zone 1 and 3 (left and right defensive sides), the increasing of ball possession grants more time to apply all stages of behaviour of first defender. In zone 4 and 6 (left and right defensive midfield) the first defender avoiding the risk of trying to disarm the player with ball possession. In zone 7 and 9 (left and right offensive midfield) the objective of the first defender is to take place between the ball and is goal avoiding the entrance of the ball into the zone 5. In zone 8 (central offensive midfielder), the first defender shows a vigilant attitude, like a first blockage for the offensive players. In zone 10 and 12 (left and right offensive sides) the first defender tries to retake the ball possession, while all companions are in attack position. The zone 11 (central offensive) is a zone where the first defender waits a mistake of the ball possession player.

Conclusion
The obtained data permits us to assume that there were found significant differences in application of the defensive behaviour on 1x1, over the several defined zones of the field. The first stage (approach): highly used, reducing only in zone 2 and a little increased over the self goal to the attack goal; second stage (adequate speed): reduce over the self goal to the attack goal and from lateral sides to the central side, third stage (leading to the side field): reduce substantially over the self goal to the attack goal and from lateral sides to the central side; fourth stage (disarm): less used in the midfield, offensive and defensive, highly used in zone 2 and corner sides (zones 1, 3, 10 and 12).

IMPACT OF FASTING DURING RAMADAN ON ATHLETIC PERFORMANCE IN TUNISIAN ELITE JUDO ATHLETES
Chaouachi, A., Coutts, A., Chamari, K., Moalla, W., Amri, M.
National Center of Medicine and Science in Sports (CNMSS), Tunisia
During Ramadan, Muslims abstain from food and fluid intake from dawn to sunset for one month. However, at present the influence of the Ramadan intermittent fast (RIF) on athletic performance is not well known. Therefore, the aim of the present study was to evaluate the influence of the RIF on the level of aerobic and anaerobic power in elite judo athletes maintaining their usual training loads. A battery of physical performance tests (squat jump (SJ), countermovement jump (CMJ), 30-s-repeated jump, 30-m sprint test, and the multistage fitness test), fatigue questionnaire and haematological parameters were measured from 15 elite judo athletes on four occasions: before Ramadan, at the beginning, the end and after Ramadan. The results showed that 30-m-sprint performance, multistage shuttle run test, SJ, and CMJ did not change during Ramadan. However, the 30-s repeated jumps test decreased at the end of Ramadan (P<0.05). There were also a significant reductions in body mass (P<0.05) and an increase in total fatigue score (P<0.05) during Ramadan in comparison with the control period. These results show that the RIF has little effect on performance in most of the aerobic and anaerobic power test in judo athletes. Additionally, athletes can maintain both sufficient energy intake and normal training loads during the RIF. The reduction in the 30-s jump test may be associated with reduced central drive and reductions in body mass. Future studies should examine the effects of the RIF on sport-specific athletic performance. Coaches should carefully plan training loads during the RIF to avoid maladaptive training and to avoid increases of athlete's fatigue which can be an early sign of overreaching. Therefore we suggest that careful periodisation of training, diet and recovery may all be important factors that coaches should consider when training Muslim athletes during the RIF.

STUDY CONCERNING THE IDENTIFICATION OF TALENTS FOR THE HANDBALL GAME FOR DEBUTANTS
Ion, M., Iancu, A.
UNIVERSITY OF PITESTI, Romania
Introduction.
The prognosis of the sporting performance for debutant children is a compulsory condition for obtaining some exceptional results in the sport of high performance. In this sense, the identification of young talents with special skills for practicing the game of handball, did and will permanently attract the attention of the specialists in the domain, as a specific element, included in the sport of performance and directed towards obtaining some superior results in the great world-wide competitions.

Methods.
In order to experiment the theoretic considerations presented and to identify the abilities which favor the practicing of the game of handball, we undertook an experimental study concerning their finding in the initial phase and their degree of manifestation at an early age, inside the Sports Club Sport Team Pitesti, which made a selection in order to form a group of children of beginners in the game of handball. To this action, took part a number of 96 children with the ages between 10 and 11 (born in 1996 and 1997), a number of 18 with inclinations towards the practicing of this game being selected. The measurements were done over the main anthropometric, motric, psycho-motric, functional and psychological parameters, decisive for the practicing of the game of handball, the relationship between these categories being established by parameters and limits of trust in which one can request the physical capability at the age of growing up.

Conclusions.
The basis of the general and specific sporting talent must be searched in the type of physical constitution of the athlete and in his capability to achieve performances, as well as in the perfectibility of the basic motric skills. At the level of the beginners’ children groups, the curriculum of training must rely on the general sporting development, and not on the obtaining of special results in the competitions of handball. The analysis of the current system of sporting selection leads to the conclusion that this is made from measurements which identify with priority the athletic qualities and less those ludic, which forecast the favorable features for the practicing of the game of handball. The selection of talented children can be made at maximum parameters, only if this is made from a biological, functional, bio-chemical, psychological and motric point of view.
HEART RATE RESPONSE TO DURATION AND PLAYERS' NUMBER VARIATIONS IN FUTSAL SPECIFIC DRILL

Duarte, R., Folgado, H., Batalha, N., Sampaio, J.
University of Evora and University of Trás-os-Montes e Alto Douro, Portugal

Introduction: Recent findings demonstrate that Futsal is a multiple-sprint sport in which high-intensity exercise constitutes a greater proportion of match time than all other team sports (Barbero-Alvarez et al., 2008), but the research of training intensity is a unknown way. Specific drills with variations are constantly used in Futsal practices, however the knowledge about how these variations influence drill intensity is very insufficient (Duarte et al., 2007). Therefore, this study aimed to measure the effects of duration and players’ number variations in a Futsal specific drill by the elicited percentage of maximal Heart Rate (HRmax%) and percentage of time spent in three Heart Rate intensity zones (HRzone1<65%HRmax; HRzone2=65-85%HRmax; HRzone3>85%HRmax).

Methods: The studied sample was constituted by eight players from a Portuguese First Division team (age 25.9±4.5; weight 67.6±7.5; height 1.70±1.0; BMI 22.2±2.0). The exercise testing consists in a half-pitch game with official rules. To test the effect of players’ numerical relations, the drill was played in 4v4, 3v3 and 2v2 conditions, during 4 minutes and followed with an active break (continuous running with low intensity) of 4 minutes. In order to test the effect of exercise duration, the drill was played during 4 minutes and 10 minutes conditions, maintaining an active break of 4 minutes.

Results: In players’ number variation statistically significant differences were found in HRmax% [4v4 81.5±10.6 to 3v3 86.8±7.3 and to 2v2 87.9±11.7; p=0.01] and in percentage of time spent in HRzone2 [35.4% in 4v4, 12.5% in 3v3 and 10.4% in 2v2; p=0.01]. In the exercise duration statistically significant differences were found only in percentage of time spent in higher Heart Rate zone and induce more elevated physiological stimulation.

Conclusions: The decrease in the number of players resulted in an intensity increase, probably due to the larger ratio of area per player and to the progressive decision making constraint by the limited choices of the ball carrier to cooperating with the teams-mate. The variation of the exercise duration did not induce any change in HRmax%. However, playing the half-pitch game during 4 minutes period brings more significant percentage of time spent in higher Heart Rate zone and induce more elevated physiological stimulation.

IMPROVEMENT OF EXTENSION STRENGTH OF THE LOWER LIMBS USING PROGRAMS OF STRENGTH TRAINING COMBINED WITH ELECTROMYOSTIMULATION: STUDY CARRIED OUT IN MALE SENIOR PRE-LEAGUE BASKETBALL ATHLETES

Carvalho, C., Vieira, L., Cardoso, J., Carvalho, A.
Instituto Superior da Maia, Portugal

The main purpose of the present study consists on researching the best procedures for morphologic and functional development of the extensor muscles of the lower limbs. We want to evaluate if the electrical stimulation (EMS) could improve the training process, i.e., whether the results would be optimized if the 'conventional' training of the extensor muscles of the lower limbs was added EMS as well as if the results were consistent after 2 or 3 weeks, keeping the athletes under regular training according to the respective sport.

Our sample, 8 pre-League Basketball athletes, had been split in 2 groups: the control group (GC) composed by 4 Maia Basket athletes only submitted to the initial and final evaluation, and the experimental group (GE) composed by 4 Vitoria de Guimarães athletes who were submitted to a mixed training program - the 'conventional' and the 'electromyostimulation' programs. The training program lasted 8 weeks, with 2 weekly sessions. Each session of about 90’ with an initial warming up, followed by a circuit where the GE worked the different muscular groups, with predominance of the lower limbs extensor muscles [leg-extension, leg-press and squat] normal exercises in 1st set and EMS exercises in the 2nd set bench press, military press, horizontal row, curl Scott and triceps 10RM[s]. Each athlete had been submitted to anthropometric measurements of weight and height. The tests to assess the different strength expressions were: (1) knee extension in the ‘Leg-extension’ - continuous maximum force, (2) leg-press - dynamic maximum force, (3) Counter Movement Jump (CMJ) - explosive and reactive long duration force, (4) Squat Jump (SJ) - explosive force, (5) Drop Jump (DJ) - reactive short duration force, (6) isokinetics Dynamometer - Peak Torque.

The results show that GE improved the lower limbs extensor muscles strength from the 1st to the 2nd evaluation moment, in the different tests. The 3rd moment only showed a positive evolution in the ‘Leg-Extension’ and the ‘Leg-Press’. In the GC, the ‘Leg-Extension’ improvements reached 15.8% and from the 2nd to 3rd moment 15.4%, both statistically relevant. The GC had a loss of 2.7%. In the ‘Leg-Press’, the improvement reached 18.8%, for the GE from the 1st to 2nd moment and 6.9% in the detraining period. The GC got a deficit of 2.7% between the 1st and the 2nd evaluation. During isokinetic force (extension) the improvements reached 3.3% for the GE, on the right lower limb 7.6% (p=0.03) and on the left one 6.1% (p = 0.087).

The CMJ improvements reached 14.3% in the GE from the 1st to the 2nd moment and a decrease of 3.4% from the 2nd to the 3rd, the GC decreased 2.4% between the 2 first moments. The SJ improvement was 14.3% in the GE between the first 2 tests and -5.3% from the 2nd to the 3rd, the GC reached -7.7% from the 1st to the 2nd moment! In the DJ, the improvements reached 10.3% for the GE from the 1st to the 2nd moment, and -2.9% from the 2nd to the 3rd, and there was

**CHOICE REACTION TIME RELATED TO SEX, AGE, ANXIETY, STRENGTH AND MAXIMUM MOVEMENT FREQUENCY**

Martinez de Quel, O., Saucedo, F., Adán, E., Zapico, A. 
University Complutense of Madrid, Spain

**INTRODUCTION**

The relation between reaction time and other characteristics is not clear in the literature. The aim of this study was to compare choice reaction time (CRT) with other subject characteristics in order to see which of them better predict CRT.

**MATERIAL AND METHODS**

After signing an informed consent, 201 subjects (86 women and 115 men), of whom 169 were Karate players and 32 sedentary people, participated in the study. Choice Reaction Time was measured using the software SuperLab Pro 2.0 (Cedrus, San Pedro, CA, USA). Every participant performed 4 blocks of 25 trials. The whole first block and the first trial of each block were excluded from the statistical analysis. Two variables were calculated: CRT [mean of 72 the trials] and efficiency in the test [number of correct responses divided by reaction time and multiplied by a constant to avoid decimals]. A 30 second tapping task was designed to set the maximum movement frequency (MMF). Strength per body mass was measured with a (Grip-D.T.K.K. 5401 Takei) dynamometer and the State Trait Anxiety Inventory (STAI[II]) was used to measure anxiety. Using SPSS 9.0, groups (men/women) were compared with a Student T-test after confirming the equality of variances with the Levene's test.

**RESULTS**

CRT correlates with MMF (r=-.285, p<0.01), efficiency (r=.318, p<0.01) and hand grip strength related to body mass (r=-.165, p<0.05). Also a relation was found between hand grip strength and efficiency (r=.220, p<0.01). No relations were found between CRT, age and anxiety. Men and women CRT was similar and differences were found in efficiency (r=2.69, p<0.01).

**DISCUSSION**

CRT has been related to other performance components (2), in contrast with results of RT as an independent variable (3). Our results suggest a relation between CRT, strength and MMF. These differences could be done to the measuring protocol used, as we measured all variables in the same muscle groups. The independence of CRT and trait-anxiety, in opposition to previous studies (4,5), could be done to our task, developed without stress and without emotional charge. Results suggest better performance in a CRT task in men, according with previous studies where initial differences were avoided increasing the motivation of both groups (6). The evolution of CRT with age previously reported in women between 20 and 89 years (7), has not been demonstrated here, in young adults. In conclusion, RT is related with other subject characteristics.

**PHYSIOLOGICAL DETERMINANTS OF AGILITY IN BASKETBALL**

Chaouachi, A., Brugnelli, M., Chamari, K., Gregory, L., Castagna, C.

National Center of Medicine and Science in Sports (CNMSS), Tunisia

Agility is a prerequisite for the successful performance in various modern team sports. Little is known about its physiological and Muscular determinants in elite basketball. To get more insight into the physiological and muscular determinants of agility performance and given the proposed importance of this motor quality in sporting performance it would seem beneficial for coaches, strength and conditioning practitioners to identify possible best predictors of a court sport specific agility performance and exercises training to develop training strategies that may best optimize it. The aims of this study were to examine the relationship between squat 1RM and basketball-relevant tests and the variables that influence agility (T-Test) in elite male professional basketball players (n=14, age 23.3±2.7 years, height 195.6±8.3cm, body-mass 94.2±10.2 kg). Testing consisted of anthropometric and physiological measures of height, body mass, %body fat and endurance (VO2max), performance measures of speed (5, 10, and 30 meters), strength (Bench press and squat), vertical jump, horizontal jump test (SJ) and agility. T-test performance was significantly related to body mass (r=0.58, p=0.03) and to % of body-fat (r=0.80, p<0.001). A significant negative correlation was observed between T-Test and 5-Jump test performance (r=-0.61, p=0.02). Squat 1RM was significantly related to 5-m, 10-m and 30-m sprint times. Stepwise correlation analysis showed % body fat percentage was the best single predictor factor (p<0.05) of agility. Squat 1RM performance was the best single predictor of 5-m and 10-m sprint times.
understand the effect of biological maturation on VO2max. Biological maturation has an effect upon VB2 in any way it is expressed, but aerobic capacity development.

The aim of the present study was to evaluate the effects of biological maturation on maximal oxygen uptake (VO2max) and ventilatory breakpoints (VB1 and VB2) in young football players on three separate scales. One hundred and twenty male amateur athletes were allocated into three groups, prepubescent (PreP), pubescent (Pub) and postpubescent (PostP) according to Tanner’s maturation stage. Ventilatory and respiratory parameters were measured by indirect calorimetry (CPX-D, MIC, USA). The VO2max and VB were determined according to the following plots: ventilation (VE) and ventilatory equivalents (VE/VO2 and VE/VCO2), as a function of VO2. VO2max was defined as the highest VO2 achieved during the test. The values of VO2 were expressed in absolute (l.min-1), relative (ml.kg-1.min-1) and allometric (ml.kg-0.75.min-1) forms. VB1 was considered the lowest workload in which VE/VO2 showed a systematic increase without a concomitant increase in VE/VCO2. VB2 was considered the lowest workload in which VE/VO2 showed a concomitant increase in VE/VCO2. The absolute form of VO2 was different among groups in VB1, VB2 and VO2max, whereas in the relative form, there was no difference among groups in VB1 and VO2max. Nevertheless, in VB2, Pub (44.3±3.1) and PostP (44.1±3.0) presented higher VO2 than PreP (42.0±3.9). Allometric VO2max was different among groups (151.3±15.1, 168.9±11.5, 176.3±14.0 for PreP, Pub and PostP, respectively). VB2 in allometric form was higher in Pub (125.1±7.8) and PostP (129.2±9.7) groups when compared with PreP (111.6±9.0). In relation to VB1 allometric, Pub (82.4±9.1) and PostP (81.9±9.1) groups were higher than PreP (71.6±9.0). A multiple linear regression was used to express the relative contribution of the chronologic age, years of training, biological maturation, body mass and height on VB1, VB2 and VO2max in three separate scalings. The main variables explaining absolute, relative and allometric VO2max were body mass and biological maturation (82.8%), whereas body mass and biological maturation only accounted for 7.5% and biological maturation 34.1%. Body mass was the main variable explaining absolute VO2 (71.8%) and allometric VO2 (18.4%). Body mass and biological maturation explained 84.5% and 6.6% of absolute and relative body mass VB2 respectively. Biological maturation explained allometric VB2 in 32.2%. All differences were significant when p<0.05. In conclusion, biological maturation has an effect upon absolute and allometric VO2max. However, relative VO2max does not seem to properly adjust for the effect of body mass on VO2max in young soccer players. This makes it difficult to understand the effect of biological maturation on VO2max. Biological maturation has an effect upon VB2 in any way it is expressed, but does not show an effect on VB1. Also, it seems that the transition of the PreP stage from to Pub stage is the most significant period for aerobic capacity development.

RELATIONSHIP BETWEEN SEASON OF BIRTH BIAS, ASSESSMENT OF MATURATION AND YEARS OF SPORT EXPERIENCE IN THE TALENT SELECTION PROCESS

Simpson, B., Hill, R., Price, A.
Aspire Academy for Sports Excellence, Qatar

PURPOSE: Previous research has found that season of birth bias has an influence in the selection process for many sports. A common cause for this bias was thought to be the selection of early maturing students and greater sporting experience. The primary purpose of this study was to determine if the talent selection process for a youth sport academy had a season of birth bias influence and if so, were early maturation or previous sporting experience contributing factors. METHODS: Measurements were collected during the second phase of ASPIRE’s annual Talent Identification program in 2007 (283 males, age 12.93 ± 1.00 yr). There were three phases involved in the selection process (Silver, Gold and Aspire) were collected during the second phase (Silver) and during all further phases, the successful students initial Silver results were carried forward and grouped for further analysis. Date of birth, standing height, sitting height, and self assessed training experience was collected for all students participating in the program. The year was divided into four quarters when Q1 included Jan, Feb, Mar, Q2 included Apr, May, Jun, Q3 included Jul, Aug, Sep, and Q4 included Oct, Nov, Dec. RESULTS: The first selection (Silver) phase showed no season of birth bias between the quarters (Q1 = 50, Q2 = 58, Q3 = 52, Q4 = 43; p = 0.520). This phase of the selection process was purely objective in that selection was based upon predetermined standards. However the second selection (Gold) phase that involved both subjective and objective evaluations produced a season of birth bias (Q1 = 24, Q2 = 16, Q3 = 11, Q4 = 4; x2 = 15.5, p = 0.001). The third and final selection (Aspire) phase was not found to be statistically significant, however a clear trend was evident towards the first two quarters of the year (Q1 = 9, Q2 = 10, Q3 = 3, Q4 = 3, x2 = 6.8; p = 0.077). Although objective measures were included in the final selection, more importance was given to the coaches subjective evaluation. When the maturation assessment (determined as age at peak height velocity) was evaluated for the three groups (Silver 14.1 ± 0.68 yrs, Gold 13.9 ± 0.75 yrs, and Aspire ± 14.0 ± 0.78 yrs) no differences were evident (x2 = 1.57, p = 0.45). When the self assessed years of training experience was evaluated for the three groups (Silver 1.35 ± 1.51 yrs, Gold 1.30 ± 1.41 yrs, Aspire 1.16 ± 1.18 yrs) no differences were found (x2 = 0.83, p = 0.96). CONCLUSIONS: These results found that a season a birth bias was clearly evident in our selection process even when measures were put in place to prevent this from occurring. Closer evaluation determined that early maturation and more training experience were not significantly different between the groups and thus did not contribute to the season of birth bias. Further research is required to determine the cause of the season of birth bias in the selection process.

EFFECTS OF A STRENGTH PROGRAM TRAINING ASSOCIATED TO SPECIFIC PLYOMETRICS

Carvalho, C., Abade, E., Gonçalves, T.
Instituto Superior da Maia, Portugal

In the plan of the current sport profil, the contemplation at short and long term of the strenght training is essential, being a type of work accepted in all the modern methodologies of the athletic training. In Handball, such as in other collective sports, the training of the strength is very important for the improvement of the athlete’s sport.
The main goal of this study was to check the effects of a program of strength associated to specific plyometric training in the strength of vertical jump, in the different forms of demonstration of the strength and in the body composition of senior Handball athletes. Following this idea, we did practice a twelve week training program of strength, being the last seven weeks dedicated to a program in which simultaneously was applied a specific plyometric training twice a week.

The sample was constituted by twelve male senior Handball athletes with ages between twenty and twenty five years old, an average of height and weight of 183.9 cm and 81.7 kg respectively, all players of Associação Desportiva académica do ISMAI, which competed in Campeonato Nacional da 1ª divisão. The evaluation, which was made in two moments of the experimental work, consisted in the following tests: anthropometric measures (weight, height, wingspan, tricipital, bicipital, sub-escapular, supra-iliaca, abdominal, crural, geminal and iliacs skinfolds, bicôndilo umeral e bicôndilo femural diameters and body perimeters such as braquial relaxado, braquial tenso, crural e geminal) and evaluations of vertical jump, expressed in the resistant explosive, reactive and quick resistant of the inferior members, using an electromechanical device Ergojump.

The applied tests were the Squat Jump (SJ) and Counter Mouvement Jump (CMJ), to which were added the Free Jump and forty Consecutive Jumps. The dynamic concentric muscular strength, isometric and dynamic eccentric of the extensors and flexores of the knee were measured through the isocinetic dynamometer REV 9000.

The group evolved in all forms of demonstration of strength, however, the biggest differences happened at the isometric strength of the knees and in the eccentric strength of the flexores and extensors. Simultaneously, improvements happened at the vertical jump between the two moments of evaluation, namely in the resistant explosive, reactive and quick strength of the inferior members, noted by the values obtained in the tests of SJ, CMJ and forty Consecutive Jumps.

In what concerns to the body composition, the group to which the program was applied had statistically significant reductions in the percentage of fat, reducing also the fat mass and increasing thin mass.

VARIABILITY AND RELIABILITY IN ANALYSING BACK POSTURE

Beeger, H.
University of Leipzig, Germany

The working Group on Guidelines for Prevention in low back pain (LBP) advocates randomized controlled trails evaluating the possible positive effect of preventive programmes and risk factor modifications in childhood, because this field is neglected (Burton et al., 2004). One risk factor may be the posture in general or postural habits in particular. Posture is very variable (McEvoy & Grimmer, 2005), especially in children. This variability increases the challenge to generate reproducible data. To solve this problem of low reliability, we refer to a neurocybernetic approach. Longier phases of a regulative process has to be examined, as posturography or Armvorhalte-Test (Matthias, 1966) does. Armvorhalte-Test is an easy and traditionally used clinical screening-test. Its quantification of this functional test is possible in sagittal view by videometry. The task is to hold erect for 30 seconds with arms spread forward. The method tests the skill to stabilize posture while provacating the risk factor of a hollow-backposition. One reason of low reliability of this test shown by Bös et al. (2004) can be deficits in standardization. However, high reliability is an important requirement in general and as well to make sure of its validation. Therefore, correlation of 'Armvorhalte-Test' with LBP in childhood or its predictive value of LBP in adulthood have to be verified.

The aim of the present study is to modify the test to enhance its reliability in primary school children as a requirement for further studies to proof its relevance in the genesis of specific low back pain. In the presentation, the original method of Armvorhalte-Test is discussed critically, and coefficients of reliability of a modified test in the present study will be shown. Moreover, following experiments to examine causes of risk behavior in Armvorhalte-Test (e.g. deficits in proprioception/bodyperception, strength of trunk or shoulder muscles) will be discussed.

RELATIONSHIP BETWEEN ANTHROPOMETRIC AND PHYSICAL CHARACTERISTICS IN THE TALENT SELECTION PROCESS

Price, A., Hill, R., Simpson, B.
Aspire Academy for Sports Excellence, Qatar

PURPOSE: Talent search programs around the world have emphasized anthropometric and physical characteristics in the selection of talent. However, it is well known that to be an elite level performer also requires more than just physical prowess. Thus, the purpose of this study was to evaluate the importance of anthropometric and physical characteristics in the overall selection process for a youth sport academy. METHODS: Measurements were collected during ASPIRE’s annual Talent Identification Program during the 2006/2007 school year (5956 males, aged 12 to 15 yrs). All students were assessed on standing height, sitting height, body mass, arm span, 2 kg seated shot throw, 100 g over-arm throw, 40 m sprint, counter movement jump (Yardstick) and 20 m shuttle run. Four phases were involved in the selection process (Bronze, Silver, Gold and Aspire). Measures were collected once during the first phase (Bronze) and during all further phases, the successful students initial Bronze results were carried forward and grouped for further analysis. RESULTS: An initial nonparametric test for independent samples performed between the four groups showed significant differences for all tests (p = 0.01) except body mass (Z = 4.544, p = 0.216). A more detailed analysis was then undertaken (Mann-Whitney U test) to determine specific differences between the groups. All measured values were significantly different between Bronze and Silver except body mass (Z = 0.762, p = 0.446). When Silver was compared to Gold, all the measured characteristics were found to be significantly different except body mass (Z = 1.434, p = 0.152), BMI (Z = 0.529, p = 0.597) and CMJ (Z = 1.904, p = 0.057). Finally when Gold was compared to Aspire, none of the characteristics was found to be significantly different. The anthropometric and physical characteristics were found to be important during the early stages of the talent search process, but other characteristics became more important in the later stages of the talent selection process. CONCLUSIONS: These results suggested that although anthropometric and physical characteristics were very important early in the talent selection process they became less important as the process continued. It was thought that as the quality of the students within the groups increased other characteristics such as motivation, work ethic, and ability to learn new skills became more...
important. In other words, a successful candidate required a minimum standard for the anthropometric and physical characteristics (1st tier), however once these standards had been met, then other characteristics became more important (2nd tier).

**A MULTIDIMENSIONAL TRAINING PROGRAM TO IMPROVE PHYSICAL FITNESS IN ELDERLY PEOPLE**

**Dupont, S., Gauthier, A., Davenne, D.**

**UFR STAPS, EA3917, France**

Today it is classically admitted, that at any age the participation in a program of regular physical exercises can reduce the noxious effects of ageing. However, obtaining physiological metabolic, psychological and functional adaptations requires exercises adapted in terms of intensity and duration. This study tested the assumption that a multidimensional program based on muscular and cardiovascular exercises is necessary to hope to improve both the physical and functional capacities and, in term, the quality of life of the retired people.

Moreover, to minimize the risks of injuries, the training program as to be done with a progressive intensity and length of the exercise. Lastly, the training program has to be based on various physical activities to avoid monotonous and to consider that the subjects will keep their desire to go with physical activities at the end of the protocol.

**Methods:** Twenty four sedentary subjects were selected. They were retired and in good health (67±5). They were then randomly divided into two groups: An experimental group (EG, n=12) and a control group (CG, n = 12). EG had to perform our training program of 1 hour, 3 times a week. This program consisted of an alternation of 2 cardiovascular and 1 muscular resistance session each week. It lasted 4 months. CG had to maintain their usual activities for the same period of 4 months. Before (T0) and after (T4) the experimental period, a test session was set up during which the following parameters were recorded on each subject: VO2max (maximal grade cycling test), hand force (dynamometer), power of legs (vertical jump), flexibility and body fat and mass.

**Results:** An ANOVA (groups x time) on each parameter shows that only EG evolved significantly. After 4 months in EG, by comparison between T0 and T4, our training program produced a significant increase of VO2max (23.7±8.2 vs 25.3±7.7 ml kg-1 min-1, +7%), hand force (28.6±8 vs 33.5±8.6 Nm; +8,6%), vertical jump (28.2±8 vs 33.5±9.7 W; +8%) and flexibility (93.5±11 vs 99.2±7.5). The data revealed also a reduction of body fat (-16.9%), and of the index of body mass (-3%). The body weight was not significantly reduced. No significant differences were noted for CG for all these parameters. One year later 90% of the EG subjects are still involved in personal training program.

In conclusion, these results prove that it is possible to improve both the cardiovascular and muscular capacities throughout the same training program. They also suggest that it is of primary importance to apply exercises in a progressive way in order (i) to prevent injuries, (ii) to optimize the physical performances and (iii) to maintain a sufficient motivation so that the subjects can pursue the exercises. The diversity of the tasks, the intensities of work and the modes of action suggested during our training program being effective means to preserve the pleasure of practising a physical activity.

**ASSOCIATION BETWEEN THE BEGINNING AND CONCLUSION OF THE OFFENSIVE PROCESS IN ELITE FEMALE HANDBALL**

**Gomes, I., Sampaio, J., Vaz, L., João, P., Maçãs, V.**

**University of Trás-os-Montes and Alto Douro, Portugal**

The purpose of the present study was to determine association between the beginning and conclusion of the offensive process in elite female Handball games. We have analysed twelve games performed by Portuguese teams (classified in pool position at the National Championship 2001/02) and nine games from international teams (European competition, National Selection 2001/02). The Spearman’s rho correlation was used to determine association between variables. The results showed in Portuguese teams’ fast break and fast attack, a strong positive association between goals scored and balls introduced by goalkeeper (rs=0.60, p=0.03), interceptions (rs = 0.63, p = 0.02) and lateral throws (rs=0.61, p=0.03). We also found significant and positive correlations in international teams’ fast break and fast attack. Goals scored had strong association with block situations (rs=0.81, p=0.00) and interceptions (rs=0.75, p=0.02). The Portuguese teams committed more mistakes and received more balls from the goalkeeper and lateral throws, while in the international teams the ball came from block situations.
